The SymPy CAS can be installed on virtually any computer with Python. SymPy does require `mpmath` Python library to be installed first. The recommended method of installation is through Anaconda, which includes mpmath, as well as several other useful libraries. Alternatively, some Linux distributions have SymPy packages available.

SymPy officially supports Python 3.8, 3.9, 3.10, and PyPy.

### 1.1 Anaconda

Anaconda is a free Python distribution from Continuum Analytics that includes SymPy, Matplotlib, IPython, NumPy, and many more useful packages for scientific computing. This is recommended because many nice features of SymPy are only enabled when certain libraries are installed. For example, without Matplotlib, only simple text-based plotting is enabled. With the IPython notebook or qtconsole, you can get nicer LATEX printing by running `init_printing()`.

If you already have Anaconda and want to update SymPy to the latest version, use:

```
conda update sympy
```

### 1.2 Git

If you wish to contribute to SymPy or like to get the latest updates as they come, install SymPy from git. To download the repository, execute the following from the command line:

```
git clone https://github.com/sympy/sympy.git
```

To update to the latest version, go into your repository and execute:

```
git pull origin master
```

If you want to install SymPy, but still want to use the git version, you can run from your repository:

```
python -m pip install -e .
```

This will cause the installed version to always point to the version in the git directory.
1.3 Other Methods

You may also install SymPy using pip or from source. In addition, most Linux and Python distributions have some SymPy version available to install using their package manager. Here is a list of several such Python distributions:

- Anaconda
- Enthought Deployment Manager
- ActivePython
- Spack

1.4 Run SymPy

After installation, it is best to verify that your freshly-installed SymPy works. To do this, start up Python and import the SymPy libraries:

```
$ python
>>> from sympy import *
```

From here, execute some simple SymPy statements like the ones below:

```
>>> x = Symbol('x
>>> limit(sin(x)/x, x, 0)
1
>>> integrate(1/x, x)
log(x)
```

For a starter guide on using SymPy effectively, refer to the *Introductory Tutorial* (page 5).

1.5 mpmath

Versions of SymPy prior to 1.0 included mpmath, but it now depends on it as an external dependency. If you installed SymPy with Anaconda, it will already include mpmath. Use:

```
conda install mpmath
```

to ensure that it is installed.

If you do not wish to use Anaconda, you can use `pip install mpmath`.

If you use mpmath via `sympy.mpmath` in your code, you will need to change this to use just `mpmath`. If you depend on code that does this that you cannot easily change, you can work around it by doing:

```
import sys
import mpmath
sys.modules['sympy.mpmath'] = mpmath
```

before the code that imports `sympy.mpmath`. It is recommended to change code that uses `sympy.mpmath` to use `mpmath` directly wherever possible.
1.6 Questions

If you have a question about installation or SymPy in general, feel free to visit our chat on Gitter. In addition, our mailing list is an excellent source of community support.

If you think there’s a bug or you would like to request a feature, please open an issue ticket.
Tutorials are the best place to start for anyone new to SymPy or one of SymPy’s features.

## 2.1 Introductory Tutorial

If you are new to SymPy, start here.

### 2.1.1 Introductory Tutorial

This tutorial aims to give an introduction to SymPy for someone who has not used the library before. Many features of SymPy will be introduced in this tutorial, but they will not be exhaustive. In fact, virtually every functionality shown in this tutorial will have more options or capabilities than what will be shown. The rest of the SymPy documentation serves as API documentation, which extensively lists every feature and option of each function.

These are the goals of this tutorial:

- To give a guide, suitable for someone who has never used SymPy (but who has used Python and knows the necessary mathematics).
- To be written in a narrative format, which is both easy and fun to follow. It should read like a book.
- To give insightful examples and exercises, to help the reader learn and to make it entertaining to work through.
- To introduce concepts in a logical order.
- To use good practices and idioms, and avoid antipatterns. Functions or methodologies that tend to lead to antipatterns are avoided. Features that are only useful to advanced users are not shown.
- To be consistent. If there are multiple ways to do it, only the best way is shown.
- To avoid unnecessary duplication, it is assumed that previous sections of the tutorial have already been read.

Feedback on this tutorial, or on SymPy in general is always welcome. Just write to our mailing list.

Content
**Preliminaries**

This tutorial assumes that the reader already knows the basics of the Python programming language. If you do not, the official Python tutorial is excellent.

This tutorial assumes a decent mathematical background. Most examples require knowledge lower than a calculus level, and some require knowledge at a calculus level. Some of the advanced features require more than this. If you come across a section that uses some mathematical function you are not familiar with, you can probably skip over it, or replace it with a similar one that you are more familiar with. Or look up the function on Wikipedia and learn something new. Some important mathematical concepts that are not common knowledge will be introduced as necessary.

**Installation**

You will need to install SymPy first. See the installation guide (page 1).

**Exercises**

This tutorial was the basis for a tutorial given at the 2013 SciPy conference in Austin, TX. The website for that tutorial is here. It has links to videos, materials, and IPython notebook exercises. The IPython notebook exercises in particular are recommended to anyone going through this tutorial.

**Introduction**

What is Symbolic Computation?

Symbolic computation deals with the computation of mathematical objects symbolically. This means that the mathematical objects are represented exactly, not approximately, and mathematical expressions with unevaluated variables are left in symbolic form.

Let’s take an example. Say we wanted to use the built-in Python functions to compute square roots. We might do something like this

```
>>> import math
>>> math.sqrt(9)
3.0
```

9 is a perfect square, so we got the exact answer, 3. But suppose we computed the square root of a number that isn’t a perfect square

```
>>> math.sqrt(8)
2.82842712475
```

Here we got an approximate result. 2.82842712475 is not the exact square root of 8 (indeed, the actual square root of 8 cannot be represented by a finite decimal, since it is an irrational number). If all we cared about was the decimal form of the square root of 8, we would be done.

But suppose we want to go further. Recall that $\sqrt{8} = \sqrt{4 \cdot 2} = 2\sqrt{2}$. We would have a hard time deducing this from the above result. This is where symbolic computation comes in. With
a symbolic computation system like SymPy, square roots of numbers that are not perfect squares are left unevaluated by default

```python
>>> import sympy
>>> sympy.sqrt(3)
sqrt(3)
```

Furthermore—and this is where we start to see the real power of symbolic computation—symbolic results can be symbolically simplified.

```python
>>> sympy.sqrt(8)
2*sqrt(2)
```

**A More Interesting Example**

The above example starts to show how we can manipulate irrational numbers exactly using SymPy. But it is much more powerful than that. Symbolic computation systems (which by the way, are also often called computer algebra systems, or just CASs) such as SymPy are capable of computing symbolic expressions with variables.

As we will see later, in SymPy, variables are defined using `symbols`. Unlike many symbolic manipulation systems, variables in SymPy must be defined before they are used (the reason for this will be discussed in the next section (page 10)).

Let us define a symbolic expression, representing the mathematical expression \( x + 2y \).

```python
>>> from sympy import symbols
>>> x, y = symbols('x y')
>>> expr = x + 2*y
>>> expr
x + 2*y
```

Note that we wrote \( x + 2y \) just as we would if \( x \) and \( y \) were ordinary Python variables. But in this case, instead of evaluating to something, the expression remains as just \( x + 2y \). Now let us play around with it:

```python
>>> expr + 1
x + 2*y + 1
>>> expr - x
2*y
```

Notice something in the above example. When we typed `expr - x`, we did not get \( x + 2y - x \), but rather just \( 2y \). The \( x \) and the \(-x\) automatically canceled one another. This is similar to how `sqrt(8)` automatically turned into `2*sqrt(2)` above. This isn’t always the case in SymPy, however:

```python
>>> x*expr
x*(x + 2*y)
```

Here, we might have expected \( x(x + 2y) \) to transform into \( x^2 + 2xy \), but instead we see that the expression was left alone. This is a common theme in SymPy. Aside from obvious simplifications like \( x - x = 0 \) and \( \sqrt{8} = 2\sqrt{2} \), most simplifications are not performed automatically. This is because we might prefer the factored form \( x(x + 2y) \), or we might prefer the expanded form \( x^2 + 2xy \). Both forms are useful in different circumstances. In SymPy, there are functions to go from one form to the other.
The Power of Symbolic Computation

The real power of a symbolic computation system such as SymPy is the ability to do all sorts of computations symbolically. SymPy can simplify expressions, compute derivatives, integrals, and limits, solve equations, work with matrices, and much, much more, and do it all symbolically. It includes modules for plotting, printing (like 2D pretty printed output of math formulas, or $\LaTeX$), code generation, physics, statistics, combinatorics, number theory, geometry, logic, and more. Here is a small sampling of the sort of symbolic power SymPy is capable of, to whet your appetite.

This will make all further examples pretty print with unicode characters.

Take the derivative of $\sin(x)e^x$.

Compute $\int (e^x \sin(x) + e^x \cos(x)) \, dx$.

Compute $\int_{-\infty}^{\infty} \sin(x^2) \, dx$.

Find $\lim_{x \to 0} \frac{\sin(x)}{x}$.

Solve $x^2 - 2 = 0$. 

```python
>>> from sympy import expand, factor
>>> expanded_expr = expand(x*expr)
>>> expanded_expr
x**2 + 2*x*y
>>> factor(expanded_expr)
x*(x + 2*y)
```
Solve the differential equation \( y'' - y = e^t \).

\[
\begin{align*}
\text{>>> } & y = \text{Function('y')} \\
\text{>>> } & \text{dsolve(Eq(y(t).diff(t, t) - y(t), exp(t)), y(t))} \\
& y(t) = C_2 \cdot e^{-t} + \left(C_1 + \frac{t}{2}\right) \cdot e^t
\end{align*}
\]

Find the eigenvalues of \([\begin{array}{cc}1 & 2 \\ 2 & 2 \end{array}\])

\[
\begin{align*}
\text{>>> } & \text{Matrix([[1, 2], [2, 2]]).eigvals()} \\
& \left\{\begin{array}{c}
\frac{3}{2} \sqrt{17} : 1, \frac{3}{2} \sqrt{17} : 1 \\
\frac{2}{2} : 1, \frac{2}{2} : 1
\end{array}\right\}
\end{align*}
\]

Rewrite the Bessel function \( J_\nu(z) \) in terms of the spherical Bessel function \( j_\nu(z) \).

\[
\begin{align*}
\text{>>> } & \text{besselj(nu, z).rewrite(jn)} \\
& \frac{\sqrt{2} \cdot \sqrt{z} \cdot j_n(\nu - 1/2, z)}{\sqrt{\pi}}
\end{align*}
\]

Print \( \int_0^\pi \cos^2(x) \, dx \) using \LaTeX{}.

\[
\begin{align*}
\text{>>> } & \text{latex(Integral(cos(x)**2, (x, 0, pi)))} \\
& \int_0^\pi \cos^2(x) \, dx
\end{align*}
\]

**Why SymPy?**

There are many computer algebra systems out there. This Wikipedia article lists many of them. What makes SymPy a better choice than the alternatives?

First off, SymPy is completely free. It is open source, and licensed under the liberal BSD license, so you can modify the source code and even sell it if you want to. This contrasts with popular commercial systems like Maple or Mathematica that cost hundreds of dollars in licenses.

Second, SymPy uses Python. Most computer algebra systems invent their own language. Not SymPy. SymPy is written entirely in Python, and is executed entirely in Python. This means that if you already know Python, it is much easier to get started with SymPy, because you already know the syntax (and if you don’t know Python, it is really easy to learn). We already know that Python is a well-designed, battle-tested language. The SymPy developers are confident in their abilities in writing mathematical software, but programming language design is a completely different thing. By reusing an existing language, we are able to focus on those things that matter: the mathematics.

Another computer algebra system, Sage also uses Python as its language. But Sage is large, with a download of over a gigabyte. An advantage of SymPy is that it is lightweight. In addition to being relatively small, it has no dependencies other than Python, so it can be used almost anywhere easily. Furthermore, the goals of Sage and the goals of SymPy are different. Sage aims to be a full featured system for mathematics, and aims to do so by compiling all the major open source mathematical systems together into one. When you call some function in Sage, such as \text{integrate}, it calls out to one of the open source packages that it includes. In

2.1. Introductory Tutorial
fact, SymPy is included in Sage. SymPy on the other hand aims to be an independent system, with all the features implemented in SymPy itself.

A final important feature of SymPy is that it can be used as a library. Many computer algebra systems focus on being usable in interactive environments, but if you wish to automate or extend them, it is difficult to do. With SymPy, you can just as easily use it in an interactive Python environment or import it in your own Python application. SymPy also provides APIs to make it easy to extend it with your own custom functions.

Gotchas

To begin, we should make something about SymPy clear: SymPy is nothing more than a Python library, like NumPy, Django, or even modules in the Python standard library sys or re. What this means is that SymPy does not add anything to the Python language. Limitations that are inherent in the Python language are also inherent in SymPy. It also means that SymPy tries to use Python idioms whenever possible, making programming with SymPy easy for those already familiar with programming with Python. As a simple example, SymPy uses Python syntax to build expressions. Implicit multiplication (like 3x or 3 \times x) is not allowed in Python, and thus not allowed in SymPy. To multiply 3 and \(x\), you must type 3\times x with the \(*\).

Symbols

One consequence of this fact is that SymPy can be used in any environment where Python is available. We just import it, like we would any other library:

```python
>>> from sympy import *
```

This imports all the functions and classes from SymPy into our interactive Python session. Now, suppose we start to do a computation.

```python
>>> x + 1
Traceback (most recent call last):
... NameError: name 'x' is not defined
```

Oops! What happened here? We tried to use the variable \(x\), but it tells us that \(x\) is not defined. In Python, variables have no meaning until they are defined. SymPy is no different. Unlike many symbolic manipulation systems you may have used, in SymPy, variables are not defined automatically. To define variables, we must use `symbols`.

```python
>>> x = symbols('x')
>>> x + 1
x + 1
```

`symbols` takes a string of variable names separated by spaces or commas, and creates Symbols out of them. We can then assign these to variable names. Later, we will investigate some convenient ways we can work around this issue. For now, let us just define the most common variable names, \(x\), \(y\), and \(z\), for use through the rest of this section

```python
>>> x, y, z = symbols('x y z')
```

As a final note, we note that the name of a Symbol and the name of the variable it is assigned to need not have anything to do with one another.
Here we have done the very confusing thing of assigning a Symbol with the name `a` to the variable `b`, and a Symbol of the name `b` to the variable `a`. Now the Python variable named `a` points to the SymPy Symbol named `b`, and vice versa. How confusing. We could have also done something like

```
>>> crazy = symbols('unrelated')
>>> crazy + 1
unrelated + 1
```

This also shows that Symbols can have names longer than one character if we want.

Usually, the best practice is to assign Symbols to Python variables of the same name, although there are exceptions: Symbol names can contain characters that are not allowed in Python variable names, or may just want to avoid typing long names by assigning Symbols with long names to single letter Python variables.

To avoid confusion, throughout this tutorial, Symbol names and Python variable names will always coincide. Furthermore, the word “Symbol” will refer to a SymPy Symbol and the word “variable” will refer to a Python variable.

Finally, let us be sure we understand the difference between SymPy Symbols and Python variables. Consider the following:

```
x = symbols('x')
expr = x + 1
x = 2
print(expr)
```

What do you think the output of this code will be? If you thought 3, you’re wrong. Let’s see what really happens

```
>>> x = symbols('x')
>>> expr = x + 1
>>> x = 2
>>> print(expr)
2 + 1
```

Changing `x` to 2 had no effect on `expr`. This is because `x = 2` changes the Python variable `x` to 2, but has no effect on the SymPy Symbol `x`, which was what we used in creating `expr`. When we created `expr`, the Python variable `x` was a Symbol. After we created, it, we changed the Python variable `x` to 2. But `expr` remains the same. This behavior is not unique to SymPy. All Python programs work this way: if a variable is changed, expressions that were already created with that variable do not change automatically. For example

```
>>> x = 'abc'
>>> expr = x + 'def'
>>> expr
'abcdef'
>>> x = 'ABC'
```

(continues on next page)
Quick Tip

To change the value of a Symbol in an expression, use subs

```python
>>> x = symbols('x')
>>> expr = x + 1
>>> expr.subs(x, 2)
3
```

In this example, if we want to know what `expr` is with the new value of `x`, we need to reevaluate the code that created `expr`, namely, `expr = x + 1`. This can be complicated if several lines created `expr`. One advantage of using a symbolic computation system like SymPy is that we can build a symbolic representation for `expr`, and then substitute `x` with values. The correct way to do this in SymPy is to use `subs`, which will be discussed in more detail later.

```python
>>> x = symbols('x')
>>> expr = x + 1
>>> expr.subs(x, 2)
3
```

Equals signs

Another very important consequence of the fact that SymPy does not extend Python syntax is that `=` does not represent equality in SymPy. Rather it is Python variable assignment. This is hard-coded into the Python language, and SymPy makes no attempts to change that.

You may think, however, that `==`, which is used for equality testing in Python, is used for SymPy as equality. This is not quite correct either. Let us see what happens when we use `==`.

```python
>>> x + 1 == 4
False
```

Instead of treating `x + 1 == 4` symbolically, we just got `False`. In SymPy, `==` represents exact structural equality testing. This means that `a == b` means that we are asking if `a = b`. We always get a bool as the result of `==`. There is a separate object, called `Eq`, which can be used to create symbolic equalities

```python
>>> Eq(x + 1, 4)
Eq(x + 1, 4)
```

There is one additional caveat about `==` as well. Suppose we want to know if \((x+1)^2 = x^2 + 2x + 1\). We might try something like this:

```python
>>> (x + 1)**2 == x**2 + 2*x + 1
False
```

We got `False` again. However, \((x + 1)^2\ does equal \(x^2 + 2x + 1\). What is going on here? Did we find a bug in SymPy, or is it just not powerful enough to recognize this basic algebraic fact?
Recall from above that \texttt{==} represents \textit{exact} structural equality testing. “Exact” here means that two expressions will compare equal with \texttt{==} only if they are exactly equal structurally. Here, \((x+1)^2\) and \(x^2 + 2x + 1\) are not the same structurally. One is the power of an addition of two terms, and the other is the addition of three terms.

It turns out that when using SymPy as a library, having \texttt{==} test for exact structural equality is far more useful than having it represent symbolic equality, or having it test for mathematical equality. However, as a new user, you will probably care more about the latter two. We have already seen an alternative to representing equalities symbolically, \texttt{Eq}. To test if two things are equal, it is best to recall the basic fact that if \(a = b\), then \(a - b = 0\). Thus, the best way to check if \(a = b\) is to take \(a - b\) and simplify it, and see if it goes to 0. We will learn later (page 25) that the function to do this is called \texttt{simplify}. This method is not infallible—in fact, it can be \textit{theoretically proven} that it is impossible to determine if two symbolic expressions are identically equal in general—but for most common expressions, it works quite well.

```python
>>> a = (x + 1)**2
>>> b = x**2 + 2*x + 1
>>> simplify(a - b)
0
>>> c = x**2 - 2*x + 1
>>> simplify(a - c)
4*x
```

There is also a method called \texttt{equals} that tests if two expressions are equal by evaluating them numerically at random points.

```python
>>> a = cos(x)**2 - sin(x)**2
>>> b = cos(2*x)
>>> a.equals(b)
True
```

\textbf{Two Final Notes: ^ and /}

You may have noticed that we have been using \texttt{**} for exponentiation instead of the standard \texttt{^}. That’s because SymPy follows Python’s conventions. In Python, \texttt{^} represents logical exclusive or. SymPy follows this convention:

```python
>>> True ^ False
True
>>> True ^ True
False
>>> Xor(x, y)
x ^ y
```

Finally, a small technical discussion on how SymPy works is in order. When you type something like \(x + 1\), the SymPy Symbol \(x\) is added to the Python int \(1\). Python’s operator rules then allow SymPy to tell Python that SymPy objects know how to be added to Python ints, and so \(1\) is automatically converted to the SymPy Integer object.

This sort of operator magic happens automatically behind the scenes, and you rarely need to even know that it is happening. However, there is one exception. Whenever you combine a SymPy object and a SymPy object, or a SymPy object and a Python object, you get a SymPy object, but whenever you combine two Python objects, SymPy never comes into play, and so you get a Python object.
This is usually not a big deal. Python ints work much the same as SymPy Integers, but there is one important exception: division. In SymPy, the division of two Integers gives a Rational:

```python
>>> Integer(1)/Integer(3)
1/3
>>> type(Integer(1)/Integer(3))
<class 'sympy.core.numbers.Rational'>
```

But in Python `/` represents either integer division or floating point division, depending on whether you are in Python 2 or Python 3, and depending on whether or not you have run `from __future__ import division` in Python 2 which is no longer supported from versions above SymPy 1.5.1:

```python
>>> from __future__ import division
>>> 1/2
0.5
```

To avoid this, we can construct the rational object explicitly

```python
>>> Rational(1, 2)
1/2
```

This problem also comes up whenever we have a larger symbolic expression with int/int in it. For example:

```python
>>> x + 1/2
x + 0.5
```

This happens because Python first evaluates 1/2 into 0.5, and then that is cast into a SymPy type when it is added to x. Again, we can get around this by explicitly creating a Rational:

```python
>>> x + Rational(1, 2)
x + 1/2
```

There are several tips on avoiding this situation in the *Gotchas and Pitfalls* (page 189) document.

**Further Reading**

For more discussion on the topics covered in this section, see *Gotchas and Pitfalls* (page 189).
SymPy Features

This section discusses the common and advanced SymPy operations and features.

Content

Basic Operations

Here we discuss some of the most basic operations needed for expression manipulation in SymPy. Some more advanced operations will be discussed later in the advanced expression manipulation (page 61) section.

```python
>>> from sympy import *
>>> x, y, z = symbols("x y z")
```

Substitution

One of the most common things you might want to do with a mathematical expression is substitution. Substitution replaces all instances of something in an expression with something else. It is done using the subs method. For example

```python
>>> expr = cos(x) + 1
>>> expr.subs(x, y)
cos(y) + 1
```

Substitution is usually done for one of two reasons:

1. Evaluating an expression at a point. For example, if our expression is \( \cos(x) + 1 \) and we want to evaluate it at the point \( x = 0 \), so that we get \( \cos(0) + 1 \), which is 2.

```python
>>> expr.subs(x, 0)
2
```

2. Replacing a subexpression with another subexpression. There are two reasons we might want to do this. The first is if we are trying to build an expression that has some symmetry, such as \( x^{x^x} \). To build this, we might start with \( x^{xy} \), and replace \( y \) with \( x^{xy} \). We would then get \( x^{x^{x^{xy}}} \). If we replaced \( y \) in this new expression with \( x^{xx} \), we would get \( x^{x^{x^{x^{xx}}}} \), the desired expression.

```python
>>> expr = x**y
>>> expr
x**y
>>> expr = expr.subs(y, x**y)
>>> expr
x**(x**y)
>>> expr = expr.subs(y, x**x)
>>> expr
x**(x**(x**x))
```

The second is if we want to perform a very controlled simplification, or perhaps a simplification that SymPy is otherwise unable to do. For example, say we have \( \sin(2x) + \cos(2x) \), and we want to replace \( \sin(2x) \) with \( 2\sin(x)\cos(x) \). As we will learn later, the function
expand_trig does this. However, this function will also expand \( \cos(2x) \), which we may not want. While there are ways to perform such precise simplification, and we will learn some of them in the *advanced expression manipulation* (page 61) section, an easy way is to just replace \( \sin(2x) \) with \( 2\sin(x)\cos(x) \).

```python
>>> expr = sin(2*x) + cos(2*x)
>>> expand_trig(expr)
2*sin(x)*cos(x) + 2*cos(x)**2 - 1
```

There are two important things to note about \texttt{subs}. First, it returns a new expression. SymPy objects are immutable. That means that \texttt{subs} does not modify it in-place. For example

```python
>>> expr = cos(x)
>>> expr.subs(x, 0)
1
>>> expr
cos(x)
>>> x
x
```

### Quick Tip

SymPy expressions are immutable. No function will change them in-place.

Here, we see that performing \texttt{expr.subs(x, 0)} leaves \texttt{expr} unchanged. In fact, since SymPy expressions are immutable, no function will change them in-place. All functions will return new expressions.

To perform multiple substitutions at once, pass a list of \texttt{(old, new)} pairs to \texttt{subs}.

```python
>>> expr = x**3 + 4*x*y - z
>>> expr.subs([(x, 2), (y, 4), (z, 0)])
40
```

It is often useful to combine this with a list comprehension to do a large set of similar replacements all at once. For example, say we had \( x^4 - 4x^3 + 4x^2 - 2x + 3 \) and we wanted to replace all instances of \( x \) that have an even power with \( y \), to get \( y^4 - 4y^3 + 4y^2 - 2y + 3 \).

```python
>>> expr = x**4 - 4*x**3 + 4*x**2 - 2*x + 3
>>> replacements = [(x**i, y**i) for i in range(5) if i % 2 == 0]
>>> expr.subs(replacements)
-4*x**3 - 2*x + y**4 + 4*y**2 + 3
```
Converting Strings to SymPy Expressions

The `sympify` function (that's `sympify`, not to be confused with `simplify`) can be used to convert strings into SymPy expressions. For example:

```python
>>> str_expr = "x**2 + 3*x - 1/2"
>>> expr = sympify(str_expr)
>>> expr
x**2 + 3*x - 1/2
>>> expr.subs(x, 2)
19/2
```

**Warning:** `sympify` uses `eval`. Don’t use it on unsanitized input.

**evalf**

To evaluate a numerical expression into a floating point number, use `evalf`.

```python
>>> expr = sqrt(8)
>>> expr.evalf()
2.82842712474619
```

SymPy can evaluate floating point expressions to arbitrary precision. By default, 15 digits of precision are used, but you can pass any number as the argument to `evalf`. Let’s compute the first 100 digits of $\pi$.

```python
>>> pi.evalf(100)
3.1415926535897932384626433832795028841971693993751058209749445923078164062862089986280348
```

To numerically evaluate an expression with a Symbol at a point, we might use `subs` followed by `evalf`, but it is more efficient and numerically stable to pass the substitution to `evalf` using the `subs` flag, which takes a dictionary of Symbol: point pairs.

```python
>>> expr = cos(2*x)
>>> expr.evalf(subs={x: 2.4})
0.0874989834394464
```

Sometimes there are roundoff errors smaller than the desired precision that remain after an expression is evaluated. Such numbers can be removed at the user’s discretion by setting the `chop` flag to True.

```python
>>> one = cos(1)**2 + sin(1)**2
>>> (one - 1).evalf()
-0.e-124
>>> (one - 1).evalf(chop=True)
0
```
**lambdify**

subs and evalf are good if you want to do simple evaluation, but if you intend to evaluate an expression at many points, there are more efficient ways. For example, if you wanted to evaluate an expression at a thousand points, using SymPy would be far slower than it needs to be, especially if you only care about machine precision. Instead, you should use libraries like NumPy and SciPy.

The easiest way to convert a SymPy expression to an expression that can be numerically evaluated is to use the lambdify function. lambdify acts like a lambda function, except it converts the SymPy names to the names of the given numerical library, usually NumPy. For example

```python
>>> import numpy
>>> a = numpy.arange(10)
>>> expr = sin(x)
>>> f = lambdify(x, expr, "numpy")
>>> f(a)
[ 0.  0.84147098  0.90929743  0.14112001 -0.7568025  -0.95892427
 -0.2794155  0.6569866  0.98935825  0.41211849]
```

**Warning:** lambdify uses eval. Don’t use it on unsanitized input.

You can use other libraries than NumPy. For example, to use the standard library math module, use "math".

```python
>>> f = lambdify(x, expr, "math")
>>> f(0.1)
0.0998334166468
```

To use lambdify with numerical libraries that it does not know about, pass a dictionary of sympy_name:numerical_function pairs. For example

```python
>>> def mysin(x):
...     ...         """My sine. Note that this is only accurate for small x.""
...     ...     return x
... >>> f = lambdify(x, expr, {"sin":mysin})
... >>> f(0.1)
0.1
```
Printing

As we have already seen, SymPy can pretty print its output using Unicode characters. This is a short introduction to the most common printing options available in SymPy.

Printers

There are several printers available in SymPy. The most common ones are

- str
- srepr
- ASCII pretty printer
- Unicode pretty printer
- LaTeX
- MathML
- Dot

In addition to these, there are also “printers” that can output SymPy objects to code, such as C, Fortran, Javascript, Theano, and Python. These are not discussed in this tutorial.

Setting up Pretty Printing

If all you want is the best pretty printing, use the init_printing() function. This will automatically enable the best printer available in your environment.

```python
>>> from sympy import init_printing
>>> init_printing()
```

If you plan to work in an interactive calculator-type session, the init_session() function will automatically import everything in SymPy, create some common Symbols, setup plotting, and run init_printing().

```python
>>> from sympy import init_session
>>> init_session()
```

These commands were executed:

```python
>>> from __future__ import division
>>> from sympy import *
>>> x, y, z, t = symbols('x y z t')
>>> k, m, n = symbols('k m n', integer=True)
>>> f, g, h = symbols('f g h', cls=Function)
>>> init_printing() # doctest: +SKIP
```

Documentation can be found at https://www.sympy.org/
In any case, this is what will happen:

- In the IPython QTConsole, if \LaTeX{} is installed, it will enable a printer that uses \LaTeX{}.

  
  \begin{verbatim}
  >>>
  
  In [1]: from sympy import init_session
  In [2]: init_session(quiet=True)
  Welcome to pylab, a matplotlib-based Python environment [backend: MacOSX].
  For more information, type 'help(pylab)'.
  IPython console for SymPy 0.7.2-git (Python 2.7.5-64-bit) (ground types: python)
  In [3]: Integral(sqrt(1/x), x)
  Out[3]:
  \int \sqrt{\frac{1}{x}} \, dx
  
  In [4]:
  \end{verbatim}

If \LaTeX{} is not installed, but Matplotlib is installed, it will use the Matplotlib rendering engine. If Matplotlib is not installed, it uses the Unicode pretty printer.

- In the IPython notebook, it will use MathJax to render \LaTeX{}.

  \begin{verbatim}
  In [1]: from sympy import *
     x, y, z = symbols('x y z')
     init_printing()

  In [2]: Integral(sqrt(1/x), x)
  Out[2]:
  \int \sqrt{\frac{1}{x}} \, dx
  \end{verbatim}
• In an IPython console session, or a regular Python session, it will use the Unicode pretty printer if the terminal supports Unicode.

```python
>>> from sympy import init_session
>>> init_session()

Python console for SymPy 0.7.2-git (Python 2.7.5-64-bit) (ground types: gmpy)

These commands were executed:
>>> from __future__ import division
>>> from sympy import *
>>> x, y, z, t = symbols('x y z t')
>>> k, m, n = symbols('k m n', integer=True)
>>> f, g, h = symbols('f g h', cls=Function)

Documentation can be found at http://www.sympy.org

>>> Integral(sqrt(1/x), x)

\[
\int_1^x \frac{1}{dx}
\]

• In a terminal that does not support Unicode, the ASCII pretty printer is used.

```python
>>> from sympy import init_session
>>> init_session()

Python console for SymPy 0.7.2-git (Python 2.7.5-64-bit) (ground types: gmpy)

These commands were executed:
>>> from __future__ import division
>>> from sympy import *
>>> x, y, z, t = symbols('x y z t')
>>> k, m, n = symbols('k m n', integer=True)
>>> f, g, h = symbols('f g h', cls=Function)

Documentation can be found at http://www.sympy.org

>>> Integral(sqrt(1/x), x)

\[
\int \frac{1}{x} \, dx
\]

To explicitly not use \LaTeX, pass use_latex=False to init_printing() or init_session().

2.1. Introductory Tutorial 21
To explicitly not use Unicode, pass use_unicode=False.

**Printing Functions**

In addition to automatic printing, you can explicitly use any one of the printers by calling the appropriate function.

**str**

To get a string form of an expression, use str(expr). This is also the form that is produced by print(expr). String forms are designed to be easy to read, but in a form that is correct Python syntax so that it can be copied and pasted. The str() form of an expression will usually look exactly the same as the expression as you would enter it.

```python
>>> from sympy import *
>>> x, y, z = symbols('x y z')
>>> str(Integral(sqrt(1/x), x))
'Integral(sqrt(1/x), x)'
>>> print(Integral(sqrt(1/x), x))
Integral(sqrt(1/x), x)
```

**srepr**

The srepr form of an expression is designed to show the exact form of an expression. It will be discussed more in the *Advanced Expression Manipulation* (page 61) section. To get it, use srepr()\(^1\).

```python
>>> srepr(Integral(sqrt(1/x), x))
"Integral(Pow(Pow(Symbol('x'), Integer(-1)), Rational(1, 2)), Tuple(Symbol('x →')))"
```

The srepr form is mostly useful for understanding how an expression is built internally.

**ASCII Pretty Printer**

The ASCII pretty printer is accessed from pprint(). If the terminal does not support Unicode, the ASCII printer is used by default. Otherwise, you must pass use_unicode=False.

```python
>>> pprint(Integral(sqrt(1/x), x), use_unicode=False)
\/
| \\ 1
| | / - dx
| \/ x
```

\(^1\) SymPy does not use the Python builtin repr() function for repr printing, because in Python str(list) calls repr() on the elements of the list, and some SymPy functions return lists (such as solve()). Since srepr() is so verbose, it is unlikely that anyone would want it called by default on the output of solve().
pprint() prints the output to the screen. If you want the string form, use pretty().

```python
>>> pretty(Integral(sqrt(1/x), x), use_unicode=False)
' / 
| 
| ___ 
| / 1 
| / - dx
\| \x \n| 
| 
\ / '  

>>> print(pretty(Integral(sqrt(1/x), x), use_unicode=False))
/  
| 
| 1 
| - dx 
\| \x  

Unicode Pretty Printer

The Unicode pretty printer is also accessed from pprint() and pretty(). If the terminal supports Unicode, it is used automatically. If pprint() is not able to detect that the terminal supports unicode, you can pass use_unicode=True to force it to use Unicode.

```python
>>> pprint(Integral(sqrt(1/x), x), use_unicode=True)
⌠  
⎮  
⎮ 1 
⎮ - dx 
⎮ \x  
⌡

LaTeX

To get the LaTeX form of an expression, use latex().

```python
>>> print(latex(Integral(sqrt(1/x), x)))
\int \sqrt{\frac{1}{x}}\, dx
```

The latex() function has many options to change the formatting of different things. See its documentation (page 2245) for more details.
MathML

There is also a printer to MathML, called print_mathml(). It must be imported from sympy.printing.mathml.

```python
>>> from sympy.printing.mathml import print_mathml
>>> print_mathml(Integral(sqrt(1/x), x))
<apply>
  <int/>
  <bvar>
    <ci>x</ci>
  </bvar>
  <apply>
    <root/>
    <apply>
      <power/>
      <ci>x</ci>
      <cn>-1</cn>
    </apply>
  </apply>
</apply>
```

print_mathml() prints the output. If you want the string, use the function mathml()

Dot

The dotprint() function in sympy.printing.dot prints output to dot format, which can be rendered with Graphviz. See the Advanced Expression Manipulation (page 61) section for some examples of the output of this printer.

Here is an example of the raw output of the dotprint() function

```python
>>> from sympy.printing.dot import dotprint
>>> from sympy.abc import x
>>> print(dotprint(x+2))
digraph{
  # Graph style
  "ordering"="out"
  "rankdir"="TD"

  "Add(Integer(2), Symbol('x'))_()" ["color"="black", "label"="Add", "shape"="ellipse"];
  "Integer(2)_([0])" ["color"="black", "label"="2", "shape"="ellipse"];
  "Symbol('x')_([1])" ["color"="black", "label"="x", "shape"="ellipse"];

  # Edges #

(continues on next page)
Simplification

To make this document easier to read, we are going to enable pretty printing.

```python
from sympy import *
>>> x, y, z = symbols('x y z')
>>> init_printing(use_unicode=True)
```

**simplify**

Now let’s jump in and do some interesting mathematics. One of the most useful features of a symbolic manipulation system is the ability to simplify mathematical expressions. SymPy has dozens of functions to perform various kinds of simplification. There is also one general function called `simplify()` that attempts to apply all of these functions in an intelligent way to arrive at the simplest form of an expression. Here are some examples

```python
>>> simplify(sin(x)**2 + cos(x)**2)
1
>>> simplify((x**3 + x**2 - x - 1)/(x**2 + 2*x + 1))
x - 1
>>> simplify(gamma(x)/gamma(x - 2))
(x - 2)*(x - 1)
```

Here, `gamma(x)` is $\Gamma(x)$, the **gamma function**. We see that `simplify()` is capable of handling a large class of expressions.

But `simplify()` has a pitfall. It just applies all the major simplification operations in SymPy, and uses heuristics to determine the simplest result. But “simplest” is not a well-defined term. For example, say we wanted to “simplify” $x^2 + 2x + 1$ into $(x + 1)^2$:

```python
>>> simplify(x**2 + 2*x + 1)
2
x + 2*x + 1
```

We did not get what we want. There is a function to perform this simplification, called `factor()`, which will be discussed below.

Another pitfall to `simplify()` is that it can be unnecessarily slow, since it tries many kinds of simplifications before picking the best one. If you already know exactly what kind of simplification you are after, it is better to apply the specific simplification function(s) that apply those simplifications.

Applying specific simplification functions instead of `simplify()` also has the advantage that specific functions have certain guarantees about the form of their output. These will be discussed with each function below. For example, `factor()`, when called on a polynomial
with rational coefficients, is guaranteed to factor the polynomial into irreducible factors. `simplify()` has no guarantees. It is entirely heuristic, and, as we saw above, it may even miss a possible type of simplification that SymPy is capable of doing.

`simplify()` is best when used interactively, when you just want to whittle down an expression to a simpler form. You may then choose to apply specific functions once you see what `simplify()` returns, to get a more precise result. It is also useful when you have no idea what form an expression will take, and you need a catchall function to simplify it.

**Polynomial/Rational Function Simplification**

**expand**

`expand()` is one of the most common simplification functions in SymPy. Although it has a lot of scopes, for now, we will consider its function in expanding polynomial expressions. For example:

```python
>>> expand((x + 1)**2)
 2
x  + 2⋅x + 1
```

```python
>>> expand((x + 2)*(x - 3))
 2
x  - x - 6
```

Given a polynomial, `expand()` will put it into a canonical form of a sum of monomials.

`expand()` may not sound like a simplification function. After all, by its very name, it makes expressions bigger, not smaller. Usually this is the case, but often an expression will become smaller upon calling `expand()` on it due to cancellation.

```python
>>> expand((x + 1)*(x - 2) - (x - 1)*x)
  -2
```

**factor**

`factor()` takes a polynomial and factors it into irreducible factors over the rational numbers. For example:

```python
>>> factor(x**3 - x**2 + x - 1)
(x - 1)⋅(x + 1)
```

```python
>>> factor(x**2*z + 4*x*y*z + 4*y**2*z)
z⋅(x + 2⋅y)
```

For polynomials, `factor()` is the opposite of `expand()`. `factor()` uses a complete multivariate factorization algorithm over the rational numbers, which means that each of the factors returned by `factor()` is guaranteed to be irreducible.

If you are interested in the factors themselves, `factor_list` returns a more structured output.

```python
>>> factor_list(x**2*z + 4*x*y*z + 4*y**2*z)
(1, [(z, 1), (x + 2*y, 2)])
```
Note that the input to `factor` and `expand` need not be polynomials in the strict sense. They will intelligently factor or expand any kind of expression (though note that the factors may not be irreducible if the input is no longer a polynomial over the rationals).

```python
>>> expand((cos(x) + sin(x))**2)
  2
sin(x) + 2⋅sin(x)⋅cos(x) + cos(x)
>>> factor(cos(x)**2 + 2*cos(x)*sin(x) + sin(x)**2)
  2
(sin(x) + cos(x))
```

**collect**

`collect()` collects common powers of a term in an expression. For example

```python
>>> expr = x*y + x - 3 + 2*x**2 - z*x**2 + x**3
>>> expr
  3  2
x - x ⋅z + 2⋅x + x⋅y + x - 3
>>> collected_expr = collect(expr, x)
>>> collected_expr
  3  2
x + x ⋅(2 - z) + x⋅(y + 1) - 3
```

`collect()` is particularly useful in conjunction with the `.coeff()` method. `expr.coeff(x, n)` gives the coefficient of `x**n` in `expr`:

```python
>>> collected_expr.coeff(x, 2)
2 - z
```

**cancel**

`cancel()` will take any rational function and put it into the standard canonical form, \( \frac{p}{q} \), where \( p \) and \( q \) are expanded polynomials with no common factors, and the leading coefficients of \( p \) and \( q \) do not have denominators (i.e., are integers).

```python
>>> cancel((x**2 + 2*x + 1)/(x**2 + x))
  x + 1
_____
x
```

```python
>>> expr = 1/x + (3*x/2 - 2)/(x - 4)
>>> expr
  3⋅x
2 - 2
  1
____ + --
x - 4 x
>>> cancel(expr)
  2
```

(continues on next page)
Note that since `factor()` will completely factorize both the numerator and the denominator of an expression, it can also be used to do the same thing:

```python
>>> factor(expr)
    2
(x - z)
----
  x - 1
```

However, if you are only interested in making sure that the expression is in canceled form, `cancel()` is more efficient than `factor()`.

**apart**

`apart()` performs a **partial fraction decomposition** on a rational function.

```python
>>> expr = (4*x**3 + 21*x**2 + 10*x + 12)/(x**4 + 5*x**3 + 5*x**2 + 4*x)
>>> apart(expr)
    2
2⋅x - 1 1 3
----- - - + ----
  x + 1 2 x + x + 1
```

```
3⋅x - 2⋅x - 8
-------
2
2⋅x - 8⋅x
```
Trigonometric Simplification

**Note:** SymPy follows Python’s naming conventions for inverse trigonometric functions, which is to append an a to the front of the function’s name. For example, the inverse cosine, or arc cosine, is called acos().

```python
>>> acos(x)
acos(x)
>>> cos(acos(x))
x
>>> asin(1)
π
- 2
```

**trigsimp**

To simplify expressions using trigonometric identities, use trigsimp().

```python
>>> trigsimp(sin(x)**2 + cos(x)**2)
1
>>> trigsimp(sin(x)**4 - 2*cos(x)**2*sin(x)**2 + cos(x)**4)
\[\cos(4\cdot x) + \frac{1}{2} - \frac{1}{2}\]
>>> trigsimp(sin(x)*tan(x)/sec(x))
\[\frac{2\sin(x)}{2}\]
```

trigsimp() also works with hyperbolic trig functions.

```python
>>> trigsimp(cosh(x)**2 + sinh(x)**2)
cosh(2\cdot x)
>>> trigsimp(sinh(x)/tanh(x))
cosh(x)
```

Much like simplify(), trigsimp() applies various trigonometric identities to the input expression, and then uses a heuristic to return the “best” one.

**expand_trig**

To expand trigonometric functions, that is, apply the sum or double angle identities, use expand_trig().

```python
>>> expand_trig(sin(x + y))
sin(x)\cdot\cos(y) + \sin(y)\cdot\cos(x)
>>> expand_trig(tan(2*x))
\[\frac{2\tan(x)}{1}\]
```

(continues on next page)
Because \( \text{expand}_{\text{trig}}() \) tends to make trigonometric expressions larger, and \( \text{trigsimp}() \) tends to make them smaller, these identities can be applied in reverse using \( \text{trigsimp}() \)

```python
>>> \text{trigsimp}(\sin(x) \cdot \cos(y) + \sin(y) \cdot \cos(x))
\sin(x + y)
```

### Powers

Before we introduce the power simplification functions, a mathematical discussion on the identities held by powers is in order. There are three kinds of identities satisfied by exponents

1. \( x^a x^b = x^{a+b} \)
2. \( x^a y^a = (xy)^a \)
3. \( (x^a)^b = x^{ab} \)

Identity 1 is always true.

Identity 2 is not always true. For example, if \( x = y = -1 \) and \( a = \frac{1}{2} \), then \( x^a y^a = \sqrt{-1} \cdot \sqrt{-1} = i \cdot i = -1 \), whereas \( (xy)^a = \sqrt{-1} \cdot \sqrt{-1} = \sqrt{1} = 1 \). However, identity 2 is true at least if \( x \) and \( y \) are nonnegative and \( a \) is real (it may also be true under other conditions as well). A common consequence of the failure of identity 2 is that \( \sqrt{x} \sqrt{y} \neq \sqrt{xy} \).

Identity 3 is not always true. For example, if \( x = -1 \), \( a = 2 \), and \( b = \frac{1}{2} \), then \( (x^a)^b = \left((-1)^2\right)^{1/2} = \sqrt{1} = 1 \) and \( x^{ab} = (-1)^{2\cdot1/2} = (-1)^1 = -1 \). However, identity 3 is true when \( b \) is an integer (again, it may also hold in other cases as well). Two common consequences of the failure of identity 3 are that \( \sqrt{x^2} \neq x \) and that \( \sqrt{\frac{1}{x}} \neq \frac{1}{\sqrt{x}} \).

To summarize

<table>
<thead>
<tr>
<th>Identity</th>
<th>Sufficient conditions to hold</th>
<th>Counterexample when conditions are not met</th>
<th>Important consequences</th>
<th>consequences in general</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. ( x^a x^b = x^{a+b} )</td>
<td>always true</td>
<td>None</td>
<td>none</td>
<td>none</td>
</tr>
<tr>
<td>2. ( x^a y^a = (xy)^a )</td>
<td>( x, y \geq 0 ) and ( a \in \mathbb{R} )</td>
<td>( (1)^{1/2}(1)^{1/2} \neq (1 \cdot 1)^{1/2} )</td>
<td>( \sqrt{x} \sqrt{y} \neq \sqrt{xy} ) in general</td>
<td></td>
</tr>
<tr>
<td>3. ( (x^a)^b = x^{ab} )</td>
<td>( b \in \mathbb{Z} )</td>
<td>( ((-1)^2)^{1/2} \neq (-1)^{2\cdot1/2} )</td>
<td>( \sqrt{x^2} \neq x ) and ( \sqrt{\frac{1}{x}} \neq \frac{1}{\sqrt{x}} ) in general</td>
<td></td>
</tr>
</tbody>
</table>

This is important to remember, because by default, SymPy will not perform simplifications if they are not true in general.

In order to make SymPy perform simplifications involving identities that are only true under certain assumptions, we need to put assumptions on our Symbols. We will undertake a full discussion of the assumptions system later, but for now, all we need to know are the following.
- By default, SymPy Symbols are assumed to be complex (elements of \( \mathbb{C} \)). That is, a simplification will not be applied to an expression with a given Symbol unless it holds for all complex numbers.

- Symbols can be given different assumptions by passing the assumption to `symbols()`. For the rest of this section, we will be assuming that \( x \) and \( y \) are positive, and that \( a \) and \( b \) are real. We will leave \( z \), \( t \), and \( c \) as arbitrary complex Symbols to demonstrate what happens in that case.

```python
>>> x, y = symbols('x y', positive=True)
>>> a, b = symbols('a b', real=True)
>>> z, t, c = symbols('z t c')
```

**Note:** In SymPy, \( \sqrt{x} \) is just a shortcut to \( x^{\frac{1}{2}} \). They are exactly the same object.

```python
>>> sqrt(x) == x**Rational(1, 2)
True
```

### powsimp

`powsimp()` applies identities 1 and 2 from above, from left to right.

```python
>>> powsimp(x**a*x**b)
a + b
x
>>> powsimp(x**a*y**a)
a
(x*y)
```

Notice that `powsimp()` refuses to do the simplification if it is not valid.

```python
>>> powsimp(t**c*z**c)
c
t * z
```

If you know that you want to apply this simplification, but you don’t want to mess with assumptions, you can pass the `force=True` flag. This will force the simplification to take place, regardless of assumptions.

```python
>>> powsimp(t**c*z**c, force=True)
c
(t * z)
```

Note that in some instances, in particular, when the exponents are integers or rational numbers, and identity 2 holds, it will be applied automatically.

```python
>>> (z*t)**2
2
2
z * t
>>> sqrt(x*y)
\sqrt{x * y}
```
This means that it will be impossible to undo this identity with \texttt{powsimp()}, because even if \texttt{powsimp()} were to put the bases together, they would be automatically split apart again.

\begin{verbatim}
>>> powsimp(z**2*t**2)
  2 2
  t⋅z
>>> powsimp(sqrt(x)*sqrt(y))
  √x⋅√y
\end{verbatim}

\textbf{expand\_power\_exp / expand\_power\_base}

\texttt{expand\_power\_exp()} and \texttt{expand\_power\_base()} apply identities 1 and 2 from right to left, respectively.

\begin{verbatim}
>>> expand\_power\_exp(x**(a + b))
  a  b
  x⋅x

>>> expand\_power\_base((x*y)**a)
  a  a
  x⋅y
\end{verbatim}

As with \texttt{powsimp()}, identity 2 is not applied if it is not valid.

\begin{verbatim}
>>> expand\_power\_base((z*t)**c)
  c
  (t⋅z)
\end{verbatim}

And as with \texttt{powsimp()}, you can force the expansion to happen without fiddling with assumptions by using \texttt{force=True}.

\begin{verbatim}
>>> expand\_power\_base((z*t)**c, force=True)
  c  c
  t⋅z
\end{verbatim}

As with identity 2, identity 1 is applied automatically if the power is a number, and hence cannot be undone with \texttt{expand\_power\_exp()}.

\begin{verbatim}
>>> x**2*x**3
  5
  x
>>> expand\_power\_exp(x**5)
  5
  x
\end{verbatim}
powdenest

powdenest() applies identity 3, from left to right.

```python
given_expression = powdenest((x**a)**b)
given_expression
```

As before, the identity is not applied if it is not true under the given assumptions.

```python
given_expression = powdenest((z**a)**b)
given_expression
```

And as before, this can be manually overridden with force=True.

```python
given_expression = powdenest((z**a)**b, force=True)
given_expression
```

Exponentials and logarithms

**Note:** In SymPy, as in Python and most programming languages, log is the natural logarithm, also known as ln. SymPy automatically provides an alias \( \ln = \log \) in case you forget this.

```python
logarithm_expression = ln(x)
logarithm_expression
```

Logarithms have similar issues as powers. There are two main identities

1. \( \log(xy) = \log(x) + \log(y) \)
2. \( \log(x^n) = n \log(x) \)

Neither identity is true for arbitrary complex \( x \) and \( y \), due to the branch cut in the complex plane for the complex logarithm. However, sufficient conditions for the identities to hold are if \( x \) and \( y \) are positive and \( n \) is real.

```python
x, y = symbols('x y', positive=True)
n = symbols('n', real=True)
```

As before, \( z \) and \( t \) will be Symbols with no additional assumptions.

Note that the identity \( \log(\frac{x}{y}) = \log(x) - \log(y) \) is a special case of identities 1 and 2 by \( \log(\frac{x}{y}) = \log(x \cdot \frac{1}{y}) = \log(x) + \log(y^{-1}) = \log(x) - \log(y) \), and thus it also holds if \( x \) and \( y \) are positive, but may not hold in general.

We also see that \( \log(e^x) = x \) comes from \( \log(e^x) = x \log(e) = x \), and thus holds when \( x \) is real (and it can be verified that it does not hold in general for arbitrary complex \( x \), for example, \( \log(e^{x+2\pi i}) = \log(e^x) = x \neq x + 2\pi i \)).
**expand_log**

To apply identities 1 and 2 from left to right, use `expand_log()`. As always, the identities will not be applied unless they are valid.

```python
>>> expand_log(log(x*y))
log(x) + log(y)
>>> expand_log(log(x/y))
log(x) - log(y)
>>> expand_log(log(x**2))
2⋅log(x)
>>> expand_log(log(x**n))
n⋅log(x)
>>> expand_log(log(z**t))
log(t⋅z)
```

As with `powsimp()` and `powdenest()`, `expand_log()` has a force option that can be used to ignore assumptions.

```python
>>> expand_log(log(z**2))
log(z**2)
>>> expand_log(log(z**2), force=True)
2⋅log(z)
```

**logcombine**

To apply identities 1 and 2 from right to left, use `logcombine()`.

```python
>>> logcombine(log(x) + log(y))
log(x⋅y)
>>> logcombine(n*log(x))
n⋅log(x)
>>> logcombine(n*log(z))
n⋅log(z)
```

`logcombine()` also has a force option that can be used to ignore assumptions.

```python
>>> logcombine(n*log(z), force=True)
(n)
log(z)
```
**Special Functions**

SymPy implements dozens of special functions, ranging from functions in combinatorics to mathematical physics.

An extensive list of the special functions included with SymPy and their documentation is at the *Functions Module* (page 442) page.

For the purposes of this tutorial, let's introduce a few special functions in SymPy.

Let's define $x$, $y$, and $z$ as regular, complex Symbols, removing any assumptions we put on them in the previous section. We will also define $k$, $m$, and $n$.

```python
>>> x, y, z = symbols('x y z')
>>> k, m, n = symbols('k m n')
```

The **factorial** function is *factorial*. 

$\text{factorial}(n)$ represents $n! = 1 \cdot 2 \cdots (n - 1) \cdot n$. $n!$ represents the number of permutations of $n$ distinct items.

```python
>>> factorial(n)
```

The **binomial coefficient** function is *binomial*. 

$\text{binomial}(n, k)$ represents $\binom{n}{k}$, the number of ways to choose $k$ items from a set of $n$ distinct items. It is also often written as $nCk$, and is pronounced "$n$ choose $k$".

```python
>>> binomial(n, k)
```

The factorial function is closely related to the **gamma function**, *gamma*. $\text{gamma}(z)$ represents $\Gamma(z) = \int_0^\infty t^{z-1} e^{-t} \, dt$, which for positive integer $z$ is the same as $(z - 1)!$.

```python
>>> gamma(z)
```

The **generalized hypergeometric function** is *hyper*. $\text{hyper}([a_1, \ldots, a_p], [b_1, \ldots, b_q], z)$ represents $\left._pF_q\right(a_1, \ldots, a_p \left| \begin{array}{c} b_1, \ldots, b_q \\ z \end{array} \right. )$. The most common case is $\left._2F_1\right.$, which is often referred to as the **ordinary hypergeometric function**.

```python
>>> hyper([1, 2], [3], z)
```
rewrite

A common way to deal with special functions is to rewrite them in terms of one another. This works for any function in SymPy, not just special functions. To rewrite an expression in terms of a function, use expr.rewrite(function). For example,

```
>>> tan(x).rewrite(cos)
\cos\left(x - \frac{\pi}{2}\right)
\cos(x)
```

```
>>> factorial(x).rewrite(gamma)
\Gamma(x + 1)
```

For some tips on applying more targeted rewriting, see the Advanced Expression Manipulation (page 61) section.

expand_func

To expand special functions in terms of some identities, use expand_func(). For example

```
>>> expand_func(gamma(x + 3))
x\cdot(x + 1)\cdot(x + 2)\cdot\Gamma(x)
```

hyperexpand

To rewrite hyper in terms of more standard functions, use hyperexpand().

```
>>> hyperexpand(hyper([1, 1], [2], z))
-\log(1 - z)
\frac{1}{z}
```

hyperexpand() also works on the more general Meijer G-function (see its documentation (page 579) for more information).

```
>>> expr = meijerg([[1],[1]], [[1],[1]], -z)
>>> expr
\begin{bmatrix}
1, 1 & 1, 1 \\
2, 1 & 1, -z
\end{bmatrix}
```

```
>>> hyperexpand(expr)
1
-\frac{1}{z}
e
```
combsimp

To simplify combinatorial expressions, use combsimp().

```python
>>> n, k = symbols('n k', integer=True)
>>> combsimp(factorial(n)/factorial(n-3))
n⋅(n - 2)⋅(n - 1)
```

```python
>>> combsimp(binomial(n+1, k+1)/binomial(n, k))
n + 1
─────
k + 1
```

gammasimp

To simplify expressions with gamma functions or combinatorial functions with non-integer argument, use gammasimp().

```python
>>> gammasimp(gamma(x)*gamma(1-x))
π
────────
sin(π⋅x)
```

Example: Continued Fractions

Let’s use SymPy to explore continued fractions. A continued fraction is an expression of the form

\[ a_0 + \frac{1}{a_1 + \frac{1}{a_2 + \cdots + \frac{1}{a_n} \cdots}} \]

where \( a_0, \ldots, a_n \) are integers, and \( a_1, \ldots, a_n \) are positive. A continued fraction can also be infinite, but infinite objects are more difficult to represent in computers, so we will only examine the finite case here.

A continued fraction of the above form is often represented as a list \([a_0; a_1, \ldots, a_n]\). Let’s write a simple function that converts such a list to its continued fraction form. The easiest way to construct a continued fraction from a list is to work backwards. Note that despite the apparent symmetry of the definition, the first element, \( a_0 \), must usually be handled differently from the rest.

```python
>>> def list_to_frac(l):
...     expr = Integer(0)
...     for i in reversed(l[1:]):
...         expr += i
...     expr = 1/expr
...     return l[0] + expr
>>> list_to_frac([x, y, z])
```

(continues on next page)
We use Integer(0) in list_to_frac so that the result will always be a SymPy object, even if we only pass in Python ints.

```
>>> list_to_frac([1, 2, 3, 4])
43
──
30
```

Every finite continued fraction is a rational number, but we are interested in symbolics here, so let's create a symbolic continued fraction. The symbols() function that we have been using has a shortcut to create numbered symbols. symbols('a0:5') will create the symbols a0, a1, ..., a4.

```
>>> syms = symbols('a0:5')
>>> syms
(a0, a1, a2, a3, a4)
>>> a0, a1, a2, a3, a4 = syms
>>> frac = list_to_frac(syms)
>>> frac
a0 + ─────
a1 + ─
a2 + ─
a3 + ─
a4
```

This form is useful for understanding continued fractions, but let's put it into standard rational function form using cancel().

```
>>> frac = cancel(frac)
>>> frac
a0⋅a1⋅a2⋅a3⋅a4 + a0⋅a1⋅a2 + a0⋅a1⋅a4 + a0⋅a3⋅a4 + a0 + a2⋅a3⋅a4 + a2 + a4
─────────────────────────────────────────────────────────────────────────
a0⋅a1⋅a2⋅a3⋅a4 + a0⋅a2⋅a4 + a1⋅a2 + a1⋅a4 + a3⋅a4 + 1
```

Now suppose we were given frac in the above canceled form. In fact, we might be given the fraction in any form, but we can always put it into the above canonical form with cancel(). Suppose that we knew that it could be rewritten as a continued fraction. How could we do this with SymPy? A continued fraction is recursively \( c + \frac{1}{f} \), where \( c \) is an integer and \( f \) is a (smaller) continued fraction. If we could write the expression in this form, we could pull out each \( c \) recursively and add it to a list. We could then get a continued fraction with our list_to_frac() function.

The key observation here is that we can convert an expression to the form \( c + \frac{1}{f} \) by doing a partial fraction decomposition with respect to \( c \). This is because \( f \) does not contain \( c \). This
means we need to use the `apart()` function. We use `apart()` to pull the term out, then subtract it from the expression, and take the reciprocal to get the \( f \) part.

```python
>>> l = []
>>> frac = apart(frac, a0)
>>> frac
\[
\frac{a_2 \cdot a_3 \cdot a_4 + a_2 + a_4}{a_1 \cdot a_2 \cdot a_3 \cdot a_4 + a_1 \cdot a_2 + a_1 \cdot a_4 + a_3 \cdot a_4 + 1}
\]
>>> l.append(a0)
>>> frac = 1/(frac - a0)
>>> frac
\[
\frac{a_1 \cdot a_2 \cdot a_3 \cdot a_4 + a_1 \cdot a_2 + a_1 \cdot a_4 + a_3 \cdot a_4 + 1}{a_2 \cdot a_3 \cdot a_4 + a_2 + a_4}
\]

Now we repeat this process

```python
>>> frac = apart(frac, a1)
>>> frac
\[
\frac{a_3 \cdot a_4 + 1}{a_2 \cdot a_3 \cdot a_4 + a_2 + a_4}
\]
>>> l.append(a1)
>>> frac = 1/(frac - a1)
>>> frac = apart(frac, a2)
>>> frac
\[
\frac{a_4}{a_3 \cdot a_4 + 1}
\]
```
Of course, this exercise seems pointless, because we already know that our frac is `list_to_frac([a0, a1, a2, a3, a4])`. So try the following exercise. Take a list of symbols and randomize them, and create the canceled continued fraction, and see if you can reproduce the original list. For example

```
>>> import random
>>> l = list(symbols('a0:5'))
>>> random.shuffle(l)
>>> orig_frac = frac = cancel(list_to_frac(l))
>>> del l
```

In SymPy, on the above example, try to reproduce `l` from frac. I have deleted `l` at the end to remove the temptation for peeking (you can check your answer at the end by calling `cancel(list_to_frac(l))` on the list that you generate at the end, and comparing it to `orig_frac`.

See if you can think of a way to figure out what symbol to pass to `apart()` at each stage (hint: think of what happens to $a_0$ in the formula $a_0 + \frac{1}{a_1 + \cdots}$ when it is canceled).

### Calculus

This section covers how to do basic calculus tasks such as derivatives, integrals, limits, and series expansions in SymPy. If you are not familiar with the math of any part of this section, you may safely skip it.

```
>>> from sympy import *
>>> x, y, z = symbols('x y z')
>>> init_printing(use_unicode=True)
```

#### Derivatives

To take derivatives, use the `diff` function.

```
>>> diff(cos(x), x)
-sin(x)
```

```
>>> diff(exp(x**2), x)
\[ 2 \cdot x \cdot e^x \]
```

diff can take multiple derivatives at once. To take multiple derivatives, pass the variable as many times as you wish to differentiate, or pass a number after the variable. For example, both of the following find the third derivative of $x^4$.

```
>>> diff(x**4, x, x, x)
24 \cdot x
```

```
>>> diff(x**4, x, 3)
24 \cdot x
```

You can also take derivatives with respect to many variables at once. Just pass each derivative in order, using the same syntax as for single variable derivatives. For example, each of the following will compute $\frac{\partial^7}{\partial x \partial y \partial z} e^{xyz}$.
diff can also be called as a method. The two ways of calling diff are exactly the same, and are provided only for convenience.

To create an unevaluated derivative, use the Derivative class. It has the same syntax as diff.

To evaluate an unevaluated derivative, use the doit method.

These unevaluated objects are useful for delaying the evaluation of the derivative, or for printing purposes. They are also used when SymPy does not know how to compute the derivative of an expression (for example, if it contains an undefined function, which are described in the Solving Differential Equations section).

Derivatives of unspecified order can be created using tuple \((x, n)\) where \(n\) is the order of the derivative with respect to \(x\).
Integrals

To compute an integral, use the integrate function. There are two kinds of integrals, definite and indefinite. To compute an indefinite integral, that is, an antiderivative, or primitive, just pass the variable after the expression.

```python
>>> integrate(cos(x), x)
sin(x)
```

Note that SymPy does not include the constant of integration. If you want it, you can add one yourself, or rephrase your problem as a differential equation and use `dsolve` to solve it, which does add the constant (see Solving Differential Equations (page 50)).

Quick Tip

∞ in SymPy is oo (that’s the lowercase letter “oh” twice). This is because oo looks like ∞, and is easy to type.

To compute a definite integral, pass the argument `(integration_variable, lower_limit, upper_limit)`. For example, to compute

\[
\int_{0}^{\infty} e^{-x} \, dx,
\]

we would do

```python
>>> integrate(exp(-x), (x, 0, oo))
1
```

As with indefinite integrals, you can pass multiple limit tuples to perform a multiple integral. For example, to compute

\[
\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} e^{-x^2-y^2} \, dx \, dy,
\]

do

```python
>>> integrate(exp(-x**2 - y**2), (x, -oo, oo), (y, -oo, oo))
π
```

If `integrate` is unable to compute an integral, it returns an unevaluated `Integral` object.

```python
>>> expr = integrate(x**x, x)
>>> print(expr)
Integral(x**x, x)
>>> expr
\[
\left\{ \begin{array}{l}
x \\
x \, dx
\end{array} \right.
\]
```

As with `Derivative`, you can create an unevaluated integral using `Integral`. To later evaluate this integral, call `doit`. 
integrate uses powerful algorithms that are always improving to compute both definite and indefinite integrals, including heuristic pattern matching type algorithms, a partial implementation of the Risch algorithm, and an algorithm using Meijer G-functions that is useful for computing integrals in terms of special functions, especially definite integrals. Here is a sampling of some of the power of integrate.

```python
>>> integ = Integral((x**4 + x**2*exp(x) - x**2 - 2*x*exp(x) - 2*x - ... exp(x))**exp(x)/((x - 1)**2*(x + 1)**2*(exp(x) + 1)), x)
>>> integ
\int \left( \frac{4 \cdot 2 \cdot x^2 \cdot x^2 \cdot x^2}{x^4 + x^2 \cdot e - x^2 - 2 \cdot x \cdot e - 2 \cdot x - e} \right) \cdot e \, dx

\int \left( \frac{2 \cdot x}{x - 1} \cdot (x + 1) \cdot (e + 1) \right) dx

>>> integ.doit()
\frac{x \cdot \log(e + 1) + e}{2 \cdot x - 1}
```

```python
>>> integ = Integral(sin(x**2), x)
>>> integ
\int \sin(x^2) \, dx

>>> integ.doit()
\sqrt{2} \cdot x \sqrt{\pi} \cdot S \left( \frac{\sqrt{2} \cdot x}{\sqrt{\pi}} \right) \cdot \Gamma(3/4) \cdot 8 \cdot \Gamma(7/4)
```

```python
>>> integ = Integral(x**y*exp(-x), (x, 0, oo))
>>> integ
\int x^y \cdot e^{-x} \, dx
```

(continues on next page)
This last example returned a Piecewise expression because the integral does not converge unless \( \Re(y) > 1 \).

## Limits

SymPy can compute symbolic limits with the `limit` function. The syntax to compute

\[
\lim_{x \to x_0} f(x)
\]

is `limit(f(x), x, x0)`.

```python
>>> limit(sin(x)/x, x, 0)
1
```

`limit` should be used instead of `subs` whenever the point of evaluation is a singularity. Even though SymPy has objects to represent \( \infty \), using them for evaluation is not reliable because they do not keep track of things like rate of growth. Also, things like \( \infty - \infty \) and \( \frac{\infty}{\infty} \) return `nan` (not-a-number). For example

```python
>>> expr = x**2/exp(x)
>>> expr.subs(x, oo)
nan
>>> limit(expr, x, oo)
0
```

Like `Derivative` and `Integral`, `limit` has an unevaluated counterpart, `Limit`. To evaluate it, use `doit`.

```python
>>> expr = Limit((cos(x) - 1)/x, x, 0)
>>> expr
\lim_{x \to 0^+} \frac{\cos(x) - 1}{x}
>>> expr.doit()
0
```
To evaluate a limit at one side only, pass `'+` or `'-` as a fourth argument to `limit`. For example, to compute

\[ \lim_{x \to 0^+} \frac{1}{x} \]

do

```python
>>> limit(1/x, x, 0, '+')
\infty
```

As opposed to

```python
>>> limit(1/x, x, 0, '-')
-\infty
```

### Series Expansion

Sympy can compute asymptotic series expansions of functions around a point. To compute the expansion of \( f(x) \) around the point \( x = x_0 \) terms of order \( x^n \), use \( f(x).series(x, x_0, n) \). \( x_0 \) and \( n \) can be omitted, in which case the defaults \( x_0=0 \) and \( n=6 \) will be used.

```python
>>> expr = exp(sin(x))
>>> expr.series(x, 0, 4)
2
\quad x + \frac{4}{2} + \frac{0\{x\}}{2}
```

The \( O(x^4) \) term at the end represents the Landau order term at \( x = 0 \) (not to be confused with big O notation used in computer science, which generally represents the Landau order term at \( x \) where \( x \to \infty \)). It means that all \( x \) terms with power greater than or equal to \( x^4 \) are omitted. Order terms can be created and manipulated outside of `series`. They automatically absorb higher order terms.

```python
>>> x + x**3 + x**6 + 0(x**4)
3
\quad x + \frac{4}{0\{x\}}
>>> x*O(1)
0(x)
```

If you do not want the order term, use the `removeO` method.

```python
>>> expr.series(x, 0, 4).removeO()
2
\quad x + x + 1
```

The \( O \) notation supports arbitrary limit points (other than 0):

```python
>>> exp(x - 6).series(x, x0=6)
2 \quad 3 \quad 4 \quad 5
```

(continues on next page)
Finite differences

So far we have looked at expressions with analytic derivatives and primitive functions respectively. But what if we want to have an expression to estimate a derivative of a curve for which we lack a closed form representation, or for which we don’t know the functional values for yet. One approach would be to use a finite difference approach.

The simplest way the differentiate using finite differences is to use the differentiate_finite function:

```python
>>> f, g = symbols('f g', cls=Function)
>>> differentiate_finite(f(x)*g(x))
-f(x - 1/2)\cdot g(x - 1/2) + f(x + 1/2)\cdot g(x + 1/2)
```

If you already have a Derivative instance, you can use the as_finite_difference method to generate approximations of the derivative to arbitrary order:

```python
>>> f = Function('f')
>>> dfdx = f(x).diff(x)
>>> dfdx.as_finite_difference()
-f(x - 1/2) + f(x + 1/2)
```

Here the first order derivative was approximated around x using a minimum number of points (2 for 1st order derivative) evaluated equidistantly using a step-size of 1. We can use arbitrary steps (possibly containing symbolic expressions):

```python
>>> f = Function('f')
>>> d2fdx2 = f(x).diff(x, 2)
>>> h = Symbol('h')
>>> d2fdx2.as_finite_difference([-3*h, -h, 2*h])
f(-3\cdot h) - f(-h) + 2\cdot f(2\cdot h)
\begin{align*}
&\frac{1}{2} &\frac{1}{2} &\frac{2}{15} \\
&5\cdot h &3\cdot h &15\cdot h
\end{align*}
```

If you are just interested in evaluating the weights, you can do so manually:

```python
>>> finite_diff_weights(2, [-3, -1, 2], 0)[-1][-1]
[1/5, -1/3, 2/15]
```

Note that we only need the last element in the last sublist returned from finite_diff_weights. The reason for this is that the function also generates weights for lower derivatives and using fewer points (see the documentation of finite_diff_weights for more details).

If using finite_diff_weights directly looks complicated, and the as_finite_difference method of Derivative instances is not flexible enough, you can use apply_finite_diff which takes order, x_list, y_list and x0 as parameters:
```python
>>> x_list = [-3, 1, 2]
>>> y_list = symbols('a b c')
>>> apply_finite_diff(1, x_list, y_list, 0)
   3⋅a  b  2⋅c
- ─── - ─ + ───
   20  4  5
```

## Solvers

**Note:** For a beginner-friendly guide focused on solving common types of equations, refer to *Solve Equations* (page 131).

```python
>>> from sympy import *
>>> x, y, z = symbols('x y z')
>>> init_printing(use_unicode=True)
```

### A Note about Equations

Recall from the *gotchas* (page 12) section of this tutorial that symbolic equations in SymPy are not represented by = or ==, but by `Eq`.

```python
>>> Eq(x, y)
x = y
```

However, there is an even easier way. In SymPy, any expression not in an `Eq` is automatically assumed to equal 0 by the solving functions. Since \( a = b \) if and only if \( a - b = 0 \), this means that instead of using \( x == y \), you can just use \( x - y \). For example

```python
>>> solveset(Eq(x**2, 1), x)
{-1, 1}
>>> solveset(Eq(x**2 - 1, 0), x)
{-1, 1}
>>> solveset(x**2 - 1, x)
{-1, 1}
```

This is particularly useful if the equation you wish to solve is already equal to 0. Instead of typing `solveset(Eq(expr, 0), x)`, you can just use `solveset(expr, x)`.  

---

2.1. Introductory Tutorial
Solving Equations Algebraically

The main function for solving algebraic equations is `solve`. The syntax for `solve` is `solve(equation, variable=None, domain=S.Complexes)` where equations may be in the form of `Eq` instances or expressions that are assumed to be equal to zero.

Please note that there is another function called `solve` which can also be used to solve equations. The syntax is `solve(equations, variables)` However, it is recommended to use `solve` instead.

When solving a single equation, the output of `solve` is a `FiniteSet` or an `Interval` or `ImageSet` of the solutions.

```
>>> solveset(x**2 - x, x)
{0, 1}
>>> solveset(x - x, x, domain=S.Reals)
ℝ
>>> solveset(sin(x) - 1, x, domain=S.Reals)
⎧ π │ ⎫
⎨2⋅n⋅π + ─ │ n ∊ ℤ⎬
⎩ 2 │ ⎭
```

If there are no solutions, an `EmptySet` is returned and if it is not able to find solutions then a `ConditionSet` is returned.

```
>>> solveset(exp(x), x)  # No solution exists
∅
>>> solveset(cos(x) - x, x)  # Not able to find solution
{x | x ∈ ℂ ∧ (-x + cos(x) = 0)}
```

In the `solve` module, the non linear system of equations is solved using `nonlinsolve`. Following are examples of `nonlinsolve`.

```
• List of Equations Form:
    >>> nonlinsolve([x + y + z - 1, x + y + 2*z - 3], (x, y, z))
    {(-y - 1, y, 2)}

• Augmented Matrix Form:
    >>> nonlinsolve(Matrix(([1, 1, 1], [1, 2, 3])), (x, y, z))
    {(-y - 1, y, 2)}

• A*x = b Form
    >>> M = Matrix(([1, 1, 1], (1, 1, 2, 3)))
    >>> system = A, b = M[:, :-1], M[:, -1]
    >>> nonlinsolve(system, x, y)
    {(-y - 1, y, 2)}
```

Note: The order of solution corresponds the order of given symbols.

In the `solve` module, the non linear system of equations is solved using `nonlinsolve`. Following are examples of `nonlinsolve`.
1. When only real solution is present:

```python
>>> a, b, c, d = symbols('a, b, c, d', real=True)
>>> nonlinsolve([a**2 + a, a - b], [a, b])
{(-1, -1), (0, 0)}
>>> nonlinsolve([x*y - 1, x - 2], x, y)
{(2, 1/2)}
```

2. When only complex solution is present:

```python
>>> nonlinsolve([x**2 + 1, y**2 + 1], [x, y])
{(-i, -i), (i, i)}
```

3. When both real and complex solution are present:

```python
>>> from sympy import sqrt
>>> system = [x**2 - 2*y**2 - 2, x*y - 2]
>>> vars = [x, y]
>>> nonlinsolve(system, vars)
{(-2, -1), (2, 1), (-sqrt(2)*i, sqrt(2)*i), (sqrt(2)*i, -sqrt(2)*i)}
```

```python
>>> system = [exp(x) - sin(y), 1/y - 3]
>>> nonlinsolve(system, vars)
{{(2·n·i·π + log(sin(1/3)) │ n ∊ ℤ}, 1/3}
```

4. When the system is positive-dimensional system (has infinitely many solutions):

```python
>>> nonlinsolve([x*y, x**y - x], [x, y])
{(0, y)}
```

```python
>>> system = [a**2 + a*c, a - b]
>>> nonlinsolve(system, [a, b])
{(0, 0), (-c, -c)}
```

**Note:**

1. The order of solution corresponds the order of given symbols.
2. Currently `nonlinsolve` doesn’t return solution in form of LambertW (if there is solution present in the form of LambertW).

`solve` can be used for such cases:

```python
>>> solve([x**2 - y**2/exp(x)], [x, y], dict=True)
[[{x: y/sqrt(exp(x))}, {y: -x/sqrt(exp(x))}]]
>>> solve(x**2 - y**2/exp(x), x, dict=True)
[[{x: 2·W[y]}, {x: -2·W[y]}]]
```

3. Currently `nonlinsolve` is not properly capable of solving the system of equations having trigonometric functions.
solve can be used for such cases (but does not give all solution):

```python
>>> solve([sin(x + y), cos(x - y)], [x, y])
```

\[
\begin{bmatrix}
\left(-3\pi, 3\pi\right), \\
\left(-\pi, -\pi\right), \\
\left(\pi, 3\pi\right), \\
\left(3\pi, -\pi\right)
\end{bmatrix}
\]

solveset reports each solution only once. To get the solutions of a polynomial including multiplicity use roots.

```python
>>> solveset(x**3 - 6*x**2 + 9*x, x)
{0, 3}
```
```python
>>> roots(x**3 - 6*x**2 + 9*x, x)
{0: 1, 3: 2}
```

The output \{0: 1, 3: 2\} of roots means that 0 is a root of multiplicity 1 and 3 is a root of multiplicity 2.

**Note:** Currently solveset is not capable of solving the following types of equations:

- Equations solvable by LambertW (Transcendental equation solver).

solve can be used for such cases:

```python
>>> solve(x*exp(x) - 1, x )
```

```
[W(1)]
```

### Solving Differential Equations

To solve differential equations, use `dsolve`. First, create an undefined function by passing `cls=Function` to the `symbols` function.

```python
>>> f, g = symbols('f g', cls=Function)
```

f and g are now undefined functions. We can call f(x), and it will represent an unknown function.

```python
>>> f(x)
```

```
f(x)
```

Derivatives of f(x) are unevaluated.

```python
>>> f(x).diff(x)
```

```
d (f(x))
--
dx
```

(see the Derivatives (page 40) section for more on derivatives).

To represent the differential equation \(f''(x) - 2f'(x) + f(x) = \sin(x)\), we would thus use
```python
>>> diffeq = Eq(f(x).diff(x, x) - 2*f(x).diff(x) + f(x), sin(x))
>>> diffeq
\[
\frac{d^2}{dx^2}f(x) - 2\frac{d}{dx}(f(x)) + \frac{1}{2}(f(x)) = \sin(x)
\]
```

To solve the ODE, pass it and the function to solve for to `dsolve`.

```python
>>> dsolve(diffeq, f(x))
f(x) = (C_1 + C_2\cdot x)\cdot e^{\frac{\cos(x)}{2}}
```

`dsolve` returns an instance of `Eq`. This is because, in general, solutions to differential equations cannot be solved explicitly for the function.

```python
>>> dsolve(f(x).diff(x)*(1 - sin(f(x))) - 1, f(x))
x - f(x) - \cos(f(x)) = C_1
```

The arbitrary constants in the solutions from `dsolve` are symbols of the form `C1`, `C2`, `C3`, and so on.

### Matrices

```python
>>> from sympy import *
>>> init_printing(use_unicode=True)
```

To make a matrix in SymPy, use the `Matrix` object. A matrix is constructed by providing a list of row vectors that make up the matrix. For example, to construct the matrix

\[
\begin{bmatrix}
1 & -1 \\
3 & 4 \\
0 & 2
\end{bmatrix}
\]

use

```python
>>> Matrix([[1, -1], [3, 4], [0, 2]])
```

To make it easy to make column vectors, a list of elements is considered to be a column vector.

```python
>>> Matrix([[1, 2, 3]])
```

2.1. Introductory Tutorial
Matrices are manipulated just like any other object in SymPy or Python.

```python
>>> M = Matrix([[1, 2, 3], [3, 2, 1]])
>>> N = Matrix([0, 1, 1])
>>> M*N
[5]
[3]
```

One important thing to note about SymPy matrices is that, unlike every other object in SymPy, they are mutable. This means that they can be modified in place, as we will see below. The downside to this is that `Matrix` cannot be used in places that require immutability, such as inside other SymPy expressions or as keys to dictionaries. If you need an immutable version of `Matrix`, use `ImmutableMatrix`.

### Basic Operations

Here are some basic operations on `Matrix`.

#### Shape

To get the shape of a matrix, use `shape()` (page 1199) function.

```python
>>> from sympy import shape
>>> M = Matrix([[1, 2, 3], [-2, 0, 4]])
>>> M
[1  2  3]
[-2  0  4]
>>> shape(M)
(2, 3)
```

#### Accessing Rows and Columns

To get an individual row or column of a matrix, use `row` or `col`. For example, `M.row(0)` will get the first row. `M.col(-1)` will get the last column.

```python
>>> M.row(0)
[1 2 3]
>>> M.col(-1)
[3]
[4]
```
Deleting and Inserting Rows and Columns

To delete a row or column, use row_del or col_del. These operations will modify the Matrix in place.

```python
>>> M.col_del(0)
>>> M
[2 3]
[0 4]
>>> M.row_del(1)
>>> M
[2 3]
```

To insert rows or columns, use row_insert or col_insert. These operations do not operate in place.

```python
>>> M
[2 3]
>>> M = M.row_insert(1, Matrix([[0, 4]]))
>>> M
[2 3]
[0 4]
>>> M = M.col_insert(0, Matrix([1, -2]))
>>> M
[1 2 3]
[-2 0 4]
```

Unless explicitly stated, the methods mentioned below do not operate in place. In general, a method that does not operate in place will return a new Matrix and a method that does operate in place will return None.

Basic Methods

As noted above, simple operations like addition, multiplication and power are done just by using +, *, and **. To find the inverse of a matrix, just raise it to the -1 power.

```python
>>> M = Matrix([[1, 3], [-2, 3]])
>>> N = Matrix([[0, 3], [0, 7]])
>>> M + N
[1  6]
[ 10]
>>> M*N
[0 24]
[0 15]
>>> 3*M
[3  9]
```
To take the transpose of a Matrix, use T.

```python
>>> M = Matrix([[1, 2, 3], [4, 5, 6]])
>>> M
[1 2 3]
[4 5 6]
>>> M.T
[1 4]
[2 5]
[3 6]
```

### Matrix Constructors

Several constructors exist for creating common matrices. To create an identity matrix, use eye. eye(n) will create an \( n \times n \) identity matrix.

```python
>>> eye(3)
[1 0 0]
[0 1 0]
[0 0 1]
>>> eye(4)
[1 0 0 0]
[0 1 0 0]
[0 0 1 0]
[0 0 0 1]
```
To create a matrix of all zeros, use zeros. `zeros(n, m)` creates an $n \times m$ matrix of 0s.

```python
>>> zeros(2, 3)
[[0, 0, 0],
 [0, 0, 0]]
```

Similarly, ones creates a matrix of ones.

```python
>>> ones(3, 2)
[[1, 1],
 [1, 1],
 [1, 1]]
```

To create diagonal matrices, use diag. The arguments to diag can be either numbers or matrices. A number is interpreted as a $1 \times 1$ matrix. The matrices are stacked diagonally. The remaining elements are filled with 0s.

```python
>>> diag(1, 2, 3)
[[1, 0, 0],
 [0, 2, 0],
 [0, 0, 3]]

>>> diag(-1, ones(2, 2), Matrix([[5, 7, 5]]))
[[-1, 0, 0, 0],
 [0, 1, 1, 0],
 [0, 1, 1, 0],
 [0, 0, 0, 5],
 [0, 0, 0, 7],
 [0, 0, 0, 5]]
```

**Advanced Methods**

**Determinant**

To compute the determinant of a matrix, use det.

```python
>>> M = Matrix([[1, 0, 1], [2, -1, 3], [4, 3, 2]])
>>> M
[1 0 1]
[2 -1 3]
```

(continues on next page)
RREF

To put a matrix into reduced row echelon form, use \texttt{rref}. \texttt{rref} returns a tuple of two elements. The first is the reduced row echelon form, and the second is a tuple of indices of the pivot columns.

\begin{verbatim}
>>> M = Matrix([[1, 0, 1, 3], [2, 3, 4, 7], [-1, -3, -3, -4]])
>>> M

\begin{bmatrix}
1 & 0 & 1 & 3 \\
2 & 3 & 4 & 7 \\
-1 & -3 & -3 & -4 \\
\end{bmatrix}

>>> M.rref()

\begin{bmatrix}
1 & 0 & 1 & 3 \\
0 & 1 & 2/3 & 1/3 \\
0 & 0 & 0 & 0 \\
\end{bmatrix}, (0, 1)
\end{verbatim}

Note: The first element of the tuple returned by \texttt{rref} is of type \texttt{Matrix}. The second is of type \texttt{tuple}.

Nullspace

To find the nullspace of a matrix, use \texttt{nullspace}. \texttt{nullspace} returns a list of column vectors that span the nullspace of the matrix.

\begin{verbatim}
>>> M = Matrix([[1, 2, 3, 0, 0], [4, 10, 0, 0, 1]])
>>> M

\begin{bmatrix}
1 & 2 & 3 & 0 & 0 \\
4 & 10 & 0 & 0 & 1 \\
\end{bmatrix}

>>> M.nullspace()

\begin{bmatrix}
-15 & 0 & 1 \\
6 & 0 & -1/2 \\
1 & 0 & 0 \\
\end{bmatrix}
\end{verbatim}
Columnspace

To find the columnspace of a matrix, use columnspace. columnspace returns a list of column vectors that span the columnspace of the matrix.

```
>>> M = Matrix([[1, 1, 2], [2, 1, 3], [3, 1, 4]])
>>> M
[1 1 2]
[2 1 3]
[3 1 4]
>>> M.columnspace()
[1 1]
[2 1]
[3 1]
```

Eigenvalues, Eigenvectors, and Diagonalization

To find the eigenvalues of a matrix, use eigenvals. eigenvals returns a dictionary of eigenvalue: algebraic_multiplicity pairs (similar to the output of roots (page 50)).

```
>>> M = Matrix([[3, -2, 4, -2], [5, 3, -3, -2], [5, -2, 2, -2], [5, -2, -3, 3]])
>>> M
[3 -2 4 -2]
[5  3 -3 -2]
[5 -2 2 -2]
[5 -2 -3 3]
>>> M.eigenvals()
{-2: 1, 3: 1, 5: 2}
```

This means that M has eigenvalues -2, 3, and 5, and that the eigenvalues -2 and 3 have algebraic multiplicity 1 and that the eigenvalue 5 has algebraic multiplicity 2.

To find the eigenvectors of a matrix, use eigenvects. eigenvects returns a list of tuples of the form (eigenvalue, algebraic_multiplicity, [eigenvectors]).
This shows us that, for example, the eigenvalue 5 also has geometric multiplicity 2, because it has two eigenvectors. Because the algebraic and geometric multiplicities are the same for all the eigenvalues, \( M \) is diagonalizable.

To diagonalize a matrix, use `diagonalize`. `diagonalize` returns a tuple \((P, D)\), where \( D \) is diagonal and \( M = PDP^{-1} \).

```
>>> P, D = M.diagonalize()
>>> P
[ 0  1  1  0 ]
[ 1  1  1 -1]
[ 1  1  1  0 ]
[ 1  1  0  1 ]

>>> D
[-2  0  0  0]
[ 0  3  0  0]
[ 0  0  5  0]
[ 0  0  0  5]

>>> P*D*P**-1
[ 3 -2  4 -2]
[ 5  3 -3 -2]
[ 5 -2  2 -2]
[ 5 -2 -3  3]

>>> P*D*P**-1 == M
True
```

**Quick Tip**

`lambda` is a reserved keyword in Python, so to create a Symbol called \( \lambda \), while using the same names for SymPy Symbols and Python variables, use `lamda` (without the `b`). It will still pretty print as \( \lambda \).
Note that since eigenvects also includes the eigenvalues, you should use it instead of eigenvals if you also want the eigenvectors. However, as computing the eigenvectors may often be costly, eigenvals should be preferred if you only wish to find the eigenvalues.

If all you want is the characteristic polynomial, use charpoly. This is more efficient than eigenvals, because sometimes symbolic roots can be expensive to calculate.

```python
>>> lamda = symbols('lamda')
>>> p = M.charpoly(lamda)
>>> factor(p.as_expr())
2
(λ - 5) ⋅(λ - 3)⋅(λ + 2)
```

### Possible Issues

#### Zero Testing

If your matrix operations are failing or returning wrong answers, the common reasons would likely be from zero testing. If there is an expression not properly zero-tested, it can possibly bring issues in finding pivots for gaussian elimination, or deciding whether the matrix is invertible, or any high level functions which relies on the prior procedures.

Currently, the SymPy’s default method of zero testing `_iszero` is only guaranteed to be accurate in some limited domain of numerics and symbols, and any complicated expressions beyond its decidability are treated as `None`, which behaves similarly to logical `False`.

The list of methods using zero testing procedures are as follows:

```python
echelon_form, is_echelon, rank, rref, nullspace, eigenvects, inverse_ADJ, inverse_GE, inverse_LU, LUdecomposition, LUdecomposition_Simple, LSolve
```

They have property `iszerofunc` opened up for us to specify zero testing method, which can accept any function with single input and boolean output, while being defaulted with `_iszero`.

Here is an example of solving an issue caused by undertested zero. While the output for this particular matrix has since been improved, the technique below is still of interest.\(^1\)

```python
>>> from sympy import *
>>> q = Symbol("q", positive = True)
>>> m = Matrix([... [-2*cosh(q/3), exp(-q), 1],
... [exp(q), -2*cosh(q/3), 1],
... [1, 1, -2*cosh(q/3)]])
>>> m.nullspace()
[]
```

You can trace down which expression is being underevaluated, by injecting a custom zero test with warnings enabled.

```python
>>> import warnings
>>> (continues on next page)
```

---

1. Inspired by https://gitter.im/sympy/sympy?at=5b7c3e8ee5b40332abdb206c
2. Discovered from https://github.com/sympy/sympy/issues/15141
3. Improved by https://github.com/sympy/sympy/pull/19548
>>> def my_iszero(x):
...     try:
...         result = x.is_zero
...     except AttributeError:
...         result = None
...     # Warnings if evaluated into None
...     if result is None:
...         warnings.warn("Zero testing of {} evaluated into None".format(x))
...     return result

```python
>>> m.nullspace(iszerofunc=my_iszero)
```

In this case, \((-\exp(q) - 2\cosh(q/3))(-2\cosh(q/3) - \exp(q)) - (4\cosh(q/3)**2 - 1)**2\) should yield zero, but the zero testing had failed to catch. Possibly meaning that a stronger zero test should be introduced. For this specific example, rewriting to exponentials and applying simplify would make zero test stronger for hyperbolics, while being harmless to other polynomials or transcendental functions.

```python
>>> def my_iszero(x):
...     try:
...         result = x.rewrite(exp).simplify().is_zero
...     except AttributeError:
...         result = None
...     # Warnings if evaluated into None
...     if result is None:
...         warnings.warn("Zero testing of {} evaluated into None".format(x))
...     return result

```python

```
```

(continues on next page)
You can clearly see nullspace returning proper result, after injecting an alternative zero test. Note that this approach is only valid for some limited cases of matrices containing only numerics, hyperbolics, and exponentials. For other matrices, you should use different method opted for their domains.

Possible suggestions would be either taking advantage of rewriting and simplifying, with tradeoff of speed\(^4\), or using random numeric testing, with tradeoff of accuracy\(^5\).

If you wonder why there is no generic algorithm for zero testing that can work with any symbolic entities, it’s because of the constant problem stating that zero testing is undecidable\(^6\), and not only the SymPy, but also other computer algebra systems\(^7\) would face the same fundamental issue.

However, discovery of any zero test failings can provide some good examples to improve SymPy, so if you have encountered one, you can report the issue to SymPy issue tracker\(^8\) to get detailed help from the community.

Advanced Expression Manipulation

In this section, we discuss some ways that we can perform advanced manipulation of expressions.

Understanding Expression Trees

Before we can do this, we need to understand how expressions are represented in SymPy. A mathematical expression is represented as a tree. Let us take the expression \(x^2 + xy\), i.e., \(x**2 + x*y\). We can see what this expression looks like internally by using \texttt{srepr}

\begin{verbatim}
>>> from sympy import *
>>> x, y, z = symbols('x y z')

>>> expr = x**2 + x*y
>>> srepr(expr)
"Add(Pow(Symbol('x'), Integer(2)), Mul(Symbol('x'), Symbol('y')))"
\end{verbatim}

\(^4\) Suggested from https://github.com/sympy/sympy/issues/10120
\(^5\) Suggested from https://github.com/sympy/sympy/issues/10279
\(^6\) https://en.wikipedia.org/wiki/Constant_problem
\(^7\) How mathematica tests zero https://reference.wolfram.com/language/ref/PossibleZeroQ.html
\(^9\) https://github.com/sympy/sympy/issues
The easiest way to tear this apart is to look at a diagram of the expression tree:

```
Add
 /   \
|     |
Pow   Mul
 /     /
|     |
Symbol('x')   Integer(2)   Symbol('x')   Symbol('y')
```

**Note:** The above diagram was made using Graphviz and the `dotprint` (page 2263) function.

First, let’s look at the leaves of this tree. Symbols are instances of the class `Symbol`. While we have been doing

```python
>>> x = symbols('x')
```

we could have also done

```python
>>> x = Symbol('x')
```

Either way, we get a `Symbol` with the name “x”\(^1\). For the number in the expression, 2, we got `Integer(2)`. `Integer` is the SymPy class for integers. It is similar to the Python built-in type `int`, except that `Integer` plays nicely with other SymPy types.

When we write `x**2`, this creates a `Pow` object. `Pow` is short for “power”.

```python
>>> srepr(x**2)
"Pow(Symbol('x'), Integer(2))"
```

We could have created the same object by calling `Pow(x, 2)`

```python
>>> Pow(x, 2)
x**2
```

Note that in the `srepr` output, we see `Integer(2)`, the SymPy version of integers, even though technically, we input 2, a Python int. In general, whenever you combine a SymPy object with a non-SymPy object via some function or operation, the non-SymPy object will be converted into a SymPy object. The function that does this is `sympify`\(^2\).

\(^1\) We have been using `symbols` instead of `Symbol` because it automatically splits apart strings into multiple `Symbol`s. `symbols('x y z')` returns a tuple of three `Symbol`s. `Symbol('x y z')` returns a single `Symbol` called `x y z`.

\(^2\) Technically, it is an internal function called `_sympify`, which differs from `sympify` in that it does not convert strings. `x + '2'` is not allowed.
We have seen that $x^2$ is represented as $\text{Pow}(x, 2)$. What about $x*y$? As we might expect, this is the multiplication of $x$ and $y$. The SymPy class for multiplication is $\text{Mul}$.

Thus, we could have created the same object by writing $\text{Mul}(x, y)$.

Now we get to our final expression, $x^2 + x*y$. This is the addition of our last two objects, $\text{Pow}(x, 2)$, and $\text{Mul}(x, y)$. The SymPy class for addition is $\text{Add}$, so, as you might expect, to create this object, we use $\text{Add}(\text{Pow}(x, 2), \text{Mul}(x, y))$.

SymPy expression trees can have many branches, and can be quite deep or quite broad. Here is a more complicated example

This expression reveals some interesting things about SymPy expression trees. Let’s go through them one by one.

Let’s first look at the term $x^2$. As we expected, we see $\text{Pow}(x, 2)$. One level up, we see we
have \( \text{Mul}(-1, \text{Pow}(x, 2)) \). There is no subtraction class in SymPy. \( x - y \) is represented as \( x + -y \), or, more completely, \( x + -1*y \), i.e., \( \text{Add}(x, \text{Mul}(-1, y)) \).

```python
>>> srepr(x - y)
"Add(Symbol('x'), Mul(Integer(-1), Symbol('y')))"
```

Next, look at \( 1/y \). We might expect to see something like \( \text{Div}(1, y) \), but similar to subtraction, there is no class in SymPy for division. Rather, division is represented by a power of \(-1\). Hence, we have \( \text{Pow}(y, -1) \). What if we had divided something other than 1 by \( y \), like \( x/y \)? Let's see.

```python
>>> expr = x/y
>>> srepr(expr)
"Mul(Symbol('x'), Pow(Symbol('y'), Integer(-1)))"
```
We see that $x/y$ is represented as $x*y^{-1}$, i.e., $\text{Mul}(x, \text{Pow}(y, -1))$.

Finally, let’s look at the $\sin(x*y)/2$ term. Following the pattern of the previous example, we might expect to see $\text{Mul}(\sin(x*y), \text{Pow}(\text{Integer}(2), -1))$. But instead, we have $\text{Mul}(\text{Rational}(1, 2), \sin(x*y))$. Rational numbers are always combined into a single term in a multiplication, so that when we divide by 2, it is represented as multiplying by $1/2$.

Finally, one last note. You may have noticed that the order we entered our expression and the order that it came out from `srepr` or in the graph were different. You may have also noticed this phenomenon earlier in the tutorial. For example

```python
>>> 1 + x
x + 1
```

This because in SymPy, the arguments of the commutative operations `Add` and `Mul` are stored in an arbitrary (but consistent!) order, which is independent of the order inputted (if you’re worried about noncommutative multiplication, don’t be). In SymPy, you can create noncommutative Symbols using `Symbol('A', commutative=False)`, and the order of multiplication for noncommutative Symbols is kept the same as the input). Furthermore, as we shall see in the next section, the printing order and the order in which things are stored internally need not be the same either.

**Quick Tip**

The way an expression is represented internally and the way it is printed are often not the same.

In general, an important thing to keep in mind when working with SymPy expression trees is this: the internal representation of an expression and the way it is printed need not be the same. The same is true for the input form. If some expression manipulation algorithm is not working in the way you expected it to, chances are, the internal representation of the object is different from what you thought it was.
Recursing through an Expression Tree

Now that you know how expression trees work in SymPy, let’s look at how to dig our way through an expression tree. Every object in SymPy has two very important attributes, `func`, and `args`.

**func**

`func` is the head of the object. For example, `(x*y).func` is `Mul`. Usually it is the same as the class of the object (though there are exceptions to this rule).

Two notes about `func`. First, the class of an object need not be the same as the one used to create it. For example

```python
>>> expr = Add(x, x)
>>> expr.func
<class 'sympy.core.mul.Mul'>
```

We created `Add(x, x)`, so we might expect `expr.func` to be `Add`, but instead we got `Mul`. Why is that? Let’s take a closer look at `expr`.

```python
>>> expr
2*x
```

Add(x, x), i.e., x + x, was automatically converted into `Mul(2, x)`, i.e., 2*x, which is a `Mul`. SymPy classes make heavy use of the `_new_` class constructor, which, unlike `_init_`, allows a different class to be returned from the constructor.

Second, some classes are special-cased, usually for efficiency reasons

```python
>>> Integer(2).func
<class 'sympy.core.numbers.Integer'>
>>> Integer(0).func
<class 'sympy.core.numbers.Zero'>
>>> Integer(-1).func
<class 'sympy.core.numbers.NegativeOne'>
```

For the most part, these issues will not bother us. The special classes `Zero`, `One`, `NegativeOne`, and so on are subclasses of `Integer`, so as long as you use `isinstance`, it will not be an issue.

---

3 Classes like `One` and `Zero` are singletonized, meaning that only one object is ever created, no matter how many times the class is called. This is done for space efficiency, as these classes are very common. For example, `Zero` might occur very often in a sparse matrix represented densely. As we have seen, `NegativeOne` occurs any time we have -x or 1/x. It is also done for speed efficiency because singletonized objects can be compared by `is`. The unique objects for each singletonized class can be accessed from the `S` object.
**args**

args are the top-level arguments of the object. \((x\cdot y).\text{args}\) would be \((x, y)\). Let’s look at some examples

```python
>>> expr = 3*y**2*x
>>> expr.func
<class 'sympy.core.mul.Mul'>
>>> expr.args
(3, x, y**2)
```

From this, we can see that \(expr == \text{Mul}(3, y**2, x)\). In fact, we can see that we can completely reconstruct \(expr\) from its \(func\) and its \(args\).

```python
>>> expr.func(*expr.args)
3*x*y**2
>>> expr == expr.func(*expr.args)
True
```

Note that although we entered \(3*y**2*x\), the \(args\) are \((3, x, y**2)\). In a \(\text{Mul}\), the Rational coefficient will come first in the \(args\), but other than that, the order of everything else follows no special pattern. To be sure, though, there is an order.

```python
>>> expr = y**2*3*x
>>> expr.args
(3, x, y**2)
```

\(\text{Mul}\)'s \(args\) are sorted, so that the same \(\text{Mul}\) will have the same \(args\). But the sorting is based on some criteria designed to make the sorting unique and efficient that has no mathematical significance.

The \(s\text{repr}\) form of our \(expr\) is \(\text{Mul}(3, x, \text{Pow}(y, 2))\). What if we want to get at the \(args\) of \(\text{Pow}(y, 2)\). Notice that the \(y**2\) is in the third slot of \(expr.args\), i.e., \(expr.args[2]\).

```python
>>> expr.args[2]
y**2
```

So to get the \(args\) of this, we call \(expr.args[2].args\).

```python
>>> expr.args[2].args
(y, 2)
```

Now what if we try to go deeper. What are the \(args\) of \(y\). Or 2. Let’s see.

```python
>>> y.args
()
>>> Integer(2).args
()
```

They both have empty \(args\). In SymPy, empty \(args\) signal that we have hit a leaf of the expression tree.

So there are two possibilities for a SymPy expression. Either it has empty \(args\), in which case it is a leaf node in any expression tree, or it has \(args\), in which case, it is a branch node of any expression tree. When it has \(args\), it can be completely rebuilt from its \(func\) and its \(args\). This is expressed in the key invariant.
Key Invariant

Every well-formed SymPy expression must either have empty args or satisfy `expr == expr.func(*expr.args)`.

(Recall that in Python if `a` is a tuple, then `f(*a)` means to call `f` with arguments from the elements of `a`, e.g., `f(*(1, 2, 3))` is the same as `f(1, 2, 3)`.)

This key invariant allows us to write simple algorithms that walk expression trees, change them, and rebuild them into new expressions.

Walking the Tree

With this knowledge, let’s look at how we can recurse through an expression tree. The nested nature of args is a perfect fit for recursive functions. The base case will be empty args. Let’s write a simple function that goes through an expression and prints all the args at each level.

```python
>>> def pre(expr):
...   print(expr)
...   for arg in expr.args:
...     pre(arg)
```

See how nice it is that `()` signals leaves in the expression tree. We don’t even have to write a base case for our recursion; it is handled automatically by the for loop.

Let’s test our function.

```python
>>> expr = x*y + 1
>>> pre(expr)
x*y + 1
1
x*y
x
y
```

Can you guess why we called our function `pre`? We just wrote a pre-order traversal function for our expression tree. See if you can write a post-order traversal function.

Such traversals are so common in SymPy that the generator functions `preorder_traversal` and `postorder_traversal` are provided to make such traversals easy. We could have also written our algorithm as

```python
>>> for arg in preorder_traversal(expr):
...   print(arg)
```

```plaintext
x*y + 1
1
x*y
x
y
```
Prevent expression evaluation

There are generally two ways to prevent the evaluation, either pass an evaluate=False parameter while constructing the expression, or create an evaluation stopper by wrapping the expression with UnevaluatedExpr.

For example:

```python
>>> from sympy import Add
>>> from sympy.abc import x, y, z
>>> x + x
2*x
>>> Add(x, x)
2*x
>>> Add(x, x, evaluate=False)
x + x
```

If you don’t remember the class corresponding to the expression you want to build (operator overloading usually assumes evaluate=True), just use `sympify` and pass a string:

```python
>>> from sympy import sympify
>>> sympify("x + x", evaluate=False)
x + x
```

Note that `evaluate=False` won’t prevent future evaluation in later usages of the expression:

```python
>>> expr = Add(x, x, evaluate=False)
>>> expr
x + x
>>> expr + x
3*x
```

That’s why the class UnevaluatedExpr comes handy. UnevaluatedExpr is a method provided by SymPy which lets the user keep an expression unevaluated. By unevaluated it is meant that the value inside of it will not interact with the expressions outside of it to give simplified outputs. For example:

```python
>>> from sympy import UnevaluatedExpr
>>> expr = x + UnevaluatedExpr(S.One*5/7)*UnevaluatedExpr(S.One*3/4)
>>> expr
x + UnevaluatedExpr(S.One*5/7)*UnevaluatedExpr(S.One*3/4)
```

The `x` remaining alone is the `x` wrapped by UnevaluatedExpr. To release it:

```python
>>> (x + expr).doit()
3*x
```

Other examples:

```python
>>> from sympy import *
>>> from sympy.abc import x, y, z
>>> uexpr = UnevaluatedExpr(S.One*5/7)*UnevaluatedExpr(S.One*3/4)
>>> uexpr
(continues on next page)
```
A point to be noted is that `UnevaluatedExpr` cannot prevent the evaluation of an expression which is given as argument. For example:

```
>>> expr1 = UnevaluatedExpr(x + x)
2*x
>>> expr2 = sympify('x + x', evaluate=False)
>>> expr2
x + x
```

Remember that `expr2` will be evaluated if included into another expression. Combine both of the methods to prevent both inside and outside evaluations:

```
>>> UnevaluatedExpr(sympify("x + x", evaluate=False)) + y
y + (x + x)
```

`UnevaluatedExpr` is supported by SymPy printers and can be used to print the result in different output forms. For example

```
>>> from sympy import latex
>>> uexpr = UnevaluatedExpr(S.One*5/7)*UnevaluatedExpr(S.One*3/4)
>>> print(latex(uexpr))
\frac{5}{7} \cdot \frac{3}{4}
```

In order to release the expression and get the evaluated LaTeX form, just use `.doit()`:

```
>>> print(latex(uexpr.doit()))
\frac{15}{28}
```

**What’s Next**

Congratulations on finishing the SymPy tutorial!

If you are a developer interested in using SymPy in your code, please visit the *How-to Guides* (page 71) which discuss key developer tasks.

Intermediate SymPy users and developers might want to visit the *Explanations* (page 189) section for common pitfalls and advanced topics.

The *SymPy API Reference* (page 243) has a detailed description of the SymPy API.

If you are interested in contributing to SymPy, visit the *contribution guides* (page 3067) and the full *Development Workflow* guide on the SymPy wiki.
How-to guides are step-by-step instructions on how to do specific tasks.

For a deeper and elaborate exploration of other SymPy topics, see the *Explanations* (page 189) and *API reference* (page 243) sections.

### 3.1 Assumptions

This page outlines the core assumptions system in SymPy. It explains what the core assumptions system is, how the assumptions system is used and what the different assumptions predicates mean.

**Note:** This page describes the core assumptions system also often referred to as the “old assumptions” system. There is also a “new assumptions” system which is described elsewhere. Note that the system described here is actually the system that is widely used in SymPy. The “new assumptions” system is not really used anywhere in SymPy yet and the “old assumptions” system will not be removed. At the time of writing (SymPy 1.7) it is still recommended for users to use the old assumption system.

Firstly we consider what happens when taking the square root of the square of a concrete integer such as 2 or −2:

```python
>>> from sympy import sqrt
>>> sqrt(2**2)
2
>>> sqrt((-2)**2)
2
>>> x = 2
>>> sqrt(x**2)
2
>>> sqrt(x**2) == x
True
>>> y = -2
>>> sqrt(y**2) == y
False
>>> sqrt(y**2) == -y
True
```

What these examples demonstrate is that for a positive number $x$ we have $\sqrt{x^2} = x$ whereas for a negative number we would instead have $\sqrt{x^2} = -x$. That may seem obvious but the
situation can be more surprising when working with a symbol rather than an explicit number. For example

```python
>>> from sympy import Symbol, simplify
>>> x = Symbol('x')
>>> sqrt(x**2)
sqrt(x**2)
```

It might look as if that should simplify to \( x \) but it does not even if `simplify()` (page 719) is used:

```python
>>> simplify(sqrt(x**2))
sqrt(x**2)
```

This is because SymPy will refuses to simplify this expression if the simplification is not valid for every possible value of \( x \). By default the symbol \( x \) is considered only to represent something roughly like an arbitrary complex number and the obvious simplification here is only valid for positive real numbers. Since \( x \) is not known to be positive or even real no simplification of this expression is possible.

We can tell SymPy that a symbol represents a positive real number when creating the symbol and then the simplification will happen automatically:

```python
>>> y = Symbol('y', positive=True)
>>> sqrt(y**2)
y
```

This is what is meant by “assumptions” in SymPy. If the symbol \( y \) is created with `positive=True` then SymPy will assume that it represents a positive real number rather than an arbitrary complex or possibly infinite number. That assumption can make it possible to simplify expressions or might allow other manipulations to work. It is usually a good idea to be as precise as possible about the assumptions on a symbol when creating it.

### 3.1.1 The (old) assumptions system

There are two sides to the assumptions system. The first side is that we can declare assumptions on a symbol when creating the symbol. The other side is that we can query the assumptions on any expression using the corresponding `is_*` attribute. For example:

```python
>>> x = Symbol('x', positive=True)
>>> x.is_positive
True
```

We can query assumptions on any expression not just a symbol:

```python
>>> x = Symbol('x', positive=True)
>>> expr = 1 + x**2
>>> expr
x**2 + 1
>>> expr.is_positive
True
>>> expr.is_negative
False
```
The values given in an assumptions query use three-valued “fuzzy” logic. Any query can return True, False, or None where None should be interpreted as meaning that the result is unknown.

```python
>>> x = Symbol('x')
>>> y = Symbol('y', positive=True)
>>> z = Symbol('z', negative=True)
>>> print(x.is_positive)
None
>>> print(y.is_positive)
True
>>> print(z.is_positive)
False
```

**Note:** We need to use print in the above examples because the special value None does not display by default in the Python interpreter.

There are several reasons why an assumptions query might give None. It is possible that the query is unknowable as in the case of \( x \) above. Since \( x \) does not have any assumptions declared it roughly represents an arbitrary complex number. An arbitrary complex number might be a positive real number but it also might not be. Without further information there is no way to resolve the query \( x.\text{is\_positive} \).

Another reason why an assumptions query might give None is that there does in many cases the problem of determining whether an expression is e.g. positive is undecidable. That means that there does not exist an algorithm for answering the query in general. For some cases an algorithm or at least a simple check would be possible but has not yet been implemented although it could be added to SymPy.

The final reason that an assumptions query might give None is just that the assumptions system does not try very hard to answer complicated queries. The system is intended to be fast and uses simple heuristic methods to conclude a True or False answer in common cases. For example any sum of positive terms is positive so:

```python
>>> from sympy import symbols
>>> x, y = symbols('x, y', positive=True)
>>> expr = x + y
>>> expr
x + y
>>> expr.is_positive
True
```

The last example is particularly simple so the assumptions system is able to give a definite answer. If the sum involved a mix of positive or negative terms it would be a harder query:

```python
>>> x = Symbol('x', real=True)
>>> expr = 1 + (x - 2)**2
>>> expr
(x - 2)**2 + 1
>>> expr.is_positive
True
>>> expr2 = expr.expand()
>>> expr2
(continues on next page)
```
x**2 - 4*x + 5
>>> print(expr2.is_positive)
None

Ideally that last example would give True rather than None because the expression is always positive for any real value of x (and x has been assumed real). The assumptions system is intended to be efficient though: it is expected many more complex queries will not be fully resolved. This is because assumptions queries are primarily used internally by SymPy as part of low-level calculations. Making the system more comprehensive would slow SymPy down.

Note that in fuzzy logic giving an indeterminate result None is never a contradiction. If it is possible to infer a definite True or False result when resolving a query then that is better than returning None. However a result of None is not a bug. Any code that uses the assumptions system needs to be prepared to handle all three cases for any query and should not presume that a definite answer will always be given.

The assumptions system is not just for symbols or for complex expressions. It can also be used for plain SymPy integers and other objects. The assumptions predicates are available on any instance of Basic (page 979) which is the superclass for most classes of SymPy objects. A plain Python int is not a Basic (page 979) instance and can not be used to query assumptions predicates. We can “sympify” regular Python objects to become SymPy objects with sympify() (page 970) or S (SingletonRegistry (page 997)) and then the assumptions system can be used:

```python
>>> from sympy import S
>>> x = 2
>>> x.is_positive
Traceback (most recent call last):
... AttributeError: 'int' object has no attribute 'is_positive'
>>> x = S(2)
>>> type(x)
<class 'sympy.core.numbers.Integer'>
>>> x.is_positive
True
```

### 3.1.2 Gotcha: symbols with different assumptions

In SymPy it is possible to declare two symbols with different names and they will implicitly be considered equal under structural equality:

```python
>>> x1 = Symbol('x')
>>> x2 = Symbol('x')
>>> x1
x
>>> x2
x
>>> x1 == x2
True
```

However if the symbols have different assumptions then they will be considered to represent distinct symbols:
>>> x1 = Symbol('x', positive=True)
>>> x2 = Symbol('x')
>>> x1
x
>>> x2
x
>>> x1 == x2
False

One way to simplify an expression is to use the `posify()` (page 725) function which will replace all symbols in an expression with symbols that have the assumption `positive=True` (unless that contradicts any existing assumptions for the symbol):

```python
>>> from sympy import posify, exp
>>> x = Symbol('x')
>>> expr = exp(sqrt(x**2))
>>> expr
exp(sqrt(x**2))
>>> posify(expr)
(exp(_x), {_x: x})
>>> expr2, rep = posify(expr)
>>> expr2
exp(_x)
```

The `posify()` (page 725) function returns the expression with all symbols replaced (which might lead to simplifications) and also a dict which maps the new symbols to the old that can be used with `subs()` (page 993). This is useful because otherwise the new expression with the new symbols having the `positive=True` assumption will not compare equal to the old:

```python
>>> expr2
exp(_x)
>>> expr2 == exp(x)
False
>>> expr2.subs(rep)
exp(x)
>>> expr2.subs(rep) == exp(x)
True
```

### 3.1.3 Applying assumptions to string inputs

We have seen how to set assumptions when `Symbol` (page 1028) or `symbols()` (page 1030) explicitly. A natural question to ask is in what other situations can we assign assumptions to an object?

It is common for users to use strings as input to SymPy functions (although the general feeling among SymPy developers is that this should be discouraged) e.g.:

```python
>>> from sympy import solve
>>> solve('x**2 - 1')
[-1, 1]
```

When creating symbols explicitly it would be possible to assign assumptions that would affect the behaviour of `solve()` (page 882):
>>> x = Symbol('x', positive=True)
>>> solve(x**2 - 1)
[1]

When using string input SymPy will create the expression and create all of the symbol implicitly so the question arises how can the assumptions be specified? The answer is that rather than depending on implicit string conversion it is better to use the `parse_expr()` (page 2195) function explicitly and then it is possible to provide assumptions for the symbols e.g.:

```python
>>> from sympy import parse_expr
>>> parse_expr('x**2 - 1')
x**2 - 1
>>> eq = parse_expr('x**2 - 1', {'x':Symbol('x', positive=True)})
>>> solve(eq)
[1]
```

**Note:** The `solve()` (page 882) function is unusual as a high level API in that it actually checks the assumptions on any input symbols (the unknowns) and uses that to tailor its output. The assumptions system otherwise affects low-level evaluation but is not necessarily handled explicitly by high-level APIs.

### 3.1.4 Predicates

There are many different predicates that can be assumed for a symbol or can be queried for an expression. It is possible to combine multiple predicates when creating a symbol. Predicates are logically combined using `and` so if a symbol is declared with `positive=True` and also with `integer=True` then it is both positive and integer:

```python
>>> x = Symbol('x', positive=True, integer=True)
>>> x.is_positive
True
>>> x.is_integer
True
```

The full set of known predicates for a symbol can be accessed using the `assumptions0` (page 981) attribute:

```python
>>> x.assumptions0
{'algebraic': True, 'commutative': True, 'complex': True, 'extended_negative': False, 'extended_nonnegative': True, 'extended_nonpositive': False, 'extended_nonzero': True, 'extended_positive': True, 'extended_real': True, 'finite': True, 'hermitian': True, 'imaginary': False,
(continues on next page)```
We can see that there are many more predicates listed than the two that were used to create \(x\). This is because the assumptions system can infer some predicates from combinations of other predicates. For example if a symbol is declared with \(\text{positive=True}\) then it is possible to infer that it should have \(\text{negative=False}\) because a positive number can never be negative. Similarly if a symbol is created with \(\text{integer=True}\) then it is possible to infer that it should have \(\text{rational=True}\) because every integer is a rational number.

A full table of the possible predicates and their definitions is given below.

<table>
<thead>
<tr>
<th>Predicate</th>
<th>Definition</th>
<th>Implications</th>
</tr>
</thead>
<tbody>
<tr>
<td>commutative</td>
<td>A commutative expression. A commutative expression commutes with all other expressions under multiplication. If an expression (a) has (\text{commutative=True}) then (a * b == b * a) for any other expression (b) (even if (b) is not commutative). Unlike all other assumptions predicates commutative must always be (\text{True}) or (\text{False}) and can never be (\text{None}). Also unlike all other predicates commutative defaults to (\text{True}) in e.g. Symbol('x').</td>
<td></td>
</tr>
<tr>
<td>infinite</td>
<td>An infinite expression such as (\infty), (-\infty) or zoo. [infinite]</td>
<td>== !finite</td>
</tr>
<tr>
<td>finite</td>
<td>A finite expression. Any expression that is not infinite is considered finite. [finite]</td>
<td>== !infinite</td>
</tr>
<tr>
<td>hermitian</td>
<td>An element of the field of Hermitian operators. [antihermitian]</td>
<td></td>
</tr>
<tr>
<td>antihermitian</td>
<td>An element of the field of antihermitian operators. [antihermitian]</td>

3.1.5 Implications

The assumptions system uses the inference rules to infer new predicates beyond those immediately specified when creating a symbol:

```python
>>> x = Symbol('x', real=True, negative=False, zero=False)
>>> x.is_positive
True
```

Although $x$ was not explicitly declared positive it can be inferred from the predicates that were given explicitly. Specifically one of the inference rules is real $\Rightarrow$ negative | zero | positive so if real is True and both negative and zero are False then positive must be True.
In practice the assumption inference rules mean that it is not necessary to include redundant predicates for example a positive real number can be simply be declared as positive:

```python
>>> x1 = Symbol('x1', positive=True, real=True)
>>> x2 = Symbol('x2', positive=True)
>>> x1.is_real
True
>>> x2.is_real
True
>>> x1.assumptions0 == x2.assumptions0
True
```

Combining predicates that are inconsistent will give an error:

```python
>>> x = Symbol('x', commutative=False, real=True)
Traceback (most recent call last):
...
InconsistentAssumptions: {
    algebraic: False,
    commutative: False,
    complex: False,
    composite: False,
    even: False,
    extended_negative: False,
    extended_nonnegative: False,
    extended_nonpositive: False,
    extended_nonzero: False,
    extended_positive: False,
    extended_real: False,
    imaginary: False,
    integer: False,
    irrational: False,
    negative: False,
    noninteger: False,
    nonnegative: False,
    nonpositive: False,
    nonzero: False,
    odd: False,
    positive: False,
    prime: False,
    rational: False,
    real: False,
    transcendental: False,
    zero: False}, real=True
```
3.1.6 Interpretation of the predicates

Although the predicates are defined in the table above it is worth taking some time to think about how to interpret them. Firstly many of the concepts referred to by the predicate names like “zero”, “prime”, “rational” etc have a basic meaning in mathematics but can also have more general meanings. For example when dealing with matrices a matrix of all zeros might be referred to as “zero”. The predicates in the assumptions system do not allow any generalizations such as this. The predicate zero is strictly reserved for the plain number 0. Instead matrices have an is_zero_matrix() (page 1390) property for this purpose (although that property is not strictly part of the assumptions system):

```python
>>> from sympy import Matrix
>>> M = Matrix([[0, 0], [0, 0]])
>>> M.is_zero
False
>>> M.is_zero_matrix
True
```

Similarly there are generalisations of the integers such as the Gaussian integers which have a different notion of prime number. The prime predicate in the assumptions system does not include those and strictly refers only to the standard prime numbers $\mathbb{P} = \{2, 3, 5, 7, 11, \ldots\}$. Likewise integer only means the standard concept of the integers $\mathbb{Z} = \{0, \pm 1, \pm 2, \ldots\}$, rational only means the standard concept of the rational numbers $\mathbb{Q}$ and so on.

The predicates set up schemes of subsets such as the chain beginning with the complex numbers which are considered as a superset of the reals which are in turn a superset of the rationals and so on. The chain of subsets

$$Z \subset \mathbb{Q} \subset \mathbb{R} \subset \mathbb{C}$$

corresponds to the chain of implications in the assumptions system

| integer -> rational -> real -> complex |

A “vanilla” symbol with no assumptions explicitly attached is not known to belong to any of these sets and is not even known to be finite:

```python
>>> x = Symbol('x')
>>> x.assumptions0
{'commutative': True}
>>> print(x.is_commutative)
True
>>> print(x.is_rational)
None
>>> print(x.is_complex)
None
>>> print(x.is_real)
None
>>> print(x.is_integer)
None
>>> print(x.is_finite)
None
```

It is hard for SymPy to know what it can do with such a symbol that is not even known to be finite or complex so it is generally better to give some assumptions to the symbol explicitly.
Many parts of SymPy will implicitly treat such a symbol as complex and in some cases SymPy will permit manipulations that would not strictly be valid given that \( x \) is not known to be finite. In a formal sense though very little is known about a vanilla symbol which makes manipulations involving it difficult.

Defining *something* about a symbol can make a big difference. For example if we declare the symbol to be an integer then this implies a suite of other predicates that will help in further manipulations:

```python
>>> n = Symbol('n', integer=True)
>>> n.assumptions0
{'algebraic': True,
 'commutative': True,
 'complex': True,
 'extended_real': True,
 'finite': True,
 'hermitian': True,
 'imaginary': False,
 'infinite': False,
 'integer': True,
 'irrational': False,
 'noninteger': False,
 'rational': True,
 'real': True,
 'transcendental': False}
```

These assumptions can lead to very significant simplifications e.g. \( \text{integer}=\text{True} \) gives:

```python
>>> from sympy import sin, pi
>>> n1 = Symbol('n1')
>>> n2 = Symbol('n2', integer=True)
>>> sin(n1 * pi)
sin(pi*n1)
>>> sin(n2 * pi)
0
```

Replacing a whole expression with 0 is about as good as simplification can get!

It is normally advisable to set as many assumptions as possible on any symbols so that expressions can be simplified as much as possible. A common misunderstanding leads to defining a symbol with a False predicate e.g.:

```python
>>> x = Symbol('x', negative=False)
>>> print(x.is_negative)
False
>>> print(x.is_nonnegative)
None
>>> print(x.is_real)
None
>>> print(x.is_complex)
None
>>> print(x.is_finite)
None
```

If the intention is to say that \( x \) is a real number that is not positive then that needs to be explicitly stated. In the context that the symbol is known to be real, the predicate \( \text{positive}=\text{False} \)
becomes much more meaningful:

```python
>>> x = Symbol('x', real=True, negative=False)
>>> print(x.is_negative)
False
>>> print(x.is_nonnegative)
True
>>> print(x.is_real)
True
>>> print(x.is_complex)
True
>>> print(x.is_finite)
True
```

A symbol declared as `Symbol('x', real=True, negative=False)` is equivalent to a symbol declared as `Symbol('x', nonnegative=True)`. Simply declaring a symbol as `Symbol('x', positive=False)` does not allow the assumptions system to conclude much about it because a vanilla symbol is not known to be finite or even complex.

A related confusion arises with `Symbol('x', complex=True)` and `Symbol('x', real=False)`. Often when either of these is used neither is what is actually wanted. The first thing to understand is that all real numbers are complex so a symbol created with `real=True` will also have `complex=True` and a symbol created with `complex=True` will not have `real=True`. If the intention was to create a complex number that is not a real number then it should be `Symbol('x', complex=True, real=False)`. On the other hand declaring `real=False` alone is not sufficient to conclude that `complex=True` because knowing that it is not a real number does not tell us whether it is finite or whether or not it is some completely different kind of object from a complex number.

A vanilla symbol is defined by not knowing whether it is finite etc but there is no clear definition of what it should actually represent. It is tempting to think of it as an “arbitrary complex number or possibly one of the infinities” but there is no way to query an arbitrary (non-symbol) expression in order to determine if it meets those criteria. It is important to bear in mind that within the SymPy codebase and potentially in downstream libraries many other kinds of mathematical objects can be found that might also have `commutative=True` while being something very different from an ordinary number (in this context even SymPy’s standard infinities are considered “ordinary”).

The only predicate that is applied by default for a symbol is commutative. We can also declare a symbol to be noncommutative e.g.:

```python
>>> x, y = symbols('x, y', commutative=False)
>>> z = Symbol('z')  # defaults to commutative=True
>>> x*y + y*x
x*y + y*x
>>> x*z + z*x
2*z*x
```

Note here that since `x` and `y` are both noncommutative `x` and `y` do not commute so `x*y != y*x`. On the other hand since `z` is commutative `x` and `z` commute and `x*z == z*x` even though `x` is noncommutative.

The interpretation of what a vanilla symbol represents is unclear but the interpretation of an expression with `commutative=False` is entirely obscure. Such an expression is necessarily not a complex number or an extended real or any of the standard infinities (even `zoo` is commutative). We are left with very little that we can say about what such an expression *does*
represent.

### 3.1.7 Other is_* properties

There are many properties and attributes in SymPy that have names beginning with `is_` that look similar to the properties used in the (old) assumptions system but are not in fact part of the assumptions system. Some of these have a similar meaning and usage as those of the assumptions system such as the `is_zero_matrix()` (page 1390) property shown above. Another example is the `is_empty` property of sets:

```python
>>> from sympy import FiniteSet, Intersection
>>> S1 = FiniteSet(1, 2)
>>> print(S1.is_empty)
False
>>> S2 = Intersection(FiniteSet(1), FiniteSet(Symbol('x')))
>>> print(S2.is_empty)
None
```

The `is_empty` property gives a fuzzy-bool indicating whether or not a `Set` (page 1229) is the empty set. In the example of `S2` it is not possible to know whether or not the set is empty without knowing whether or not `x` is equal to `1` so `S2.is_empty` gives `None`. The `is_empty` property for sets plays a similar role to the `is_zero` property for numbers in the assumptions system: `is_empty` is normally only `True` for the `EmptySet` (page 1245) object but it is still useful to be able to distinguish between the cases where `is_empty=False` and `is_empty=None`.

Although `is_zero_matrix` and `is_empty` are used for similar purposes to the assumptions properties such as `is_zero` they are not part of the (old) assumptions system. There are no associated inference rules connecting e.g. `Set.is_empty` and `Set.is_finite_set` because the inference rules are part of the (old) assumptions system which only deals with the predicates listed in the table above. It is not possible to declare a `MatrixSymbol` (page 1417) with e.g. `zero_matrix=False` and there is no `SetSymbol` class but if there was it would not have a system for understanding predicates like `empty=False`.

The properties `is_zero_matrix()` (page 1390) and `is_empty` are similar to those of the assumptions system because they concern *semantic* aspects of an expression. There are a large number of other properties that focus on *structural* aspects such as `is_Number`, `is_number()` (page 1019), `is_comparable()` (page 987). Since these properties refer to structural aspects of an expression they will always give `True` or `False` rather than a fuzzy bool that also has the possibility of being `None`. Capitalised properties such as `is_Number` are usually shorthand for `isinstance` checks e.g.:

```python
>>> from sympy import Number, Rational
>>> x = Rational(1, 2)
>>> isinstance(x, Number)
True
>>> x.is_Number
True
>>> y = Symbol('y', rational=True)
>>> isinstance(y, Number)
```

(continues on next page)
The `Number` (page 1033) class is the superclass for `Integer` (page 1038), `Rational` (page 1036) and `Float` (page 1033) so any instance of `Number` (page 1033) represents a concrete number with a known value. A symbol such as `y` that is declared with `rational=True` might represent the same value as `x` but it is not a concrete number with a known value so this is a structural rather than a semantic distinction. Properties like `is_Number` are sometimes used in SymPy in place of e.g. `isinstance(obj, Number)` because they do not have problems with circular imports and checking `x.is_Number` can be faster than a call to `isinstance`.

The `is_number` (page 1019) (lower-case) property is very different from `is_Number`. The `is_number` property is `True` for any expression that can be numerically evaluated to a floating point complex number with `evalf` (page 1111):

```python
>>> from sympy import I
>>> expr1 = I + sqrt(2)
>>> expr1
sqrt(2) + I
>>> expr1.is_number
True
>>> expr1.evalf()
1.4142135623731 + 1.0*I
>>> x = Symbol('x')
>>> expr2 = 1 + x
>>> expr2
x + 1
>>> expr2.is_number
False
>>> expr2.evalf()
x + 1.0
```

The primary reason for checking `expr.is_number` is to predict whether a call to `evalf` (page 1111) will fully evaluate. The `is_comparable()` (page 987) property is similar to `is_number()` (page 1019) except that if `is_comparable` gives `True` then the expression is guaranteed to numerically evaluate to a `real Float` (page 1033). When `a.is_comparable` and `b.is_comparable` the inequality `a < b` should be resolvable as something like `a.evalf() < b.evalf()`.

The full set of `is_*` properties, attributes and methods in SymPy is large. It is important to be clear though that only those that are listed in the table of predicates above are actually part of the assumptions system. It is only those properties that are involved in the `mechanism` that implements the assumptions system which is explained below.
3.1.8 Implementing assumptions handlers

We will now work through an example of how to implement a SymPy symbolic function so that we can see how the old assumptions are used internally. SymPy already has an exp function which is defined for all complex numbers but we will define an expreal function which is restricted to real arguments.

```python
>>> from sympy import Function
>>> from sympy.core.logic import fuzzy_and, fuzzy_or

>>> class expreal(Function):  # exponentail function E**x restricted to the extended reals
...
...     is_extended_nonnegative = True
...
...     @classmethod
...     def eval(cls, x):
...         # Validate the argument
...         if x.is_extended_real is False:
...             raise ValueError("non-real argument to expreal")
...         # Evaluate for special values
...         if x.is_zero:
...             return S.One
...         elif x.is_infinite:
...             if x.is_extended_negative:
...                 return S.Zero
...             elif x.is_extended_positive:
...                 return S.Infinity
...
...     @property
...     def x(self):
...         return self.args[0]
...
...     def _eval_is_finite(self):
...         return fuzzy_or([self.x.is_real, self.x.is_extended_nonpositive])
...
...     def _eval_is_algebraic(self):
...         if fuzzy_and([self.x.is_rational, self.x.is_nonzero]):
...             return False
...
...     def _eval_is_integer(self):
...         if self.x.is_zero:
...             return True
...
...     def _eval_is_zero(self):
...         return fuzzy_and([self.x.is_infinite, self.x.is_extended_negative])
```

The `Function.eval` method is used to pick up on special values of the function so that we can return a different object if it would be a simplification. When `expreal(x)` is called the `expreal.__new__` class method (defined in the superclass `Function`) will call `expreal.eval(x)`. If `expreal.eval` returns something other than `None` then that will be returned instead of an unevaluated `expreal(x)`: 

3.1. Assumptions 87
>>> from sympy import oo
>>> expreal(1)
expreal(1)
>>> expreal(0)
1
>>> expreal(-oo)
0
>>> expreal(oo)
oo

Note that the `expreal.eval` method does not compare the argument using `==`. The special values are verified using the assumptions system to query the properties of the argument. That means that the `expreal` method can also evaluate for different forms of expression that have matching properties e.g.

```python
>>> x = Symbol('x', extended_negative=True, infinite=True)
>>> x
x
>>> expreal(x)
0
```

Of course the assumptions system can only resolve a limited number of special values so most `eval` methods will also check against some special values with `==` but it is preferable to check e.g. `x.is_zero` rather than `x==0`.

Note also that the `expreal.eval` method validates that the argument is real. We want to allow ±∞ as arguments to `expreal` so we check for `extended_real` rather than `real`. If the argument is not extended real then we raise an error:

```python
>>> expreal(I)
Traceback (most recent call last):
...       
ValueError: non-real argument to expreal
```

Importantly we check `x.is_extended_real is False` rather than not `x.is_extended_real` which means that we only reject the argument if it is definitely not extended real: if `x.is_extended_real` gives `None` then the argument will not be rejected. The first reason for allowing `x.is_extended_real=None` is so that a vanilla symbol can be used with `expreal`. The second reason is that an assumptions query can always give `None` even in cases where an argument is definitely real e.g.:

```python
>>> x = Symbol('x')
>>> print(x.is_extended_real)
None
>>> expreal(x)
expreal(x)
>>> expr = (1 + I)/sqrt(2) + (1 - I)/sqrt(2)
>>> print(expr.is_extended_real)
None
>>> expr.expand()
sqrt(2)
>>> expr.expand().is_extended_real
True

(continues on next page)
Validating the argument in `expreal.eval` does mean that it will not be validated when `evaluate=False` is passed but there is not really a better place to perform the validation:

```python
>>> expreal(I, evaluate=False)
expreal(I)
```

The `extended_nonnegative` class attribute and the `_eval_is_*` methods on the `expreal` class implement queries in the assumptions system for instances of `expreal`:

```python
>>> expreal(2)
expreal(2)
>>> expreal(2).is_finite
True
>>> expreal(2).is_integer
False
>>> expreal(2).is_rational
False
>>> expreal(2).is_algebraic
False
>>> z = expreal(-oo, evaluate=False)
>>> z
expreal(-oo)
>>> z.is_integer
True
>>> x = Symbol('x', real=True)
>>> expreal(x)
expreal(x)
>>> expreal(x).is_nonnegative
True
```

The assumptions system resolves queries like `expreal(2).is_finite` using the corresponding handler `expreal._eval_is_finite` and also the implication rules. For example it is known that `expreal(2).is_rational` is `False` because `expreal(2)._eval_is_algebraic` returns `False` and there is an implication rule `rational -> algebraic`. This means that an `is_rational` query can be resolved in this case by the `_eval_is_algebraic` handler. It is actually better not to implement assumptions handlers for every possible predicate but rather to try and identify a minimal set of handlers that can resolve as many queries as possible with as few checks as possible.

Another point to note is that the `_eval_is_*` methods only make assumptions queries on the argument `x` and do not make any assumptions queries on `self`. Recursive assumptions queries on the same object will interfere with the assumptions implications resolver potentially leading to non-deterministic behaviour so they should not be used (there are examples of this in the SymPy codebase but they should be removed).

Many of the `expreal` methods implicitly return `None`. This is a common pattern in the assumptions system. The `eval` method and the `_eval_is_*` methods can all return `None` and often will. A Python function that ends without reaching a `return` statement will implicitly return `None`. We take advantage of this by leaving out many of the `else` clauses from the `if` statements and allowing `None` to be returned implicitly. When following the control flow of these methods it is important to bear in mind firstly that any queried property can give `True`,

3.1. Assumptions
False or None and also that any function will implicitly return None if all of the conditionals fail.

### 3.1.9 Mechanism of the assumptions system

**Note:** This section describes internal details that could change in a future SymPy version.

This section will explain the inner workings of the assumptions system. It is important to understand that these inner workings are implementation details and could change from one SymPy version to another. This explanation is written as of SymPy 1.7. Although the (old) assumptions system has many limitations (discussed in the next section) it is a mature system that is used extensively in SymPy and has been well optimised for its current usage. The assumptions system is used implicitly in most SymPy operations to control evaluation of elementary expressions.

There are several stages in the implementation of the assumptions system within a SymPy process that lead up to the evaluation of a single query in the assumptions system. Briefly these are:

1. At import time the assumptions rules defined in `sympy/core/assumptions.py` are processed into a canonical form ready for efficiently applying the implication rules. This happens once when SymPy is imported before even the `Basic` class is defined.

2. The `Basic.__init_subclass__` method will post-process every `Basic` subclass to add the relevant properties needed for assumptions queries. This also adds the `default_assumptions` attribute to the class. This happens each time a `Basic` subclass is defined (when its containing module is imported).

3. Every `Basic` instance initially uses the `default_assumptions` class attribute. When an assumptions query is made on a `Basic` instance in the first instance the query will be answered from the `default_assumptions` for the class.

4. If there is no cached value for the assumptions query in the `default_assumptions` for the class then the default assumptions will be copied to make an assumptions cache for the instance. Then the `_ask()` function is called to resolve the query which will firstly call the relevant instance handler `_eval_is` method. If the handler returns non-None then the result will be cached and returned.

5. If the handler does not exist or gives None then the implications resolver is tried. This will enumerate (in a randomised order) all possible combinations of predicates that could potentially be used to resolve the query under the implication rules. In each case the handler `_eval_is` method will be called to see if it gives non-None. If any combination of handlers and implication rules leads to a definitive result for the query then that result is cached in the instance cache and returned.

6. Finally if the implications resolver failed to resolve the query then the query is considered unresolvable. The value of None for the query is cached in the instance cache and returned.

The assumptions rules defined in `sympy/core/assumptions.py` are given in forms like `real == negative | zero | positive`. When this module is imported these are converted into a `FactRules` instance called `_assume_rules`. This preprocesses the implication rules into the form of "A" and "B" rules that can be used for the implications resolver. This is explained in
the code in sympy/core/facts.py. We can access this internal object directly like (full output omitted):

```python
>>> from sympy.core.assumptions import _assume_rules
>>> _assume_rules.defined_facts
{'algebraic',
 'antihermitian',
 'commutative',
 'complex',
 'composite',
 'even',
 ...

>>> _assume_rules.full_implications
defaultdict(set,
    {('extended_positive', False): {('composite', False),
      ('positive', False),
      ('prime', False)},
     ('finite', False): {('algebraic', False),
      ('complex', False),
      ('composite', False),
      ...

The Basic.__init_subclass__ method will inspect the attributes of each Basic class to see if any assumptions related attributes are defined. An example of these is the `is_extended_nonnegative = True` attribute defined in the `expreal` class. The implications of any such attributes will be used to precompute any statically knowable assumptions. For example `is_extended_nonnegative=True` implies `real=True` etc. A StdFactKB instance is created for the class which stores those assumptions whose values are known at this stage. The StdFactKB instance is assigned as the class attribute `default_assumptions`. We can see this with

```python
>>> from sympy import Expr
...
>>> class A(Expr):
    ...
    is_positive = True
    ...
    ...
    def _eval_is_rational(self):
        ...
        # Let's print something to see when this method is called...
        ...
        print('!!! calling _eval_is_rational')
        ...
        return True
    ...

>>> A.is_positive
True
>>> A.is_real  # inferred from is_positive
True
```

Although only `is_positive` was defined in the class `A` it also has attributes such as `is_real` which are inferred from `is_positive`. The set of all such assumptions for class `A` can be seen in `default_assumptions` which looks like a dict but is in fact a StdFactKB instance:

```python
>>> type(A.default_assumptions)
<class 'sympy.core.assumptions.StdFactKB'>
>>> A.default_assumptions
{'commutative': True,
 (continues on next page)}
When an instance of any `Basic` (page 979) subclass is created, `Basic.__new__` will assign its `_assumptions` attribute, which will initially be a reference to `cls.default_assumptions` shared amongst all instances of the same class. The instance will use this to resolve any assumptions queries until that fails to give a definitive result at which point a copy of `cls.default_assumptions` will be created and assigned to the instance’s `_assumptions` attribute. The copy will be used as a cache to store any results computed for the instance by its `_eval_is_` handlers.

When the `_assumptions` attribute fails to give the relevant result it is time to call the `_eval_is_` handlers. At this point the `_ask()` function is called. The `_ask()` function will initially try to resolve a query such as `is_rational` by calling the corresponding method i.e. `_eval_is_rational`. If that gives non-None then the result is stored in `_assumptions` and any implications of that result are computed and stored as well. At that point the query is resolved and the value returned.

```python
>>> a = A()
>>> a._assumptions is A.default_assumptions
True
>>> a.is_rational
!!! calling _eval_is_rational
True
>>> a._assumptions is A.default_assumptions
False
>>> a._assumptions  # rational now shows as True
{'algebraic': True,
 'commutative': True,
 'complex': True,
 'extended_negative': False,
 'extended_nonnegative': True,
 'extended_nonpositive': False,
 'extended_nonzero': True,
 'extended_positive': True,
 'extended_real': True,
 'finite': True,
 'hermitian': True,
 'imaginary': False,
 'infinite': False,
 'negative': False,
 'nonnegative': True,
 'nonpositive': False,
 'nonzero': True,
 'positive': True,
 'real': True,
 'zero': False}
```
If e.g. `_eval_is_rational` does not exist or gives `None` then `_ask()` will try all possibilities to use the implication rules and any other handler methods such as `_eval_is_integer`, `_eval_is_algebraic` etc that might possibly be able to give an answer to the original query. If any method leads to a definite result being known for the original query then that is returned. Otherwise once all possibilities for using a handler and the implication rules to resolve the query are exhausted `None` will be cached and returned.

```python
>>> b = A()
>>> b.is_algebraic  # called _eval_is_rational indirectly
!!! calling _eval_is_rational
True
>>> c = A()
>>> print(c.is_prime)  # called _eval_is_rational indirectly
!!! calling _eval_is_rational
None
>>> c.assumptions  # prime now shows as None
```
Note: In the ask() function the handlers are called in a randomised order which can mean that execution at this point is non-deterministic. Provided all of the different handler methods are consistent (i.e. there are no bugs) then the end result will still be deterministic. However a bug where two handlers are inconsistent can manifest in non-deterministic behaviour because this randomisation might lead to the handlers being called in different orders when the same program is run multiple times.

3.1.10 Limitations

Combining predicates with or

In the old assumptions we can easily combine predicates with and when creating a Symbol e.g.:

```python
>>> x = Symbol('x', integer=True, positive=True)
>>> x.is_positive
True
>>> x.is_integer
True
```

We can also easily query whether two conditions are jointly satisfied with

```python
>>> fuzzy_and([x.is_positive, x.is_integer])
True
>>> x.is_positive and x.is_integer
True
```

However there is no way in the old assumptions to create a Symbol (page 1028) with assumptions predicates combined with or. For example if we wanted to say that “x is positive or x is an integer” then it is not possible to create a Symbol (page 1028) with those assumptions.

It is also not possible to ask an assumptions query based on or e.g. “is expr an expression that is positive or an integer”. We can use e.g.

```python
>>> fuzzy_or([x.is_positive, x.is_integer])
True
```

However if all that is known about x is that it is possibly positive or otherwise a negative integer then both queries x.is_positive and x.is_integer will resolve to None. That means that the query becomes

```python
>>> fuzzy_or([None, None])
```

which then also gives None.
Relations between different symbols

A fundamental limitation of the old assumptions system is that all explicit assumptions are properties of an individual symbol. There is no way in this system to make an assumption about the relationship between two symbols. One of the most common requests is the ability to assume something like \( x < y \) but there is no way to even specify that in the old assumptions.

The new assumptions have the theoretical capability that relational assumptions can be specified. However, the algorithms to make use of that information are not yet implemented and the exact API for specifying relational assumptions has not been decided upon.

3.2 Symbolic and fuzzy booleans

This page describes what a symbolic Boolean (page 1207) in SymPy is and also how that relates to three-valued fuzzy-bools that are used in many parts of SymPy. It also discusses some common problems that arise when writing code that uses three-valued logic and how to handle them correctly.

3.2.1 Symbolic Boolean vs three valued bool

Assumptions queries like \( \text{x.ispositive} \) give fuzzy-bool True, False or None results\(^1\). These are low-level Python objects rather than SymPy’s symbolic Boolean (page 1207) expressions.

\[
\begin{align*}
>>> & \text{from sympy import Symbol, symbols} \\
& \text{xpos = Symbol('xpos', positive=True)} \\
& \text{xneg = Symbol('xneg', negative=True)} \\
& \text{x = Symbol('x')} \\
& \text{print(xpos.is_positive)} \\
& \text{True} \\
& \text{print(xneg.is_positive)} \\
& \text{False} \\
& \text{print(x.is_positive)} \\
& \text{None}
\end{align*}
\]

A None result as a fuzzy-bool should be interpreted as meaning “maybe” or “unknown”.

An example of a symbolic Boolean (page 1207) class in SymPy can be found when using inequalities. When an inequality is not known to be true or false a Boolean (page 1207) can represent indeterminate results symbolically:

\[
\begin{align*}
>>> & \text{xpos > 0} \\
& \text{True} \\
& \text{xneg > 0} \\
& \text{False} \\
& \text{x > 0} \\
& \text{x > 0} \\
& \text{type(x > 0)} \\
& \text{<class 'sympy.core.relational.StrictGreaterThan'>}
\end{align*}
\]

\(^1\) Note that what is referred to in SymPy as a “fuzzy bool” is really about using three-valued logic. In normal usage “fuzzy logic” refers to a system where logical values are continuous in between zero and one which is something different from three-valued logic.
The last example shows what happens when an inequality is indeterminate: we get an instance of `StrictGreaterThan` (page 1079) which represents the inequality as a symbolic expression. Internally when attempting to evaluate an inequality like \( a > b \) SymPy will compute \((a - b)\).\text{is\,extended\,positive}. If the result is True or False then SymPy’s symbolic \( S.true \) or \( S.false \) will be returned. If the result is None then an unevaluated `StrictGreaterThan` (page 1079) is returned as shown for \( x > 0 \) above.

It is not obvious that queries like `xpos > 0` return `S.true` rather than `True` because both objects display in the same way but we can check this using the Python `is` operator:

```python
>>> from sympy import S
>>> xpos.is_positive is True
True
>>> xpos.is_positive is S.true
False
>>> (xpos > 0) is True
False
>>> (xpos > 0) is S.true
True
```

There is no general symbolic analogue of None in SymPy. In the cases where a low-level assumptions query gives None the symbolic query will result in an unevaluated symbolic `Boolean` (page 1207) (e.g, \( x > 0 \)). We can use a symbolic `Boolean` (page 1207) as part of a symbolic expression such as a `Piecewise` (page 472):

```python
>>> from sympy import Piecewise
>>> p = Piecewise((1, x > 0), (2, True))
>>> p
Piecewise((1, x > 0), (2, True))
>>> p.subs(x, 3)
1
```

Here \( p \) represents an expression that will be equal to 1 if \( x > 0 \) or otherwise it will be equal to 2. The unevaluated `Boolean` (page 1207) inequality \( x > 0 \) represents the condition for deciding the value of the expression symbolically. When we substitute a value for \( x \) the inequality will resolve to \( S.true \) and then the `Piecewise` (page 472) can evaluate to 1 or 2.

The same will not work when using a fuzzy-bool instead of a symbolic `Boolean` (page 1207):

```python
>>> p2 = Piecewise((1, x.is_positive), (2, True))
Traceback (most recent call last):
...
TypeError: Second argument must be a Boolean, not `NoneType`
```

The `Piecewise` (page 472) cannot use None as the condition because unlike the inequality \( x > 0 \) it gives no information. With the inequality it is possible to decide in future if the condition might True or False once a value for \( x \) is known. A value of None can not be used in that way so it is rejected.

**Note:** We can use True in the `Piecewise` (page 472) because True sympifies to \( S.true \). Sympifying None just gives None again which is not a valid symbolic SymPy object.

There are many other symbolic `Boolean` (page 1207) types in SymPy. The same considerations about the differences between fuzzy bool and symbolic `Boolean` (page 1207) apply to all other
SymPy Boolean types. To give a different example there is Contains (page 1258) which represents the statement that an object is contained in a set:

```
>>> from sympy import Reals, Contains
>>> x = Symbol('x', real=True)
>>> y = Symbol('y')
>>> Contains(x, Reals)
True
>>> Contains(y, Reals)
Contains(y, Reals)
>>> Contains(y, Reals).subs(y, 1)
True
```

The Python operator corresponding to Contains (page 1258) is `in`. A quirk of `in` is that it can only evaluate to a bool (True or False) so if the result is indeterminate then an exception will be raised:

```
>>> from sympy import I
>>> 2 in Reals
True
>>> I in Reals
False
>>> x in Reals
True
>>> y in Reals
Traceback (most recent call last):
  ...
TypeError: did not evaluate to a bool: (-oo < y) & (y < oo)
```

The exception can be avoided by using `Contains(x, Reals)` or `Reals.contains(x)` rather than `x in Reals`.

### 3.2.2 Three-valued logic with fuzzy bools

Whether we use the fuzzy-bool or symbolic Boolean (page 1207) we always need to be aware of the possibility that a query might be indeterminate. How to write code that handles this is different in the two cases though. We will look at fuzzy-bools first.

Consider the following function:

```
>>> def both_positive(a, b):
...     """ask whether a and b are both positive""
...     if a.is_positive and b.is_positive:
...         return True
...     else:
...         return False
```

The `both_positive` function is supposed to tell us whether or not `a` and `b` are both positive. However the `both_positive` function will fail if either of the `is_positive` queries gives `None`:

```
>>> print(both_positive(S(1), S(1)))
True
>>> print(both_positive(S(1), S(-1)))
```

(continues on next page)
>>> print(both_positive(S(-1), S(-1)))
False
>>> x = Symbol('x') # may or may not be positive
>>> print(both_positive(S(1), x))
False

Note: We need to sympify the arguments to this function using S because the assumptions are only defined on SymPy objects and not regular Python int objects.

Here False is incorrect because it is possible that x is positive in which case both arguments would be positive. We get False here because x.is_positive gives None and Python will treat None as “falsey”.

In order to handle all possible cases correctly we need to separate the logic for identifying the True and False cases. An improved function might be:

```python
>>> def both_positive_better(a, b):
...     """ask whether a and b are both positive""
...     if a.is_positive is False or b.is_positive is False:
...         return False
...     elif a.is_positive is True and b.is_positive is True:
...         return True
...     else:
...         return None

This function now can handle all cases of True, False or None for both a and b and will always return a fuzzy bool representing whether the statement “a and b are both positive” is true, false or unknown:

```python
>>> print(both_positive_better(S(1), S(1)))
True
>>> print(both_positive_better(S(1), S(-1)))
False
>>> x = Symbol('x')
>>> y = Symbol('y', positive=True)
>>> print(both_positive_better(S(1), x))
None
>>> print(both_positive_better(S(-1), x))
False
>>> print(both_positive_better(S(1), y))
True
```

Another case that we need to be careful of when using fuzzy-bools is negation with Python’s not operator e.g.:

```python
>>> x = Symbol('x')
>>> print(x.is_positive)
None
>>> not x.is_positive
True
```
The correct negation of a fuzzy bool None is None again. If we do not know whether the statement “x is positive” is True or False then we also do not know whether its negation “x is not positive” is True or False. The reason we get True instead is again because None is considered “falsey”. When None is used with a logical operator such as not it will first be converted to a bool and then negated:

```python
>>> bool(None)
False
>>> not bool(None)
True
>>> not None
True
```

The fact that None is treated as falsey can be useful if used correctly. For example we may want to do something only if x is known to positive in which case we can do:

```python
>>> x = Symbol('x', positive=True)
>>> if x.is_positive:
...     print("x is definitely positive")
... else:
...     print("x may or may not be positive")
x is definitely positive
```

Provided we understand that an alternate condition branch refers to two cases (False and None) then this can be a useful way of writing conditionals. When we really do need to distinguish all cases then we need to use things like x.is_positive is False. What we need to be careful of though is using Python’s binary logic operators like not or and with fuzzy bools as they will not handle the indeterminate case correctly.

In fact SymPy has internal functions that are designed to handle fuzzy-bools correctly:

```python
>>> from sympy.core.logic import fuzzy_not, fuzzy_and
>>> print(fuzzy_not(True))
False
>>> print(fuzzy_not(False))
True
>>> print(fuzzy_not(None))
None
>>> print(fuzzy_and([True, True]))
True
>>> print(fuzzy_and([True, None]))
None
>>> print(fuzzy_and([False, None]))
False
```

Using the fuzzy_and function we can write the both_positive function more simply:

```python
>>> def both_positive_best(a, b):
...     """ask whether a and b are both positive""
...     return fuzzy_and([a.is_positive, b.is_positive])
```

Making use of fuzzy_and, fuzzy_or and fuzzy_not leads to simpler code and can also reduce the chance of introducing a logic error because the code can look more like it would in the case of ordinary binary logic.
3.2.3 Three-valued logic with symbolic Booleans

When working with symbolic Boolean (page 1207) rather than fuzzy-bool the issue of None silently being treated as falsey does not arise so it is easier not to end up with a logic error. However instead the indeterminate case will often lead to an exception being raised if not handled carefully.

We will try to implement the both_positive function this time using symbolic Boolean (page 1207):

```python
>>> def both_positive(a, b):
...    
...    """ask whether a and b are both positive""
...    
...    if a > 0 and b > 0:
...        return S.true
...    
...    else:
...        return S.false

The first difference is that we return the symbolic Boolean (page 1207) objects S.true and S.false rather than True and False. The second difference is that we test e.g. a > 0 rather than a.is_positive. Trying this out we get

```python
>>> both_positive(1, 2)
True
>>> both_positive(-1, 1)
False
>>> x = Symbol('x')  # may or may not be positive
>>> both_positive(x, 1)
Traceback (most recent call last):
...
TypeError: cannot determine truth value of Relational
```

What happens now is that testing x > 0 gives an exception when x is not known to be positive or not positive. More precisely x > 0 does not give an exception but if x > 0 does and that is because the if statement implicitly calls bool(x > 0) which raises.

```python
>>> x > 0
x > 0
>>> bool(x > 0)
Traceback (most recent call last):
...
TypeError: cannot determine truth value of Relational
>>> if x > 0:
...
print("x is positive")
Traceback (most recent call last):
...
TypeError: cannot determine truth value of Relational
```

The Python expression x > 0 creates a SymPy Boolean (page 1207). Since in this case the Boolean (page 1207) can not evaluate to True or False we get an unevaluated StrictGreaterThan (page 1079). Attempting to force that into a bool with bool(x > 0) raises an exception. That is because a regular Python bool must be either True or False and neither of those are known to be correct in this case.

The same kind of issue arises when using and, or or not with symbolic Boolean (page 1207). The solution is to use SymPy’s symbolic And (page 1210), Or (page 1211) and Not (page 1211) or equivalently Python’s bitwise logical operators & and | and ~:
As before we can make a better version of `both_positive` if we avoid directly using a SymPy Boolean (page 1207) in an if, and, or, or not. Instead we can test whether or not the Boolean (page 1207) has evaluated to `S.true` or `S.false`:

```python
>>> def both_positive_better(a, b):
...     
...     """ask whether a and b are both positive""
...     ...         if (a > 0) is S.false or (b > 0) is S.false:
...         ...             return S.false
...     ...         elif (a > 0) is S.true and (b > 0) is S.true:
...         ...             return S.true
...     ...         else:
...         ...             return And(a > 0, b > 0)
```

Now with this version we don’t get any exceptions and if the result is indeterminate we will get a symbolic Boolean (page 1207) representing the conditions under which the statement “a and b are both positive” would be true:

```python
>>> both_positive_better(S(1), S(2))
True
>>> both_positive_better(S(1), S(-1))
False
>>> x, y = symbols("x, y")
>>> both_positive_better(x, y + 1)
(x > 0) & (y + 1 > 0)
>>> both_positive_better(x, S(3))
x > 0
```

The last case shows that actually using the `And` (page 1210) with a condition that is known to be true simplifies the `And` (page 1210). In fact we have

```python
>>> And(x > 0, 3 > 0)
x > 0
>>> And(4 > 0, 3 > 0)
True
>>> And(-1 > 0, 3 > 0)
False
```
What this means is that we can improve `both_positive_better`. The different cases are not needed at all. Instead we can simply return the `And` and let it simplify if possible:

```python
>>> def both_positive_best(a, b):
...     
...
...     return And(a > 0, b > 0)
```

Now this will work with any symbolic real objects and produce a symbolic result. We can also substitute into the result to see how it would work for particular values:

```python
>>> both_positive_best(2, 1)
True
>>> both_positive_best(-1, 2)
False
>>> both_positive_best(x, 3)
x > 0
>>> condition = both_positive_best(x/y, x + y)
>>> condition
(x + y > 0) & (x/y > 0)
>>> condition.subs(x, 1)
(1/y > 0) & (y + 1 > 0)
>>> condition.subs(x, 1).subs(y, 2)
True
```

The idea when working with symbolic `Boolean` objects is as much as possible to avoid trying to branch on them with `if`/`else` and other logical operators like and etc. Instead think of computing a condition and passing it around as a variable. The elementary symbolic operations like `And` (page 1210), `Or` (page 1211) and `Not` (page 1211) can then take care of the logic for you.

### 3.3 Writing Custom Functions

This guide will describe how to create custom function classes in SymPy. Custom user defined functions use the same mechanisms as the `functions` (page 441) that are included with SymPy such as the common `elementary functions` (page 442) like `exp()` (page 468) or `sin()` (page 449), `special functions` (page 506) like `gamma()` (page 515) or `Si()` (page 548), and `combinatorial functions` (page 483) and `number theory functions` (page 1522) like `factorial()` (page 490) or `primepi()` (page 1525). Consequently, this guide serves both as a guide to end users who want to define their own custom functions and to SymPy developers wishing to extend the functions included with SymPy.

This guide describes how to define complex valued functions, that is functions that map a subset of \( \mathbb{C}^n \) to \( \mathbb{C} \). Functions that accept or return other kinds of objects than complex numbers should subclass another class, such as `Boolean` (page 1207), `MatrixExpr` (page 1414), `Expr` (page 999), or `Basic` (page 979). Some of what is written here will apply to general `Basic` (page 979) or `Expr` (page 999) subclasses, but much of it only applies to `Function` (page 1096) subclasses.
3.3.1 Easy Cases: Fully Symbolic or Fully Evaluated

Before digging into the more advanced functionality for custom functions, we should mention two common cases, the case where the function is fully symbolic, and the case where the function is fully evaluated. Both of these cases have much simpler alternatives than the full mechanisms described in this guide.

The Fully Symbolic Case

If your function \( f \) has no mathematical properties you want to define on it, and should never evaluate on any arguments, you can create an undefined function using \( \text{Function}(\text{'}f\text{'}) \)

```
>>> from sympy import symbols, Function
>>> x = symbols('x')
>>> f = Function('f')
```

```
>>> f(x)
f(x)
>>> f(0)
f(0)
```

This is useful, for instance, when solving **ODEs** (page 807).

This is also useful if you only wish to create a symbol that depends on another symbol for the purposes of differentiation. By default, SymPy assumes all symbols are independent of one another:

```
>>> from sympy.abc import x, y
>>> y.diff(x)
0
```

To make a symbol that depends on another symbol, you can use a function that explicitly depends on that symbol.

```
>>> y = Function('y')
>>> y(x).diff(x)
Derivative(y(x), x)
```

If you want your function to have additional behavior, for example, to have a custom derivative, or to evaluate on certain arguments, you should create a custom Function subclass as **described below** (page 105). However, undefined functions do support one additional feature, which is that assumptions can be defined on them, using the same syntax as used by symbols. This defines the assumptions of the output of the function, not the input (that is, it defines the function’s range, not its domain).

```
>>> g = Function('g', real=True)
```

```
>>> g(x)
g(x)
>>> g(x).is_real
True
```

To make a function’s assumptions depend on its input in some way, you should create a custom Function subclass and define assumptions handlers as **described below** (page 111).
The Fully Evaluated Case

At the other end of the spectrum are functions that always evaluate to something no matter what their inputs are. These functions are never left in an unevaluated, symbolic form like \( f(x) \).

In this case, you should use a normal Python function using the `def` keyword:

```python
>>> def f(x):
...     if x == 0:
...         return 0
...     else:
...         return x + 1

>>> f(0)
0
>>> f(1)
2
>>> f(x)
x + 1
```

If you find yourself defining an `eval()` (page 106) method on a Function subclass where you always return a value and never return `None`, you should consider just using a normal Python function instead, as there is no benefit to using a symbolic Function subclass in that case (see the Best Practices for `eval()` (page 107) section below).

Note that in many cases, functions like these can be represented directly using SymPy classes. For example, the above function can be represented symbolically using `Piecewise` (page 472). The `Piecewise` expression can be evaluated for specific values of \( x \) using `subs()` (page 993).

```python
>>> from sympy import Piecewise, Eq, pprint

>>> f = Piecewise((0, Eq(x, 0)), (x + 1, True))

>>> pprint(f, use_unicode=True)
\[
\begin{cases}
0 & \text{for } x = 0 \\
x + 1 & \text{otherwise}
\end{cases}
\]

>>> f.subs(x, 0)
0
>>> f.subs(x, 1)
2
```

Fully symbolic representations like `Piecewise` have the advantage that they accurately represent symbolic values. For example, in the above Python def definition of \( f \), \( f(x) \) implicitly assumes that \( x \) is nonzero. The `Piecewise` version handles this case correctly and won’t evaluate to the \( x \neq 0 \) case unless \( x \) is known to not be zero.

Another option, if you want a function that not only evaluates, but always evaluates to a numerical value, is to use `lambdify()` (page 2173). This will convert a SymPy expression into a function that can be evaluated using NumPy.

```python
>>> from sympy import lambdify

>>> func = lambdify(x, Piecewise((0, Eq(x, 0)), (x + 1, True)))

>>> import numpy as np

(continues on next page)
Ultimately, the correct tool for the job depends on what you are doing and what exact behavior you want.

### 3.3.2 Creating a Custom Function

The first step to creating a custom function is to subclass `Function` (page 1096). The name of the subclass will be the name of the function. Different methods should then be defined on this subclass, depending on what functionality you want to provide.

As a motivating example for this document, let’s create a custom function class representing the versine function. Versine is a trigonometric function which was used historically alongside some of the more familiar trigonometric functions like sine and cosine. It is rarely used today. Versine can be defined by the identity

\[
\text{versin}(x) = 1 - \cos(x).
\]

SymPy does not already include versine because it is used so rarely in modern mathematics and because it is so easily defined in terms of the more familiar cosine.

Let us start by subclassing `Function`.

```python
>>> class versin(Function):
...     pass
```

At this point, `versin` has no behaviors defined on it. It is very similar to the undefined functions (page 103) we discussed above. Note that `versin` is a class, and `versin(x)` is an instance of this class.

```python
>>> versin(x)
versin(x)
>>> isinstance(versin(x), versin)
True
```

**Note:** All the methods described below are optional. They can be included if you want to define the given behavior, but if they are omitted, SymPy will default to leaving things unevaluated. For example, if you do not define differentiation (page 118), `diff()` (page 1094) will just return an unevaluated `Derivative` (page 1088).
Defining Automatic Evaluation with eval()

Reminder

Remember that eval() should be defined with the @classmethod decorator.

The first and most common thing we might want to define on our custom function is automatic evaluation, that is, the cases where it will return an actual value instead of just remaining unevaluated as-is.

This is done by defining the class method eval(). eval() should take the arguments of the function and return either a value or None. If it returns None, the function will remain unevaluated in that case. This also serves to define the signature of the function (by default, without an eval() method, a Function subclass will accept any number of arguments).

For our function versin, we might recall that \( \cos(n\pi) = (-1)^n \) for integer \( n \), so versin\((n\pi) = 1 - (-1)^n \). We can make versin automatically evaluate to this value when passed an integer multiple of pi:

```python
>>> from sympy import pi, Integer
>>> class versin(Function):
...     @classmethod
...     def eval(cls, x):
...         # If x is an integer multiple of pi, x/pi will cancel and be an Integer
...         n = x/pi
...         if isinstance(n, Integer):
...             return 1 - (-1)**n
```

```python
>>> versin(pi)
2
>>> versin(2*pi)
0
```

Here we make use of the fact that if a Python function does not explicitly return a value, it automatically returns None. So in the cases where the if isinstance\((n, Integer)\) statement is not triggered, eval() returns None and versin remains unevaluated.

```python
>>> versin(x*pi)
versin(pi*x)
```

Note: Function subclasses should not redefine __new__ or __init__. If you want to implement behavior that isn’t possible with eval(), it might make more sense to subclass Expr (page 999) rather than Function.

eval() can take any number of arguments, including an arbitrary number with *args and optional keyword arguments. The .args of the function will always be the arguments that were passed in by the user. For example:

```python
>>> class f(Function):
...     @classmethod
```
def eval(cls, x, y=1, *args):
    return None

>>> f(1).args
(1,)

>>> f(1, 2).args
(1, 2)

>>> f(1, 2, 3).args
(1, 2, 3)

Finally, note that automatic evaluation on floating-point inputs happens automatically once `evalf()` is defined (page 114), so you do not need to handle it explicitly in `eval()`.

**Best Practices for eval()**

Certain antipatterns are common when defining `eval()` methods and should be avoided.

- **Don’t just return an expression.**

  In the above example, we might have been tempted to write

  ```python
  >>> from sympy import cos
  >>> class versin(Function):
  ...     @classmethod
  ...     def eval(cls, x):
  ...         # !! Not actually a good eval() method !!
  ...         return 1 - cos(x)
  ...
  
  However, this would make it so that `versin(x)` would always return `1 - cos(x)`, regardless of what `x` is. If all you want is a quick shorthand to `1 - cos(x)`, that is fine, but would be much simpler and more explicit to just use a Python function as described above (page 104). If we defined `versin` like this, it would never actually be represented as `versin(x)`, and none of the other behavior we define below would matter, because the other behaviors we are going to define on the `versin` class only apply when the returned object is actually a `versin` instance. So for example, `versin(x).diff(x)` would actually just be `(1 - cos(x)).diff(x)`, instead of calling the `fdiff()` method we define below (page 118).

  ```python
  
  Key Point
  
  The purpose of `eval()` is not to define what the function *is*, mathematically, but rather to specify on what inputs it should automatically evaluate. The mathematical definition of a function is determined through the specification of various mathematical properties with the methods outlined below, like numerical evaluation (page 114), differentiation (page 118), and so on.

  If you find yourself doing this, you should think about what you actually want to achieve. If you just want a shorthand function for an expression, it will be simpler to just define a Python function (page 104). If you really do want a symbolic function, think about when you want it to evaluate to something else and when you want it to stay unevaluated. One option is to make your function unevaluated in `eval()` and define a `doit()` method (page 116) to evaluate it.

3.3. Writing Custom Functions
• **Avoid too much automatic evaluation.**

It is recommended to minimize what is evaluated automatically by `eval()`. It is typically better to put more advanced simplifications in other methods (page 115), like `doit()` (page 116). Remember that whatever you define for automatic evaluation will always evaluate.¹ As in the previous point, if you evaluate every value, there is little point to even having a symbolic function in the first place. For example, we might be tempted to evaluate some trig identities on `versin` in `eval()`, but then these identities would always evaluate, and it wouldn’t be possible to represent one half of the identity.

One should also avoid doing anything in `eval()` that is slow to compute. SymPy generally assumes that it is cheap to create expressions, and if this is not true, it can lead to performance issues.

Finally, it is recommended to avoid performing automatic evaluation in `eval()` based on assumptions. Instead, `eval()` should typically only evaluate explicit numerical special values and return `None` for everything else. You might have noticed in the example above (page 106) that we used `isinstance(n, Integer)` instead of checking `n.is_integer` using the assumptions system. We could have done that instead, which would make `versin(n*pi)` evaluate even if `n = Symbol('n', integer=True)`. But this is a case where we might not always want evaluation to happen, and if `n` is a more complicated expression, `n.is_integer` might be more expensive to compute.

Let’s consider an example. Using the identity \( \cos(x + y) = \cos(x)\cos(y) - \sin(x)\sin(y) \), we can derive the identity

\[
\text{versin}(x + y) = \text{versin}(x)\text{versin}(y) - \text{versin}(x) - \text{versin}(y) - \sin(x)\sin(y) + 1.
\]

Suppose we decided to automatically expand this in `eval()`:

```python
>>> from sympy import Add, sin
>>> class versin(Function):
...     @classmethod
...     def eval(cls, x):
...         # !! Not actually a good eval() method !!
...         if isinstance(x, Add):
...             a, b = x.as_two_terms()
...             return (versin(a)*versin(b) - versin(a) - versin(b) - sin(a)*sin(b) + 1)
```

This method recursively splits `Add` terms into two parts and applies the above identity.

```python
>>> x, y, z = symbols('x y z')
>>> versin(x + y)
-sin(x)*sin(y) + versin(x)*versin(y) - versin(x) - versin(y) + 1
```

But now it’s impossible to represent `versin(x + y)` without it expanding. This will affect other methods too. For example, suppose we define differentiation (see below) (page 118):

¹ While it is technically possible to bypass automatic evaluation by using `evaluate=False`, this is recommended against for two reasons. Firstly, `evaluate=False` is fragile because any function that rebuilds the expression from its `.args` will not keep the `evaluate=False` flag, causing it to evaluate. Secondly, `evaluate=False` tends to be bug prone, because other code may be written expecting the invariants from the automatic evaluation to hold. It is much better to not evaluate such cases at all in `eval()`, and move such simplifications to `doit()` (page 116) instead.
>> class versin(Function):
...    @classmethod
...    def eval(cls, x):
...        # !! Not actually a good eval() method !!
...        if isinstance(x, Add):
...            a, b = x.as_two_terms()
...            return (versin(a)*versin(b) - versin(a) - versin(b)
...                    - sin(a)*sin(b) + 1)
...    def fdiff(self, argindex=1):
...        return sin(self.args[0])

We would expect \( \text{versin}(x + y) \).\text{diff}(x) \) to return \( \sin(x + y) \), and indeed, if we hadn't expanded this identity in eval(), it would (page 119). But with this version, \( \text{versin}(x + y) \) gets automatically expanded before \text{diff}() \ gets called, instead we get a more complicated expression:

>> \text{versin}(x + y).\text{diff}(x)
\sin(x)\text{versin}(y) - \sin(x) - \sin(y)\cos(x)

And things are even worse than that. Let's try an Add with three terms:

>> \text{versin}(x + y + z)
\(-\sin(y)\sin(z) + \text{versin}(y)\text{versin}(z) - \text{versin}(y) - \text{versin}(z) +
1)\text{versin}(x) - \sin(x)\sin(y + z) + \sin(y)\sin(z) - \text{versin}(x) -
\text{versin}(y)\text{versin}(z) + \text{versin}(y) + \text{versin}(z)

We can see that things are getting out of control quite quickly. In fact, \( \text{versin}(\text{Add(*symbols('x:100'))}) \) (\text{versin}() \ on \ an \ Add \ with \ 100 \ terms) \ takes \ over \ a \ second \ to \ evaluate, \ and \ that's \ just \ to \ create \ the \ expression, \ without \ even \ doing \ anything \ with \ it \ yet.

Identities like this are better left out of eval and implemented in other methods instead (in the case of this identity, \text{expand_trig}() \ (page 118)).

• **When restricting the input domain: allow None input assumptions.**

Our example function \( \text{versin}(x) \) is a function from \( \mathbb{C} \) to \( \mathbb{C} \), so it can accept any input. But suppose we had a function that only made sense with certain inputs. As a second example, let's define a function divides as

\[
\text{divides}(m, n) = \begin{cases} 
1 & \text{for } m \mid n \\
0 & \text{for } m \nmid n.
\end{cases}
\]

That is, \( \text{divides}(m, n) \) \ will \ be \ 1 \ if \ \text{m} \ \text{divides} \ n \ and \ 0 \ otherwise. \ \text{divides} \ clearly \ only \ makes \ sense \ if \ \text{m} \ and \ n \ are \ integers.

We might be tempted to define the eval() method for divides like this:

>> class divides(Function):
...    @classmethod
...    def eval(cls, m, n):
...        # !! Not actually a good eval() method !!

(continues on next page)
The problem here is that by using `if not m.is_integer`, we are requiring `m.is_integer` to be `True`. If it is `None`, it will fail (see the [guide on booleans and three-valued logic](page95) for details on what it means for an assumption to be `None`). This is problematic for two reasons. Firstly, it forces the user to define assumptions on any input variable. If the user omits them, it will fail:

```
>>> n, m = symbols('n m')
>>> print(n.is_integer)
None
>>> divides(m, n)
Traceback (most recent call last):
  ...TypeError: m and n should be integers
```

Instead they have to write:

```
>>> n, m = symbols('n m', integer=True)
>>> divides(m, n)
divides(m, n)
```

This may seem like an acceptable restriction, but there is a bigger problem. Sometimes, SymPy’s assumptions system cannot deduce an assumption, even though it is mathematically true. In this case, it will give `None` (`None` means both “undefined” and “cannot compute” in SymPy’s assumptions). For example:

```
>>> # n and m are still defined as integer=True as above
>>> divides(2, (m**2 + m)/2)
Traceback (most recent call last):
  ...TypeError: m and n should be integers
```

Here the expression `(m**2 + m)/2` is always an integer, but SymPy’s assumptions system is not able to deduce this:

```
>>> print(((m**2 + m)/2).is_integer)
None
```

SymPy’s assumptions system is always improving, but there will always be cases like this that it cannot deduce, due to the fundamental computational complexity of the problem, and the fact that the general problem is often undecidable.

Consequently, one should always test *negated* assumptions for input variables, that is, fail if the assumption is `False` but allow the assumption to be `None`. 
```python
>>> class divides(Function):
...     @classmethod
...     def eval(cls, m, n):
...         # Evaluate for explicit integer m and n. This part is fine.
...         if isinstance(m, Integer) and isinstance(n, Integer):
...             return int(n % m == 0)
...         # For symbolic arguments, require m and n to be integer.
...         # This is the better way to write this logic.
...         if m.is_integer is False or n.is_integer is False:
...             raise TypeError("m and n should be integers")

This still disallows non-integer inputs as desired:

```python
>>> divides(1.5, 1)
Traceback (most recent call last):
...
TypeError: m and n should be integers
```

But it does not fail in cases where the assumption is None:

```python
>>> divides(2, (m**2 + m)/2)
>>> _.subs(m, 2)
0
>>> n, m = symbols('n m') # Redefine n and m without the integer assumption
>>> divides(m, n)
divides(m, n)
```

**Note:** This rule of allowing None assumptions only applies to instances where an exception would be raised, such as type checking an input domain. In cases where simplifications or other operations are done, one should treat a None assumption as meaning “can be either True or False” and not perform an operation that might not be mathematically valid.

### Assumptions

The next thing you might want to define are the assumptions on our function. The assumptions system allows defining what mathematical properties your function has given its inputs, for example, “$f(x)$ is positive when $x$ is real.”

The guide on the assumptions system (page 71) goes into the assumptions system in great detail. It is recommended to read through that guide first to understand what the different assumptions mean and how the assumptions system works.

The simplest case is a function that always has a given assumption regardless of its input. In this case, you can define is_assumption directly on the class.

For example, our example divides function (page 109) is always an integer, because its value is always either 0 or 1:
Note

From here on out in this guide, in the interest of space, we will omit the previous method definitions in the examples unless they are needed for the given example to work. There are complete examples (page 122) at the end of this guide with all the methods.

```python
>>> class divides(Function):
...       is_integer = True
...       is_negative = False
```

```python
>>> divides(m, n).is_integer
True
>>> divides(m, n).is_nonnegative
True
```

In general, however, the assumptions of a function depend on the assumptions of its inputs. In this case, you should define an _eval_assumption method.

For our versin(x) example (page 105), the function is always in [0,2] when x is real, and it is 0 exactly when x is an even multiple of π. So versin(x) should be nonnegative whenever x is real and positive whenever x is real and not an even multiple of π. Remember that by default, a function’s domain is all of C, and indeed versin(x) makes perfect sense with non-real x.

To see if x is an even multiple of pi, we can use as_independent() (page 1004) to match x structurally as coeff*π. Pulling apart subexpressions structurally like this in assumptions handlers is preferable to using something like (x/pi).is_even, because that will create a new expression x/pi. The creation of a new expression is much slower. Furthermore, whenever an expression is created, the constructors that are called when creating the expression will often themselves cause assumptions to be queried. If you are not careful, this can lead to infinite recursion. So a good general rule for assumptions handlers is, never create a new expression in an assumptions handler. Always pull apart the args of the function using structural methods like as_independent.

Note that versin(x) can be nonnegative for nonreal x, for example:

```python
>>> from sympy import I
>>> 1 - cos(pi + I*pi)
1 + cosh(pi)
>>> (1 - cos(pi + I*pi)).evalf()
12.5919532755215
```

So for the _eval_is_nonnegative handler, we want to return True if x.is_real is True but None if x.is_real is either False or None. It is left as an exercise to the reader to handle the cases for nonreal x that make versin(x) nonnegative, using similar logic from the _eval_is_positive handler.

In the assumptions handler methods, as in all methods, we can access the arguments of the function using self.args.

```python
>>> from sympy.core.logic import fuzzy_and, fuzzy_not
>>> class versin(Function):
...       def _eval_is_nonnegative(self):
...           # versin(x) is nonnegative if x is real
...           x = self.args[0]
```

(continues on next page)
... if x.is_real is True:
    return True
...
...
  def _eval_is_positive(self):
    # versin(x) is positive if x is real and not an even multiple of pi
    x = self.args[0]
    # x.as_independent(pi, as_Add=False) will split x as a Mul of the
    # form coeff*pi
    coeff, pi_ = x.as_independent(pi, as_Add=False)
    # If pi_ == pi, x = coeff*pi. Otherwise x is not (structurally) of
    # the form coeff*pi.
    if pi_ == pi:
      return fuzzy_and([x.is_real, fuzzy_not(coeff.is_even)])
    elif x.is_real is False:
      return False
    # else: return None. We do not know for sure whether x is an even
    # multiple of pi

>>> versin(1).is_nonnegative
True
>>> versin(2*pi).is_positive
False
>>> versin(3*pi).is_positive
True

Note the use of fuzzy_ functions in the more complicated _eval_is_positive() handler, and the careful handling of the if/elif. It is important when working with assumptions to always be careful about handling three-valued logic correctly (page 95). This ensures that the method returns the correct answer when x.is_real or coeff.is_even are None.

**Warning:** Never define is_assumption as a @property method. Doing so will break the automatic deduction of other assumptions. is_assumption should only ever be defined as a class variable equal to True or False. If the assumption depends on the .args of the function somehow, define the _eval_assumption method.

In this example, it is not necessary to define _eval_is_real() because it is deduced automatically from the other assumptions, since nonnegative -> real. In general, you should avoid defining assumptions that the assumptions system can deduce automatically given its known facts (page 77).

>>> versin(1).is_real
True

The assumptions system is often able to deduce more than you might think. For example, from the above, it can deduce that versin(2*n*pi) is zero when n is an integer.

>>> n = symbols('n', integer=True)
>>> versin(2*n*pi).is_zero
True
It’s always worth checking if the assumptions system can deduce something automatically before manually coding it.

Finally, a word of warning: be very careful about correctness when coding assumptions. Make sure to use the exact definitions (page 77) of the various assumptions, and always check that you’re handling None cases correctly with the fuzzy three-valued logic functions. Incorrect or inconsistent assumptions can lead to subtle bugs. It’s recommended to use unit tests to check all the various cases whenever your function has a nontrivial assumption handler. All functions defined in SymPy itself are required to be extensively tested.

**Numerical Evaluation with evalf()**

Here we show how to define how a function should numerically evaluate to a floating point Float (page 1033) value, for instance, via evalf(). Implementing numerical evaluation enables several behaviors in SymPy. For example, once evalf() is defined, you can plot your function, and things like inequalities can evaluate to explicit values.

If your function has the same name as a function in mpmath, which is the case for most functions included with SymPy, numerical evaluation will happen automatically and you do not need to do anything.

If this is not the case, numerical evaluation can be specified by defining the method _eval_evalf(self, prec), where prec is the binary precision of the input. The method should return the expression evaluated to the given precision, or None if this is not possible.

**Note:** The prec argument to _eval_evalf() is the binary precision, that is, the number of bits in the floating-point representation. This differs from the first argument to the evalf() method, which is the decimal precision, or dps. For example, the default binary precision of Float is 53, corresponding to a decimal precision of 15. Therefore, if your _eval_evalf() method recursively calls evalf on another expression, it should call expr._eval_evalf(prec) rather than expr.evalf(prec), as the latter will incorrectly use prec as the decimal precision.

We can define numerical evaluation for our example versin(x) function (page 105) by recursively evaluating $2\sin^2 \left(\frac{x}{2}\right)$, which is a more numerically stable way of writing $1 - \cos(x)$.

```python
>>> from sympy import sin
>>> class versin(Function):
...     def _eval_evalf(self, prec):
...         return (2*sin(self.args[0]/2)**2)._eval_evalf(prec)
```

```bash
0.459697694131860
```

Once _eval_evalf() is defined, this enables the automatic evaluation of floating-point inputs. It is not required to implement this manually in eval() (page 106).

```bash
0.459697694131860
```

Note that evalf() may be passed any expression, not just one that can be evaluated numerically. In this case, it is expected that the numerical parts of an expression will be evaluated. A general pattern to follow is to recursively call _eval_evalf(prec) on the arguments of the function.
Whenever possible, it’s best to reuse the `evalf` functionality defined in existing SymPy functions. However, in some cases it will be necessary to use `mpmath` directly.

**Rewriting and Simplification**

Various simplification functions and methods allow specifying their behavior on custom subclasses. Not every function in SymPy has such hooks. See the documentation of each individual function for details.

**rewrite()**

The `rewrite()` (page 991) method allows rewriting an expression in terms of a specific function or rule. For example,

```python
>>> sin(x).rewrite(cos)
cos(x - pi/2)
```

To implement rewriting, define a method `_eval_rewrite(self, rule, args, **hints)`, where

- `rule` is the `rule` passed to the `rewrite()` method. Typically `rule` will be the class of the object to be rewritten to, although for more complex rewrites, it can be anything. Each object that defines `_eval_rewrite()` defines what rule(s) it supports. Many SymPy functions rewrite to common classes, like `expr.rewrite(Add)`, to perform simplifications or other computations.

- `args` are the arguments of the function to be used for rewriting. This should be used instead of `self.args` because any recursive expressions in the `args` will be rewritten in `args` (assuming the caller used `rewrite(deep=True)`, which is the default).

- `**hints` are additional keyword arguments which may be used to specify the behavior of the rewrite. Unknown hints should be ignored as they may be passed to other `_eval_rewrite()` methods.

The method should return a rewritten expression, using `args` as the arguments to the function, or `None` if the expression should be unchanged.

For our `versin` example (page 105), an obvious rewrite we can implement is rewriting `versin(x)` as `1 - cos(x):

```python
>>> class versin(Function):
...     def _eval_rewrite(self, rule, args, **hints):
...         if rule == cos:
...             return 1 - cos(*args)
...     versin(x).rewrite(cos)
1 - cos(x)
```

Once we’ve defined this, `simplify()` (page 719) is now able to simplify some expressions containing `versin`:

```python
>>> from sympy import simplify
>>> simplify(versin(x) + cos(x))
1
```
doit()

The `doit()` (page 983) method is used to evaluate “unevaluated” functions. To define `doit()` implement `doit(self, deep=True, **hints)`. If `deep=True`, `doit()` should recursively call `doit()` on the arguments. **hints** will be any other keyword arguments passed to the user, which should be passed to any recursive calls to `doit()`. You can use hints to allow the user to specify specific behavior for `doit()`.

The typical usage of `doit()` in custom `Function` subclasses is to perform more advanced evaluation which is not performed in `eval()` (page 106).

For example, for our `divides` example (page 109), there are several instances that could be simplified using some identities. For example, we defined `eval()` to evaluate on explicit integers, but we might also want to evaluate examples like `divides(k, k*n)` where the divisibility is symbolically true. One of the best practices for `eval()` (page 107) is to avoid too much automatic evaluation. Automatically evaluating in this case might be considered too much, as it would make use of the assumptions system, which could be expensive. Furthermore, we might want to be able to represent `divides(k, k*n)` without it always evaluating.

The solution is to implement these more advanced evaluations in `doit()`. That way, we can explicitly perform them by calling `expr.doit()`, but they won’t happen by default. An example `doit()` for `divides` that performs this simplification (along with the above definition of `eval()` (page 111)) might look like this:

```
>>> from sympy import Integer
>>> class divides(Function):
...     # Define evaluation on basic inputs, as well as type checking that the
...     # inputs are not nonintegral.
...     @classmethod
...     def eval(cls, m, n):
...         # Evaluate for explicit integer m and n.
...         if isinstance(m, Integer) and isinstance(n, Integer):
...             return int(n % m == 0)
...         # For symbolic arguments, require m and n to be integer.
...         if m.is_integer is False or n.is_integer is False:
...             raise TypeError("m and n should be integers")
...     # Define doit() as further evaluation on symbolic arguments using
...     # assumptions.
...     def doit(self, deep=False, **hints):
...         m, n = self.args
...         # Recursively call doit() on the args whenever deep=True.
...         # Be sure to pass deep=True and **hints through here.
...         if deep:
...             m, n = m.doit(deep=deep, **hints), n.doit(deep=deep, **hints)
...         # divides(m, n) is 1 iff n/m is an integer. Note that m and n are
...         # already assumed to be integers because of the logic in eval().
...         isnt = (n/m).is_integer
```
... if isint is True:
    return Integer(1)
... elif isint is False:
    return Integer(0)
... else:
    return divides(m, n)

(Not that this uses the convention that \( k \mid 0 \) for all \( k \) so that we do not need to check if \( m \) or \( n \) are nonzero. If we used a different convention we would need to check if \( m\.is\_zero \) and \( n\.is\_zero \) before performing the simplification.)

```
>>> n, m, k = symbols('n m k', integer=True)
>>> divides(k, k*n)
```

```
divides(k, k*n)
```

```
>>> divides(k, k*n).doit()
```

```
1
```

Another common way to implement \( \text{doit()} \) is for it to always return another expression. This effectively treats the function as an “unevaluated” form of another expression.

For example, let’s define a function for fused multiply-add: \( \text{FMA}(x, y, z) = xy + z \). It may be useful to express this function as a distinct function, e.g., for the purposes of code generation, but it would also be useful in some contexts to “evaluate” \( \text{FMA}(x, y, z) \) to \( xy + z \) so that it can properly simplify with other expressions.

```
>>> from sympy import Number
```

```
>>> class FMA(Function):
```

```
    """
    FMA(x, y, z) = x*y + z
    """
    ...

    @classmethod
    ... def eval(cls, x, y, z):
    ...
        # Number is the base class of Integer, Rational, and Float
        if all(isinstance(i, Number) for i in [x, y, z]):
            return x*y + z
    ...

    def doit(self, deep=True, **hints):
    ...
        x, y, z = self.args
        # Recursively call doit() on the args whenever deep=True.
        # Be sure to pass deep=True and **hints through here.
        if deep:
            ...
            x = x.doit(deep=deep, **hints)
            ...
            y = y.doit(deep=deep, **hints)
            ...
            z = z.doit(deep=deep, **hints)
    ...
        return x*y + z
```

```
>>> x, y, z = symbols('x y z')
```

```
>>> FMA(x, y, z)
```

```
FMA(x, y, z)
```

```
>>> FMA(x, y, z).doit()
```

```
x*y + z
```

Most custom functions will not want to define \( \text{doit()} \) in this way. However, this can provide
a happy medium between having a function that always evaluates and a function that never evaluates, producing a function that doesn’t evaluate by default but can be evaluated on demand (see the discussion above (page 107)).

**expand()**

The **expand()** (page 1099) function “expands” an expression in various ways. It is actually a wrapper around several sub-expansion hints. Each function corresponds to a hint to the expand() function/method. A specific expand hint can be defined in a custom function by defining _eval_expand_hint(self, **hints). See the documentation of **expand()** (page 1099) for details on which hints are defined and the documentation for each specific expand_hint() function (e.g., **expand_trig()** (page 1107)) for details on what each hint is designed to do.

The **hints** keyword arguments are additional hints that may be passed to the expand function to specify additional behavior (these are separate from the predefined hints described in the previous paragraph). Unknown hints should be ignored as they may apply to other functions’ custom expand() methods. A common hint to define is force, where force=True would force an expansion that might not be mathematically valid for all the given input assumptions. For example, expand_log(log(x*y), force=True) produces log(x) + log(y) even though this identity is not true for all complex x and y (typically force=False is the default).

Note that expand() automatically takes care of recursively expanding expressions using its own deep flag, so _eval_expand_ methods should not recursively call expand on the arguments of the function.

For our versin example (page 105), we can define rudimentary trig expansion by defining an _eval_expand_trig method, which recursively calls expand_trig() on 1 - cos(x):

```python
>>> from sympy import expand_trig
>>> y = symbols('y')
>>> class versin(Function):
...     def _eval_expand_trig(self, **hints):
...         x = self.args[0]
...         return expand_trig(1 - cos(x))
>>> versin(x + y).expand(trig=True)
sin(x)*sin(y) - cos(x)*cos(y) + 1
```

A more sophisticated implementation might attempt to rewrite the result of expand_trig(1 - cos(x)) back into versin functions. This is left as an exercise for the reader.

**Differentiation**

To define differentiation via **diff()** (page 1094), define a method fdiff(self, argindex). fdiff() should return the derivative of the function, without considering the chain rule, with respect to the argindex-th variable. argindex is indexed starting at 1.

That is, f(x1, ..., xi, ..., xn).fdiff(i) should return $\frac{df}{dx_i}(x_1, ..., x_{i-1}, x_{i+1}, ..., x_n)$, where $x_k$ are independent of one another. diff() will automatically apply the chain rule using the result of fdiff(). User code should use diff() and not call fdiff() directly.

**Note:** Function subclasses should define differentiation using fdiff(). Subclasses of Expr (page 999) that aren’t Function subclasses will need to define _eval_derivative() instead.
It is not recommended to redefine \_eval\_derivative() on a Function subclass.

For our \texttt{versin} example function (page 105), the derivative is \(\sin(x)\).

```python
>>> class versin(Function):
...     def fdiff(self, argindex=1):
...         # argindex indexes the args, starting at 1
...         return sin(self.args[0])
```

```python
>>> versin(x).diff(x)
\sin(x)
>>> versin(x**2).diff(x)
2x\sin(x^2)
>>> versin(x + y).diff(x)
\sin(x + y)
```

As an example of a function that has multiple arguments, consider the \textit{fused multiply-add (FMA) example} (page 117) defined above (\(FMA(x, y, z) = xy + z\)).

We have

\[
\frac{d}{dx} FMA(x, y, z) = y,
\]

\[
\frac{d}{dy} FMA(x, y, z) = x,
\]

\[
\frac{d}{dz} FMA(x, y, z) = 1.
\]

So the \texttt{fdiff()} method for FMA would look like this:

```python
>>> from sympy import Number, symbols
>>> x, y, z = symbols('x y z')
>>> class FMA(Function):
...     """
FMA(x, y, z) = x*y + z
"""
...     def fdiff(self, argindex):
...         # argindex indexes the args, starting at 1
...         x, y, z = self.args
...         if argindex == 1:
...             return y
...         elif argindex == 2:
...             return x
...         elif argindex == 3:
...             return 1
```

```python
>>> FMA(x, y, z).diff(x)
y
>>> FMA(x, y, z).diff(y)
x
>>> FMA(x, y, z).diff(z)
1
>>> FMA(x**2, x + 1, y).diff(x)
x**2 + 2x*(x + 1)
```

3.3. Writing Custom Functions
To leave a derivative unevaluated, raise `sympy.core.function.ArgumentIndexError(self, argindex)`. This is the default behavior if `fdiff()` is not defined. Here is an example function $f(x, y)$ that is linear in the first argument and has an unevaluated derivative on the second argument.

```python
>>> from sympy.core.function import ArgumentIndexError
>>> class f(Function):
...     @classmethod
...     def eval(cls, x, y):
...         pass
...     def fdiff(self, argindex):
...         if argindex == 1:
...             return 1
...         raise ArgumentIndexError(self, argindex)
```

```python
>>> f(x, y).diff(x)
1
>>> f(x, y).diff(y)
Derivative(f(x, y), y)
```

**Printing**

You can define how a function prints itself with the various printers (page 2207) such as the string printer (page 2253), pretty printers (page 2212), and LaTeX printer (page 2245), as well as code printers for various languages like C (page 2214) and Fortran (page 2222).

In most cases, you will not need to define any printing methods. The default behavior is to print functions using their name. However, in some cases we may want to define special printing for a function.

For example, for our divides example above (page 109), we may want the LaTeX printer to print a more mathematical expression. Let’s make the LaTeX printer represent `divides(m, n)` as \left \lfloor m \middle| n \right \rfloor, which looks like $\lfloor m|n \rfloor$ (here $P$ is the Iverson bracket, which is 1 if $P$ is true and 0 if $P$ is false).

There are two primary ways to define printing for SymPy objects. One is to define a printer on the printer class. Most classes that are part of the SymPy library should use this method, by defining the printers on the respective classes in *sympy.printing*. For user code, this may be preferable if you are defining a custom printer, or if you have many custom functions that you want to define printing for. See Example of Custom Printer (page 2209) for an example of how to define a printer in this way.

The other way is to define the printing as a method on the function class. To do this, first look up the printmethod attribute on the printer you want to define the printing for. This is the name of the method you should define for that printer. For the LaTeX printer, `LatexPrinter.printmethod` (page 2245) is \_\_latex\_. The print method always takes one argument, printer. printer. print should be used to recursively print any other expressions, including the arguments of the function.

So to define our divides LaTeX printer, we will define the function \_\_latex(self, printer) on the class, like this:
SymPy Documentation, Release 1.12.1

```python
>>> from sympy import latex
>>> class divides(Function):
...     def _latex(self, printer):
...         m, n = self.args
...         return r'\left [ %s \middle | %s \right ]' % (_m, _n)

>>> print(latex(divides(m, n)))
\left [ m \middle | n \right ]
```

See "Example of Custom Printing Method" (page 2210) for more details on how to define printer methods and some pitfalls to avoid. Most importantly, you should always use `printer._print()` to recursively print the arguments of the function inside of a custom printer.

Other Methods

Several other methods can be defined on custom functions to specify various behaviors.

**inverse()**

The `inverse(self, argindex=1)` method can be defined to specify the inverse of the function. This is used by `solve()` (page 882) and `solveset()` (page 913). The `argindex` argument is the argument of the function, starting at 1 (similar to the same argument name for the `fdiff()` method (page 118)).

`inverse()` should return a function (not an expression) for the inverse. If the inverse is a larger expression than a single function, it can return a lambda function.

`inverse()` should only be defined for functions that are one-to-one. In other words, f(x). `inverse()` is the left inverse of f(x). Defining `inverse()` on a function that is not one-to-one may result in `solve()` not giving all possible solutions to an expression containing the function.

Our example versine function (page 105) is not one-to-one (because cosine is not), but its inverse arcversine is. We may define it as follows (using the same naming convention as other inverse trig functions in SymPy):

```python
>>> class aversin(Function):
...     def inverse(self, argindex=1):
...         return versin
```

This makes `solve()` work on `aversin(x):

```python
>>> from sympy import solve
>>> solve(aversin(x) - y, x)
[versin(y)]
```
as_real_imag()

The method `as_real_imag()` (page 1008) method defines how to split a function into its real and imaginary parts. It is used by various SymPy functions that operate on the real and imaginary parts of an expression separately.

`as_real_imag(self, deep=True, **hints)` should return a 2-tuple containing the real part and imaginary part of the function. That is `expr.as_real_imag()` returns `(re(expr), im(expr))`, where `expr == re(expr) + im(expr)*I`, and `re(expr)` and `im(expr)` are real.

If `deep=True`, it should recursively call `as_real_imag(deep=True, **hints)` on its arguments. As with `doit()` (page 116) and the `_eval_expand_*()` methods (page 118), **hints** may be any hints to allow the user to specify the behavior of the method. Unknown hints should be ignored and passed through on any recursive calls in case they are meant for other `as_real_imag()` methods.

For our `versin` example (page 105), we can recursively use the `as_real_imag()` that is already defined for `1 - cos(x)`.

```python
>>> class versin(Function):
...     def as_real_imag(self, deep=True, **hints):
...         return (1 - cos(self.args[0])).as_real_imag(deep=deep, **hints)

>>> versin(x).as_real_imag()
(-cos(re(x))*cosh(im(x)) + 1, sin(re(x))*sinh(im(x)))
```

Defining `as_real_imag()` also automatically makes `expand_complex()` (page 1108) work.

```python
>>> versin(x).expand(complex=True)
I*sin(re(x))*sinh(im(x)) - cos(re(x))*cosh(im(x)) + 1
```

**Miscellaneous _eval_* methods**

There are many other functions in SymPy whose behavior can be defined on custom functions via a custom _eval_* method, analogous to the ones described above. See the documentation of the specific function for details on how to define each method.

3.3.3 Complete Examples

Here are complete examples for the example functions defined in this guide. See the above sections for details on each method.

**Versine**

The versine (versed sine) function is defined as

\[ \text{versin}(x) = 1 - \cos(x). \]

Versine is an example of a simple function defined for all complex numbers. The mathematical definition is simple, which makes it straightforward to define all the above methods on it (in most cases we can just reuse the existing SymPy logic defined on `1 - \cos(x)`).
Definition

```python
>>> from sympy import Function, cos, expand_trig, Integer, pi, sin
>>> from sympy.core.logic import fuzzy_and, fuzzy_not

>>> class versin(Function):
...     r""
...     The versine function.
...     
...     $\operatorname{versin}(x) = 1 - \cos(x) = 2\sin(x/2)^2.$
...     
...     Geometrically, given a standard right triangle with angle x in the unit circle, the versine of x is the positive horizontal distance from the right angle of the triangle to the rightmost point on the unit circle. It was historically used as a more numerically accurate way to compute $1 - \cos(x)$, but it is rarely used today.

...     return sin(self.args[0])

Examples

Evaluation:

>>> x, y = symbols('x y')
>>> versin(x)
versin(x)
>>> versin(2*pi)
0
>>> versin(1.0)
0.459697694131860

Assumptions:

>>> n = symbols('n', integer=True)
>>> versin(n).is_real
True
>>> versin((2*n + 1)*pi).is_positive
True
>>> versin(2*n*pi).is_zero
True
>>> print(versin(n*pi).is_positive)
None
SymPy Documentation, Release 1.12.1

(continued from previous page)

```
>>> r = symbols('r', real=True)
>>> print(versin(r).is_positive)
None
>>> nr = symbols('nr', real=False)
>>> print(versin(nr).is_nonnegative)
None

Simplification:

```r
>>> a, b = symbols('a b', real=True)
>>> from sympy import I
>>> versin(x).rewrite(cos)
1 - cos(x)
```

```r
>>> versin(x).rewrite(sin)
2*sin(x/2)**2
```

```r
>>> versin(2*x).expand(trig=True)
2 - 2*cos(x)**2
```

```r
>>> versin(a + b*I).expand(complex=True)
I*sin(a)*sinh(b) - cos(a)*cosh(b) + 1
```

Differentiation:

```r
>>> versin(x).diff(x)
sin(x)
```

Solving:

(a more general version of aversin would have all the above methods defined as well)

```r
>>> class aversin(Function):
...     def inverse(self, argindex=1):
...         return versin
```

```r
>>> from sympy import solve
>>> solve(aversin(x**2) - y, x)
[-sqrt(versin(y)), sqrt(versin(y))]
```

**divides**

divides is a function defined by

\[
divides(m, n) = \begin{cases} 
1 & \text{for } m \mid n \\
0 & \text{for } m \not\mid n 
\end{cases}
\]

that is, divides(m, n) is 1 if m divides n and 0 if m does not divide m. It is only defined for integer m and n. For the sake of simplicity, we use the convention that \( m \mid 0 \) for all integer \( m \).

divides is an example of a function that is only defined for certain input values (integers).
divides also gives an example of defining a custom printer (_latex()).

3.3. Writing Custom Functions 125
Definition

```python
>>> from sympy import Function, Integer
>>> from sympy.core.logic import fuzzy_not
>>> class divides(Function):
...     r""
...     \[
...     \text{divides}(m, n) = \begin{cases} 1 & \text{for } m \mid n \\ 0 & \text{for } m \not\mid n \end{cases}.
...     \]
...     That is, \text{\texttt{divides}}(m, n) is 1 if \( m \) divides \( n \) and 0 if \( m \) does not divide \( n \). It is undefined if \( m \) or \( n \) are not integers. For simplicity, the convention is used that \text{\texttt{divides}}(m, 0) = 1 for all integers \( m \).

    if isinstance(m, Integer) and isinstance(n, Integer):
        return int(n % m == 0)
    # For symbolic arguments, require m and n to be integer.
    if m.is_integer is False or n.is_integer is False:
        raise TypeError("m and n should be integers")

    # Define basic assumptions.
    # divides is always either 0 or 1.
    is_integer = True
    is_negative = False
    # Whether divides(m, n) is 0 or 1 depends on m and n. Note that this method only makes sense because we don't automatically evaluate on such cases, but instead simplify these cases in doit() below.
    def _eval_is_zero(self):
        m, n = self.args
        if m.is_integer and n.is_integer:
            return fuzzy_not((n/m).is_integer)
    # Define doit() as further evaluation on symbolic arguments using assumptions.
    def doit(self, deep=False, **hints):
        m, n = self.args
        # Recursively call doit() on the args whenever deep=True.
        # Be sure to pass deep=True and **hints through here.
        if deep:
```

(continues on next page)
... m, n = m.doit(deep=deep, **hints), n.doit(deep=deep, **hints)
...
... # divides(m, n) is 1 iff n/m is an integer. Note that m and n are
... # already assumed to be integers because of the logic in eval().
... isint = (n/m).is_integer
... if isint is True:
...     return Integer(1)
... elif isint is False:
...     return Integer(0)
... else:
...     return divides(m, n)
...
... # Define LaTeX printing for use with the latex() function and the
... # Jupyter notebook.
... def _latex(self, printer):
...     m, n = self.args
...     _m, _n = printer._print(m), printer._print(n)
...     return r'\left [ %s \middle | %s \right ]' % (_m, _n)
...

Examples

Evaluation

```python
>>> from sympy import symbols
>>> n, m, k = symbols('n m k', integer=True)
>>> divides(3, 10)
0
>>> divides(3, 12)
1
>>> divides(m, n).is_integer
True
>>> divides(k, 2*k)
divides(k, 2*k)
>>> divides(k, 2*k).is_zero
False
>>> divides(k, 2*k).doit()
1
```

Printing:

```python
>>> str(divides(m, n))  # This is using the default str printer
'divides(m, n)'
>>> print(latex(divides(m, n)))
\left [ m \middle | n \right ]
```
Fused Multiply-Add (FMA)

Fused Multiply-Add (FMA) is a multiplication followed by an addition:

\[ \text{FMA}(x, y, z) = xy + z. \]

It is often implemented in hardware as a single floating-point operation that has better rounding and performance than the equivalent combination of multiplication and addition operations.

FMA is an example of a custom function that is defined as an unevaluated “shorthand” to another function. This is because the \texttt{doit()} (page 116) method is defined to return \( xy + z \), meaning the FMA function can easily be evaluated to the expression is represents, but the \texttt{eval()} (page 106) method does not return anything (except when \( x, y, \) and \( z \) are all explicit numeric values), meaning that it stays unevaluated by default.

Contrast this with the \texttt{versine} (page 122) example, which treats versin as a first-class function in its own regard. Even though \( \text{versin}(x) \) can be expressed in terms of other functions (\( 1 - \cos(x) \)) it does not evaluate on general symbolic inputs in \texttt{versin.eval()}, and \texttt{versin.doit()} is not defined at all.

FMA also represents an example of a continuous function defined on multiple variables, which demonstrates how \texttt{argindex} works in the \texttt{fdiff} (page 118) example.

Finally, FMA shows an example of defining some code printers for C and C++ (using the method names from \texttt{C99CodePrinter.printmethod} (page 2214) and \texttt{CXX11CodePrinter.printmethod} (page 2217)), since that is a typical use-case for this function.

The mathematical definition of FMA is very simple and it would be easy to define every method on it, but only a handful are shown here. The \texttt{versine} (page 122) and \texttt{divides} (page 125) examples show how to define the other important methods discussed in this guide.

Note that if you want to actually use fused-multiply add for code generation, there is already a version in SymPy \texttt{sympy.codegen.cfunctions.fma()} which is supported by the existing code printers. The version here is only designed to serve as an example.

Definition

```python
>>> from sympy import Number, symbols, Add, Mul
>>> x, y, z = symbols('x y z')
>>> class FMA(Function):
   ...
   ...
   FMA(x, y, z) = x*y + z
   ...
   ...
   FMA is often defined as a single operation in hardware for better rounding and performance.
   ...
   ...
   FMA can be evaluated by using the doit() method.

2*x
>>> FMA(x, y, x).diff(x)
y + 1
```

Code Printers

```python
>>> from sympy import ccode, cxxcode
>>> ccode(FMA(x, y, z))
'fma(x, y, z)'
>>> cxxcode(FMA(x, y, z))
'std::fma(x, y, z)'
```

3.3.4 Additional Tips

- SymPy includes dozens of functions. These can serve as useful examples for how to write a custom function, especially if the function is similar to one that is already implemented. Remember that everything in this guide applies equally well to functions that are included with SymPy and user-defined functions. Indeed, this guide is designed to serve as both a developer guide for contributors to SymPy and a guide for end-users of SymPy.

- If you have many custom functions that share common logic, you can use a common base class to contain this shared logic. For an example of this, see the source code for the trigonometric functions in SymPy, which use TrigonometricFunction, InverseTrigonometricFunction, and ReciprocalTrigonometricFunction base classes with some shared logic.

- As with any code, it is a good idea to write extensive tests for your function. The SymPy test suite is a good resource for examples of how to write tests for such functions. All
code included in SymPy itself is required to be tested. Functions included in SymPy should also always contain a docstring with references, a mathematical definition, and doctest examples.

## 3.4 Solve Equations

The Python package SymPy can symbolically solve equations, differential equations, linear equations, nonlinear equations, matrix problems, inequalities, Diophantine equations, and evaluate integrals. SymPy can also solve numerically.

The *Solving Guidance* (page 132) page provides recommendations applicable to many types of solving tasks.

Learn how to use SymPy computer algebra system to:

Notes:

- SymPy has a function called `solve()` (page 882) which is designed to find the solutions of an equation or system of equations, or the roots of a function. SymPy `solve()` (page 882) may or may not be what you need for a particular problem, so we recommend you use the links on this page to learn how to “solve” your problem.

- While a common, colloquial expression is, for example, “solve an integral (page 633),” in SymPy’s terminology it would be “evaluate an integral (page 633).” This page does not provide guidance for such tasks. Please search the documentation for the type of expression you want to evaluate.
3.4.1 Solving Guidance

These guidelines apply to many types of solving.

Numeric Solutions

Equations With no Closed-Form Solution

The vast majority of arbitrary nonlinear equations have no closed-form solution. The classes of equations that are solvable are basically:

1. Linear equations
2. Polynomials, except where limited by the Abel-Ruffini theorem (learn more about solving polynomials using a GroebnerBasis (page 2499))
3. Equations that can be solved by inverting some transcendental functions
4. Problems that can be transformed into the cases above (e.g., by turning trigonometric functions into polynomials)
5. A few other special cases that can be solved with something like the Lambert W function (page 469)
6. Equations that you can decompose() (page 2445) via any of the above

SymPy may reflect that your equation has no solutions that can be expressed algebraically (symbolically), or that SymPy lacks an algorithm to find a closed-form solution that does exist, by returning an error such as NotImplementedError:

```python
>>> from sympy import solve, cos
>>> from sympy.abc import x
>>> solve(cos(x) - x, x, dict=True)
Traceback (most recent call last):
  ... NotImplementedError: multiple generators [x, cos(x)]
No algorithms are implemented to solve equation -x + cos(x)
```

so you may have to solve your equation numerically instead, for example using nsolve() (page 895)

```python
>>> from sympy import nsolve, cos
>>> from sympy.abc import x
>>> nsolve(cos(x) - x, x, 2)
0.739085133215161
```

If you receive non-closed-form solutions such as CRootOf() (page 2507) (which represents an indexed complex root of a polynomial), you can evaluate them numerically using evalf() (page 1111):

```python
>>> from sympy import solve
>>> from sympy.abc import x
>>> solutions = solve(x**5 - x - 1, x, dict=True)
>>> solutions
[{x: CRootOf(x**5 - x - 1, 0)}, {x: CRootOf(x**5 - x - 1, 1)}, {x: CRootOf(x**5 - x - 1, 2)}, {x: CRootOf(x**5 - x - 1, 3)}, {x: CRootOf(x**5 - x - 1, 4)}]
```
When You Might Prefer a Numeric Solution

Even if your problem has a closed-form solution, you might prefer a numeric solution.

Solving functions such as `solve()` (page 882) and `solveset()` (page 913) will not try to find a numeric solution, only a mathematically-exact symbolic solution. So if you want a numeric solution, consider `nsolve()` (page 895).

In some situations, even though a closed-form solution is available, it may be too cumbersome to be desirable. In that case, you can use `evalf()` (page 1111) instead if a numerical solution is acceptable. For example, the following solution set contains more than 40 terms total when expressed exactly (scroll horizontally in the code block below if you want to view them all), compared to eight when expressed numerically:

```python
>>> from sympy import symbols, solve
>>> x = symbols('x')
>>> solutions = solve(x**4 + 10*x**2 + x + 1, x, dict=True)
>>> solutions
[(x: -sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2 - sqrt(-40/3 - 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2], {x: sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: -sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: sqrt(-40/3 - 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: -sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: -sqrt(-40/3 - 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: -sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: -sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: -sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: -sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: -sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: -sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}, {x: sqrt(-20/3 + 56/(9*(1307/432 + sqrt(434607)*I/144)**(1/3)) + 2*(1307/432 + sqrt(434607)*I/144)**(1/3))/2}]
```

In other situations, even if the exact solution has few terms, you may want a numeric solution so you know its approximate numerical value. For example, it may be difficult to estimate that $\sqrt{2e^\pi}/2$ is approximately 16:
Use Exact Values

If you want to preserve the exact mathematical values of symbols such as transcendental numbers and square roots (page 6), define them so that SymPy can interpret them symbolically, for example use SymPy’s $\pi$ (page 1050):

```python
>>> from sympy import symbols, solve, pi
>>> x = symbols('x')
>>> solve(x**2 - pi, x, dict=True)
[{-sqrt(pi)}, {sqrt(pi)}]
```

If you use the standard Python math version of $\pi$, Python will pass that inexact value to SymPy, leading to an inexact, numerical solution:

```python
>>> from sympy import symbols, solve
>>> from math import pi
>>> x = symbols('x')
>>> solve(x**2 - pi, x, dict=True)
[{-1.77245385090552}, {1.77245385090552}]
```

To use exact values for numbers such as 6.2 or 1/2, refer to *Python numbers vs. SymPy Numbers* (page 194).

In certain cases, using an inexact value will prevent SymPy from finding a result. For example, this exact equation can be solved:

```python
>>> from sympy import symbols, solve, sqrt
>>> x = symbols('x')
>>> eq = x**sqrt(2) - 2
>>> solve(eq, x, dict=True)
[[2**(sqrt(2)/2)]]
```

but if you use the inexact equation $eq = x**1.4142135623730951 - 2$, SymPy will not return a result despite attempting for a long time.

Include the Variable to be Solved for in the Function Call

We recommend you include the variable to be solved for as the second argument for solving functions including `solve()` (page 882) and `solveset()` (page 913). While this is optional for univariate equations, it is a good practice because it ensures SymPy will solve for the desired symbol. For example, you might be interested in a solution for $x$, but SymPy solves for $y$:

```python
>>> from sympy.abc import x, y
>>> from sympy import solve
```

(continues on next page)
Specifying the variable to solve for ensures that SymPy solves for it:

```python
>>> from sympy.abc import x, y
>>> from sympy import solve
>>> solve(x**2 - y, x, dict=True)
[{x: -sqrt(y)}, {x: sqrt(y)}]
```

### Ensure Consistent Formatting From `solve()`

`solve()` (page 882) produces a variety of output as explained in *Solve Output by Type* (page 204). Using `dict=True` will give a consistent output format which is especially important when extracting information about the solution programmatically.

To extract the solutions, you can iterate through the list of dictionaries:

```python
>>> from sympy import parse_expr, solve, solveset
>>> from sympy.abc import x
>>> expr = "x^2 = y"
>>> parsed = parse_expr(expr, transformations="all")
>>> parsed
Eq(x**2, y)
>>> solutions = solve(parsed, x, dict=True)
>>> [solution[x] for solution in solutions]
[-sqrt(y), sqrt(y)]
>>> solveset(parsed, x)
{(-sqrt(y), sqrt(y))}
```

### Options That Can Speed up `solve()`

#### Include Solutions Making Any Denominator Zero

Normally, `solve()` (page 882) checks whether any solutions make any denominator zero, and automatically excludes them. If you want to include those solutions, and speed up `solve()` (page 882) (at the risk of obtaining invalid solutions), set `check=False`:

```python
>>> from sympy import Symbol, sin, solve
>>> x = Symbol("x")
>>> solve(sin(x)/x, x, dict=True) # 0 is excluded
[{x: pi}]
>>> solve(sin(x)/x, x, dict=True, check=False) # 0 is not excluded
[{x: 0}, {x: pi}]
```
Do Not Simplify Solutions

Normally, `solve()` (page 882) simplifies many results before returning them and (if `check` is not `False`) uses the general `simplify()` (page 719) function on the solutions and the expression obtained when they are substituted into the function which should be zero. If you do not want the solutions simplified, and want to speed up `solve()` (page 882), use `simplify=False`.

```python
>>> from sympy import solve
>>> from sympy.abc import x, y
>>> expr = x**2 - (y**5 - 3*y**3 + y**2 - 3)
>>> solve(expr, x, dict=True)

[{x: -sqrt(y**5 - 3*y**3 + y**2 - 3)}, {x: sqrt(y**5 - 3*y**3 + y**2 - 3)}]

>>> solve(expr, x, dict=True, simplify=False)

[{x: -sqrt((y + 1)*(y**2 - 3)*(y**2 - y + 1))}, {x: sqrt((y + 1)*(y**2 - 3)*(y**2 - y + 1))}]
```

Parse a String Representing the Equation

If you are creating the expression yourself, we advise against using string parsing to create expressions. But if you are programmatically reading in a string, this approach is convenient.

You can parse a string representing the equation into a form that SymPy can understand (for example, `Eq` (page 1070) form), then solve the parsed expression. Parsing an equation from a string requires you to use `transformations` (page 2195) for SymPy to

- interpret equals signs
- create symbols from your variables
- use more mathematical (rather than standard Python) notation, for example the exponent operator can be parsed from `^` rather than having to use Python’s `**`.

If you already have the equation in `Eq` (page 1070) (equation) form, you can parse that string:

```python
>>> from sympy import parse_expr, solve, solveset
>>> from sympy.abc import x
>>> expr = "Eq(x^2, y)"
>>> parsed = parse_expr(expr, transformations="all")
>>> parsed

Eq(x**2, y)
```

SymPy can also parse LaTeX into expressions using `parse_latex()` (page 2202).

Report a Bug

If you find a bug with these commands, please post the problem on the SymPy mailing list.
3.4.2 Solve an Equation Algebraically

Use SymPy to solve an equation algebraically (symbolically). For example, solving $x^2 = y$ for $x$ yields $x \in \{-\sqrt{y}, \sqrt{y}\}$.

Alternatives to consider

- SymPy can also solve many other types of problems including sets of equations (page 131).
- Some equations cannot be solved algebraically (either at all or by SymPy), so you may have to solve your equation numerically (page 895) instead.

Solving Functions

There are two high-level functions to solve equations, solve() (page 882) and solveset() (page 913). Here is an example of each:

solve() (page 882)

```python
>>> from sympy.abc import x, y
>>> from sympy import solve
>>> solve(x**2 - y, x, dict=True)
[\{x: -\sqrt{y}\}, \{x: \sqrt{y}\}]
```

solveset() (page 913)

```python
>>> from sympy import solveset
>>> from sympy.abc import x, y
>>> solveset(x**2 - y, x)
\{-\sqrt{y}, \sqrt{y}\}
```

Here are recommendations on when to use:

- solve() (page 882)
  - You want to get explicit symbolic representations of the different values a variable could take that would satisfy the equation.
  - You want to substitute those explicit solution values into other equations or expressions involving the same variable using subs() (page 993)

- solveset() (page 913)
  - You want to represent the solutions in a mathematically precise way, using mathematical sets (page 1229).
  - You want a representation of all the solutions, including if there are infinitely many.
  - You want a consistent input interface.
  - You want to limit the domain of the solutions to any arbitrary set.
  - You do not need to programmatically extract solutions from the solution set: solution sets cannot necessarily be interrogated programmatically.
Guidance

Refer to *Include the Variable to be Solved for in the Function Call* (page 134) and *Ensure Consistent Formatting From solve()* (page 135).

Solve an Equation Algebraically

You can solve an equation in several ways. The examples below demonstrate using both *solve()* (page 882) and *solveset()* (page 913) where applicable. You can choose the function best suited to your equation.

Make Your Equation Into an Expression That Equals Zero

Use the fact that any expression not in an Eq (equation) is automatically assumed to equal zero (0) by the solving functions. You can rearrange the equation \( x^2 = y \) to \( x^2 - y = 0 \), and solve that expression. This approach is convenient if you are interactively solving an expression which already equals zero, or an equation that you do not mind rearranging to \( expression = 0 \).

```python
>>> from sympy import solve, solveset
>>> from sympy.abc import x, y
>>> solve(x**2 - y, x, dict=True)
[{-sqrt(y)}, {x: sqrt(y)}]
>>> solveset(x**2 - y, x)
{-sqrt(y), sqrt(y)}
```

Put Your Equation Into Eq Form

Put your equation into Eq form, then solve the Eq. This approach is convenient if you are interactively solving an equation which you already have in the form of an equation, or which you think of as an equality. It also helps to prevent sign errors when subtracting one side from the other.

```python
>>> from sympy import Eq, solve, solveset
>>> from sympy.abc import x, y
>>> eqn = Eq(x**2, y)
>>> solutions = solve(eqn, x, dict=True)
>>> print(solutions)
[{-sqrt(y)}, {x: sqrt(y)}]
>>> solutions_set = solveset(eqn, x)
>>> print(solutions_set)
{-sqrt(y), sqrt(y)}
>>> for solution_set in solutions_set:
...     print(solution_set)
  sqrt(y)
  -sqrt(y)
```
Restrict the Domain of Solutions

By default, SymPy will return solutions in the complex domain, which also includes purely real and imaginary values. Here, the first two solutions are real, and the last two are imaginary:

```python
>>> from sympy import Symbol, solve, solveset
>>> x = Symbol('x')
>>> solve(x**4 - 256, x, dict=True)
[{x: -4}, {x: 4}, {x: -4*I}, {x: 4*I}]
>>> solveset(x**4 - 256, x)
{-4, 4, -4*I, 4*I}
```

To restrict returned solutions to real numbers, or another domain or range, the different solving functions use different methods.

For `solve()` (page 882), place an assumption on the symbol to be solved for, `x`

```python
>>> from sympy import Symbol, solve
>>> x = Symbol('x', real=True)
>>> solve(x**4 - 256, x, dict=True)
[{x: -4}, {x: 4}]
```

or restrict the solutions with standard Python techniques for filtering a list such as a list comprehension:

```python
>>> from sympy import Or, Symbol, solve
>>> expr = (x-4)*(x-3)*(x-2)*(x-1)
>>> solution = solve(expr, x)
>>> print(solution)
[1, 2, 3, 4]
>>> solution_outside_2_3 = [v for v in solution if (v.is_real and Or(v<2,v>3))]
>>> print(solution_outside_2_3)
[1, 4]
```

For `solveset()` (page 913), limit the output domain in the function call by setting a domain

```python
>>> from sympy import S, solveset
>>> from sympy.abc import x
>>> solveset(x**4 - 256, x, domain=S.Reals)
{-4, 4}
```

or by restricting returned solutions to any arbitrary set, including an interval:

```python
>>> from sympy import Interval, pi, sin, solveset
>>> from sympy.abc import x
>>> solveset(sin(x), x, Interval(-pi, pi))
{0, -pi, pi}
```

and if you restrict the solutions to a domain in which there are no solutions, `solveset()` (page 913) will return the empty set, `EmptySet` (page 1229):

```python
>>> from sympy import solveset, S
>>> from sympy.abc import x
```

(continues on next page)
Explicitly Represent Infinite Sets of Possible Solutions

`solveset()` (page 913) can represent infinite sets of possible solutions (page 906) and express them in standard mathematical notation, for example \(\sin(x) = 0\) for \(x = n \pi\) for every integer value of \(n\):

```python
>>> from sympy import pprint, sin, solveset
>>> solution = solveset(sin(x), x)
>>> pprint(solution)
{2*n*pi | n in Integers} U {2*n*pi + pi | n in Integers}
```

However, `solve()` (page 882) will return only a finite number of solutions:

```python
>>> from sympy import sin, solve
>>> from sympy.calculus.util import periodicity
>>> f = sin(x)
>>> solve(f, x)
[0, pi]
>>> periodicity(f, x)
2*pi
```

`solve()` (page 882) tries to return just enough solutions so that all (infinitely many) solutions can generated from the returned solutions by adding integer multiples of the `periodicity()` (page 304) of the equation, here \(2\pi\).

Use the Solution Result

Substitute Solutions From `solve()` Into an Expression

You can substitute solutions from `solve()` (page 882) into an expression.

A common use case is finding the critical points and values for a function \(f\). At the critical points, the Derivative (page 1088) equals zero (or is undefined). You can then obtain the function values at those critical points by substituting the critical points back into the function using `subs()` (page 993). You can also tell if the critical point is a maxima or minima by substituting the values into the expression for the second derivative: a negative value indicates a maximum, and a positive value indicates a minimum.

```python
>>> from sympy.abc import x
>>> f = x**3 + x**2 - x
>>> derivative = diff(f, x)
>>> critical_points = solve(derivative, x, dict=True)
>>> print(critical_points)
[[x: -1], [x: 1/3]]
```
```python
>>> point1, point2 = critical_points
>>> print(f.subs(point1))
1
>>> print(f.subs(point2))
-5/27
>>> curvature = diff(f, x, 2)
>>> print(curvature.subs(point1))
-4
>>> print(curvature.subs(point2))
4
```

**solve()**  
_Solution Sets Cannot Necessarily Be Interrogated Programmatically_

If `solve()` (page 913) returns a finite set (class `FiniteSet` (page 1241)), you can iterate through the solutions:

```python
>>> from sympy import solveset
>>> from sympy.abc import x, y
>>> solution_set = solveset(x**2 - y, x)
>>> print(solution_set)
{-sqrt(y), sqrt(y)}
>>> solution_list = list(solution_set)
[sqrt(y), -sqrt(y)]
```

However, for more complex results, it may not be possible to list the solutions:

```python
>>> from sympy import S, solveset, symbols
>>> x, y = symbols('x, y')
>>> solution_set = solveset(x**2 - y, x, domain=S.Reals)
>>> print(solution_set)
Intersection({-sqrt(y), sqrt(y)}, Reals)
>>> list(solution_set)
Traceback (most recent call last):
  ...  
TypeError: The computation had not completed because of the undecidable set membership is found in every candidates.
```

In this case, it is because, if \(y\) is negative, its square root would be imaginary rather than real and therefore outside the declared domain of the solution set. By declaring \(y\) to be real and positive, SymPy can determine that its square root is real, and thus resolve the intersection between the solutions and the set of real numbers:

```python
>>> from sympy import S, Symbol, solveset
>>> x = Symbol('x')
>>> y = Symbol('y', real=True, positive=True)
>>> solution_set = solveset(x**2 - y, x, domain=S.Reals)
>>> print(solution_set)
{-sqrt(y), sqrt(y)}
>>> list(solution_set)
[sqrt(y), -sqrt(y)]
```

3.4. Solve Equations
Alternatively, you can extract the sets from the solution set using `args` (page 980), then create a list from the set containing the symbolic solutions:

```python
>>> from sympy import S, solveset, symbols
>>> x, y = symbols('x, y')
>>> solution_set = solveset(x**2 - y, x, domain=S.Reals)
>>> print(solution_set)
Intersection({-sqrt(y), sqrt(y)}, Reals)
>>> solution_set_args = solution_set.args
>>> print(solution_set_args)
(Reals, {-sqrt(y), sqrt(y)})
>>> list(solution_set_args[1])
[sqrt(y), -sqrt(y)]
```

**Options That Can Speed up solve()**

Refer to *solving guidance* (page 135).

**Not All Equations Can Be Solved**

**Equations With No Closed-Form Solution**

Some equations have no closed-form solution, in which case SymPy may return an empty set or give an error. For example, the following transcendental equation has no closed-form solution:

```python
>>> from sympy import cos, solve
>>> from sympy.abc import x
>>> solve(cos(x) - x, x, dict=True)
Traceback (most recent call last):
  ... NotImplementedError: multiple generators [x, cos(x)]
No algorithms are implemented to solve equation -x + cos(x)
```

**Equations Which Have a Closed-Form Solution, and SymPy Cannot Solve**

It is also possible that there is an algebraic solution to your equation, and SymPy has not implemented an appropriate algorithm. If that happens, or SymPy returns an empty set or list when there is a mathematical solution (indicating a bug in SymPy), please post it on the mailing list, or open an issue on SymPy’s GitHub page. Until the issue is resolved, you can *solve your equation numerically* (page 895) instead.
Report a Bug

If you find a bug with a solving function, please post the problem on the SymPy mailing list. Until the issue is resolved, you can use a different method listed in Alternatives to consider (page 137).

3.4.3 Solve a System of Equations Algebraically

Use SymPy to algebraically solve a system of equations, whether linear or nonlinear. For example, solving \( x^2 + y = 2z, y = -4z \) for \( x \) and \( y \) (assuming \( z \) is a constant or parameter) yields \( \{ (x = -\sqrt{6}z, y = -4z), (x = \sqrt{6}z, y = -4z) \} \).

Alternatives to Consider

- Some systems of equations cannot be solved algebraically (either at all or by SymPy), so you may have to solve your system of equations numerically (page 146) using nsolve() (page 895) instead.

Examples of Solving a System of Equations Algebraically

Whether your equations are linear or nonlinear, you can use solve() (page 882):

Solve a System of Linear Equations Algebraically

\[
\begin{align*}
\text{from sympy import solve} \\
\text{from sympy.abc import } x, y, z \\
\text{solve([}x + y - 2*z, y + 4*z\text{], }[x, y], \text{dict=True}) \\
\{x: 6*z, y: -4*z\}
\end{align*}
\]

Solve a System of Nonlinear Equations Algebraically

\[
\begin{align*}
\text{from sympy import solve} \\
\text{from sympy.abc import } x, y, z \\
\text{solve([}x^2 + y - 2*z, y + 4*z\text{], }[x, y], \text{dict=True}) \\
\{x: -sqrt(6)*sqrt(z), y: -4*z\}, \{x: sqrt(6)*sqrt(z), y: -4*z\}
\end{align*}
\]

Guidance

Refer to Include the Variable to be Solved for in the Function Call (page 134) and Ensure Consistent Formatting From solve() (page 135).

There are two methods below for containing solution results: dictionary (page 144) or set (page 144). A dictionary is easier to interrogate programatically, so if you need to extract solutions using code, we recommend the dictionary approach.
Solve and Use Results in a Dictionary

Solve Into a Solution Given as a Dictionary

You can solve a system of equations for some variables (for example, \(x\) and \(y\)) leaving another symbol as a constant or parameter (for example, \(z\)). You can specify the variables to solve for as multiple separate arguments, or as a list (or tuple):

```python
>>> from sympy import solve
>>> from sympy.abc import x, y, z
>>> equations = [x**2 + y - 2*z, y + 4*z]
>>> solutions = solve(equations, x, y, dict=True)
>>> solutions
[{x: -sqrt(6)*sqrt(z), y: -4*z}, {x: sqrt(6)*sqrt(z), y: -4*z}]
```

Use a Solution Given as a Dictionary

You can then extract solutions by indexing (specifying in brackets) the solution number, and then the symbol. For example `solutions[0][x]` gives the result for \(x\) in the first solution:

```python
>>> solutions[0][x]
-sqrt(6)*sqrt(z)
>>> solutions[0][y]
-4*z
```

Solve Results in a Set

To get a list of symbols and set of solutions, use `set=True` instead of `dict=True`:

```python
from sympy import solve
from sympy.abc import x, y, z
solve([x**2 + y - 2*z, y + 4*z], [x, y], set=True)
([x, y], {(-sqrt(6)*sqrt(z), -4*z), (sqrt(6)*sqrt(z), -4*z)})
```

Options That Can Speed up `solve()`

Refer to `Options That Can Speed up solve()` (page 135).

Not All Systems of Equations Can be Solved

Systems of Equations With no Solution

Some systems of equations have no solution. For example, the following two systems have no solution because they reduce to \(1 == 0\), so SymPy returns an empty list:
The following system reduces to \( z = 2z \), so it has no general solution, but it could be satisfied if \( z = 0 \). Note that \( \text{solve}() \) (page 882) will not assume that \( z = 0 \), even though that is the only value of \( z \) that makes the system of equations consistent, because \( z \) is a parameter rather than an unknown. That is, \( \text{solve}() \) (page 882) does not treat \( z \) as an unknown because it is not in the list of symbols specified as unknowns ([\( x, y \)]) and all such symbols are treated like parameters with arbitrary value. Whether a symbol is treated as a variable or a parameter is determined only by whether it is specified as a symbol to solve for in \( \text{solve}() \) (page 882). There is no such distinction made when creating the symbol using \( \text{symbols}() \) (page 1030) (or importing from \( \text{abc} \) (page 931)).

The following system is overconstrained, meaning there are more equations (three) than unknowns to be solved for (two, namely \( x \) and \( y \)). It has no solution:

Note that some overconstrained systems do have solutions (for example, if an equation is a linear combination of the others), in which case SymPy can solve the overconstrained system.

### Systems of Equations With no Closed-Form Solution

Some systems of equations cannot be solved algebraically, for example those containing transcendental equations:

So you can use \( \text{nsolve}() \) (page 895) to find a numerical solution (page 146):
Equations Which Have a Closed-Form Solution, and SymPy Cannot Solve

It is also possible that there is an algebraic solution to your equation, and SymPy has not implemented an appropriate algorithm. If SymPy returns an empty set or list when you know there is a closed-form solution (indicating a bug in SymPy), please post it on the mailing list, or open an issue on SymPy's GitHub page. Until the issue is resolved, you can use a different method listed in Alternatives to Consider (page 143).

Report a Bug

If you find a bug with solve() (page 882), please post the problem on the SymPy mailing list. Until the issue is resolved, you can use a different method listed in Alternatives to Consider (page 143).

3.4.4 Solve One or a System of Equations Numerically

Use SymPy to numerically solve a system of one or more equations. For example, numerically solving $\cos(x) = x$ returns $x \approx 0.739085133215161$.

Solving numerically is useful if:

- You only need a numeric solution, not a symbolic one
- A closed-form solution is not available or is overly complicated; refer to When You Might Prefer a Numeric Solution (page 133)

solve() (page 882) and solveset() (page 913) will not try to find a numeric solution, only a mathematically-exact symbolic solution. So if you want a numeric solution, use nsolve() (page 895).

SymPy is designed for symbolic mathematics. If you do not need to do symbolic operations, then for numerical operations you can use another free and open-source package such as NumPy or SciPy which will be faster, work with arrays, and have more algorithms implemented. The main reasons to use SymPy (or its dependency mpmath) for numerical calculations are:

- to do a simple numerical calculation within the context of a symbolic calculation using SymPy
- if you need the arbitrary precision capabilities to get more digits of precision than you would get from float64.
Alternatives to Consider

- SciPy's `scipy.optimize.fsolve()` can solve a system of (non-linear) equations
- NumPy's `numpy.linalg.solve()` can solve a system of linear scalar equations
- mpmath's `findroot()`, which `nsolve()` (page 895) calls and can pass parameters to

Example of Numerically Solving an Equation

Here is an example of numerically solving one equation:

```python
>>> from sympy import cos, nsolve, Symbol
>>> x = Symbol('x')
>>> nsolve(cos(x) - x, x, 1)
0.739085133215161
```

Guidance

Overdetermined systems of equations are supported.

Find Complex Roots of a Real Function

To solve for complex roots of real functions, specify a nonreal (either purely imaginary, or complex) initial point:

```python
>>> from sympy import nsolve
>>> from sympy.abc import x
>>> nsolve(x**2 + 2, 1) # Real initial point returns no root
Traceback (most recent call last):
 ... ValueError: Could not find root within given tolerance. (4.18466446988997098217 > 2.16840434497100886801e-19)
Try another starting point or tweak arguments.
>>> nsolve(x**2 + 2, I) # Imaginary initial point returns a complex root
1.4142135623731*I
>>> nsolve(x**2 + 2, 1 + I) # Complex initial point returns a complex root
1.4142135623731*I
```

Ensure the Root Found is in a Given Interval

It is not guaranteed that `nsolve()` (page 895) will find the root closest to the initial point. Here, even though the root -1 is closer to the initial point of -0.1, `nsolve()` (page 895) finds the root 1:

```python
>>> from sympy import nsolve
>>> from sympy.abc import x
>>> nsolve(x**2 - 1, -0.1)
1.0000000000000
```
You can ensure the root found is in a given interval, if such a root exists, using `solver='bisect'` by specifying the interval in a tuple. Here, specifying the interval `(-10, 0)` ensures that the root `-1` is found:

```python
>>> from sympy import nsolve
>>> from sympy.abc import x
>>> nsolve(x**2 - 1, (-10, 0), solver='bisect')
-1.00000000000000
```

### Solve a System of Equations Numerically

To solve a system of multidimensional functions, supply a tuple of

- functions `(f1, f2)`
- variables to solve for `(x1, x2)`
- starting values `(-1, 1)`

```python
>>> from sympy import Symbol, nsolve
>>> x1 = Symbol('x1')
>>> x2 = Symbol('x2')
>>> f1 = 3 * x1**2 - 2 * x2**2 - 1
>>> f2 = x1**2 - 2 * x1 + x2**2 + 2 * x2 - 8
>>> print(nsolve((f1, f2), (x1, x2), (-1, 1)))
Matrix([[1.19287309935246], [1.27844411169911]])
```

### Increase Precision of the Solution

You can increase the precision of the solution using `prec`:

```python
>>> from sympy import Symbol, nsolve
>>> x1 = Symbol('x1')
>>> x2 = Symbol('x2')
>>> f1 = 3 * x1**2 - 2 * x2**2 - 1
>>> f2 = x1**2 - 2 * x1 + x2**2 + 2 * x2 - 8
>>> print(nsolve((f1, f2), (x1, x2), (-1, 1), prec=25))
Matrix([[1.192873099352460791205211], [1.278444111699106966687122]])
```

### Create a Function That Can Be Solved With SciPy

As noted above, SymPy focuses on symbolic computation and is not optimized for numerical calculations. If you need to make many calls to a numerical solver, it can be much faster to use a solver optimized for numerical calculations such as SciPy’s `root_scalar()`. A recommended workflow is:

1. use SymPy to generate (by symbolically simplifying or solving an equation) the mathematical expression
2. convert it to a lambda function using `lambdify()` (page 2173)
3. use a numerical library such as SciPy to generate numerical solutions
Use the Solution Result

Substitute the Result Into an Expression

The best practice is to use `evalf()` (page 1111) to substitute numerical values into expressions. The following code demonstrates that the numerical value is not an exact root because substituting it back into the expression produces a result slightly different from zero:

```python
>>> from sympy import cos, nsolve, Symbol
>>> x = Symbol('x')
>>> f = cos(x) - x
>>> x_value = nsolve(f, x, 1); x_value
0.739085133215161
>>> f.evalf(subs={x: x_value})
-5.12757857962640e-17
```

Using `subs` (page 993) can give an incorrect result due to precision errors, here effectively rounding -5.12757857962640e-17 to zero:

```python
>>> f.subs(x, x_value)
0
```

When substituting in values, you can also leave some symbols as variables:

```python
>>> from sympy import cos, nsolve, Symbol
>>> x = Symbol('x')
>>> f = cos(x) - x
>>> x_value = nsolve(f, x, 1); x_value
0.739085133215161
>>> y = Symbol('y')
>>> z = Symbol('z')
>>> g = x * y**2
>>> values = {x: x_value, y: 1}
>>> (x + y - z).evalf(subs=values)
1.73908513321516 - z
```
**Not all Equations Can be Solved**

`nsolve()` (page 895) is a numerical solving function, so it can often provide a solution for equations which cannot be solved algebraically.

**Equations With no Solution**

Some equations have no solution, in which case SymPy may return an error. For example, the equation $e^x = 0$ (exp(x) in SymPy) has no solution:

```python
>>> from sympy import nsolve, exp
>>> from sympy.abc import x
>>> nsolve(exp(x), x, 1, prec=20)
Traceback (most recent call last):
  ... ValueError: Could not find root within given tolerance. (5.4877893607115270300540019e-18 > 1.6543612251060553497428174e-24)
Try another starting point or tweak arguments.
```

**Report a Bug**

If you find a bug with `nsolve()` (page 895), please post the problem on the SymPy mailing list. Until the issue is resolved, you can use a different method listed in *Alternatives to Consider* (page 147).

**3.4.5 Solve an Ordinary Differential Equation (ODE) Algebraically**

Use SymPy to solve an ordinary differential equation (ODE) algebraically. For example, solving $y''(x) + 9y(x) = 0$ yields $y(x) = C_1 \sin(3x) + C_2 \cos(3x)$.

**Alternatives to Consider**

- To numerically solve a system of ODEs, use a SciPy ODE solver such as `solve_ivp`. You can also use SymPy to create and then `lambdify()` (page 2173) an ODE to be solved numerically using SciPy’s as `solve_ivp` as described below in *Numerically Solve an ODE in SciPy* (page 156).

**Solve an Ordinary Differential Equation (ODE)**

Here is an example of solving the above ordinary differential equation algebraically using `dsolve()` (page 807). You can then use `checkodesol()` (page 814) to verify that the solution is correct.

```python
>>> from sympy import Function, dsolve, Derivative, checkodesol
>>> from sympy.abc import x
>>> y = Function('y')
>>> # Solve the ODE
```
>>> result = dsolve(Derivative(y(x), x, x) + 9*y(x), y(x))
>>> result
Eq(y(x), C1*sin(3*x) + C2*cos(3*x))
>>> # Check that the solution is correct
>>> checkodesol(Derivative(y(x), x, x) + 9*y(x), result)
(True, 0)

The output of `checkodesol()` (page 814) is a tuple where the first item, a boolean, tells whether substituting the solution into the ODE results in 0, indicating the solution is correct.

**Guidance**

**Defining Derivatives**

There are many ways to express derivatives of functions. For an undefined function, both `Derivative` (page 1088) and `diff()` (page 1094) represent the undefined derivative. Thus, all of the following `ypp` (“y prime prime”) represent $y''$, the second derivative with respect to $x$ of a function $y(x)$:

```python
ypp = y(x).diff(x, x)
ypp = y(x).diff(x, 2)
ypp = y(x).diff((x, 2))
ypp = diff(y(x), x, x)
ypp = diff(y(x), x, 2)
ypp = Derivative(y(x), x, x)
ypp = Derivative(y(x), x, 2)
ypp = Derivative(Derivative(y(x), x), x)
ypp = diff(diff(y(x), x), x)
yp = y(x).diff(x)
ypp = yp.diff(x)
```

We recommend specifying the function to be solved for, as the second argument to `dsolve()` (page 807). Note that it must be a function rather than a variable (symbol). SymPy will give an error if you specify a variable ($x$) rather than a function ($f(x)$):

```python
>>> dsolve(Derivative(y(x), x, x) + 9*y(x), x)
Traceback (most recent call last):
...
ValueError: dsolve() and classify_ode() only work with functions of one variable, not x
```

Similarly, you must specify the argument of the function: $y(x)$, not just $y$.
**Options to Define an ODE**

You can define the function to be solved for in two ways. The subsequent syntax for specifying initial conditions depends on your choice.

### Option 1: Define a Function Without Including Its Independent Variable

You can define a function without including its independent variable:

```python
>>> from sympy import symbols, Eq, Function, dsolve
>>> f, g = symbols("f g", cls=Function)
>>> x = symbols("x")
>>> eqs = [Eq(f(x).diff(x), g(x)), Eq(g(x).diff(x), f(x))]
>>> dsolve(eqs, [f(x), g(x)])
[Eq(f(x), -C1*exp(-x) + C2*exp(x)), Eq(g(x), C1*exp(-x) + C2*exp(x))]
```

Note that you supply the functions to be solved for as a list as the second argument of `dsolve()` (page 807), here `[f(x), g(x)]`.

### Specify Initial Conditions or Boundary Conditions

If your differential equation(s) have initial or boundary conditions, specify them with the `dsolve()` (page 807) optional argument `ics`. Initial and boundary conditions are treated the same way (even though the argument is called `ics`). It should be given in the form of `{f(x0): y0, f(x).diff(x).subs(x, x1): y1}` and so on where, for example, the value of \( f(x) \) at \( x = x_0 \) is \( y_0 \). For power series solutions, if no initial conditions are specified \( f(0) \) is assumed to be \( C_0 \) and the power series solution is calculated about \( 0 \).

Here is an example of setting the initial values for functions, namely namely \( f(0) = 1 \) and \( g(2) = 3 \):

```python
>>> from sympy import symbols, Eq, Function, dsolve
>>> f, g = symbols("f g", cls=Function)
>>> x = symbols("x")
>>> eqs = [Eq(f(x).diff(x), g(x)), Eq(g(x).diff(x), f(x))]
>>> dsolve(eqs, [f(x), g(x)], ics={f(0): 1, g(2): 3})
[Eq(f(x), (1 + 3*exp(2))*exp(x)/(1 + exp(4)) - (-exp(4) + 3*exp(2))*exp(-x)/
  → (1 + exp(4)), Eq(g(x), (1 + 3*exp(2))*exp(x)/(1 + exp(4)) + (-exp(4) +
  → 3*exp(2))*exp(-x)/(1 + exp(4)))]
```

Here is an example of setting the initial value for the derivative of a function, namely \( f'(1) = 2 \):

```python
>>> eqn = Eq(f(x).diff(x), f(x))
>>> dsolve(eqn, f(x), ics={f(x).diff(x).subs(x, 1): 2})
Eq(f(x), 2*exp(-1)*exp(x))
```
Option 2: Define a Function of an Independent Variable

You may prefer to specify a function (for example $y$) of its independent variable (for example $t$), so that $y$ represents $y(t)$:

```python
>>> from sympy import symbols, Function, dsolve
>>> t = symbols('t')
>>> y = Function('y')(t)
>>> y
y(t)
>>> yp = y.diff(t)
>>> ypp = yp.diff(t)
>>> eq = ypp + 2*yp + y
>>> eq
y(t) + 2*Derivative(y(t), t) + Derivative(y(t), (t, 2))
>>> dsolve(eq, y)
Eq(y(t), (C1 + C2*t)*exp(-t))
```

Using this convention, the second argument of `dsolve()` (page 807), $y$, represents $y(t)$, so SymPy recognizes it as a valid function to solve for.

Specify Initial Conditions or Boundary Conditions

Using that syntax, you specify initial or boundary conditions by substituting in values of the independent variable using `subs()` (page 993) because the function $y$ already has its independent variable as an argument $t$:

```python
>>> dsolve(eq, y, ics={y.subs(t, 0): 0})
Eq(y(t), C2*t*exp(-t))
```

Beware Copying and Pasting Results

If you choose to define a function of an independent variable, note that copying a result and pasting it into subsequent code may cause an error because $x$ is already defined as $y(t)$, so if you paste in $y(t)$ it is interpreted as $y(t)(t)$:

```python
>>> dsolve(y(t).diff(y), y)
Traceback (most recent call last):
  ...
TypeError: 'y' object is not callable
```

So remember to exclude the independent variable call $(t)$:

```python
>>> dsolve(y.diff(t), y)
Eq(y(t), C1)
```
**Use the Solution Result**

Unlike other solving functions, `dsolve()` (page 807) returns an `Equality` (page 1071) (equation) formatted as, for example, \( Eq(y(x), C1\sin(3x) + C2\cos(3x)) \) which is equivalent to the mathematical notation \( y(x) = C_1 \sin(3x) + C_2 \cos(3x) \).

**Extract the Result for One Solution and Function**

You can extract the result from an `Equality` (page 1071) using the right-hand side property `rhs` (page 1070):

```python
>>> from sympy import Function, dsolve, Derivative
>>> from sympy.abc import x
>>> y = Function('y')
>>> result = dsolve(Derivative(y(x), x, x) + 9*y(x), y(x))
>>> result
Eq(y(x), C1*sin(3*x) + C2*cos(3*x))
>>> result.rhs
C1*sin(3*x) + C2*cos(3*x)
```

**Some ODEs Cannot Be Solved Explicitly, Only Implicitly**

The above ODE can be solved explicitly, specifically \( y(x) \) can be expressed in terms of functions of \( x \). However, some ODEs cannot be solved explicitly, for example:

```python
>>> from sympy import dsolve, exp, symbols, Function
>>> f = symbols("f", cls=Function)
>>> x = symbols("x")
>>> dsolve(f(x).diff(x) + exp(-f(x))*f(x))
Eq(Ei(f(x)), C1 - x)
```

This gives no direct expression for \( f(x) \). Instead, `dsolve()` (page 807) expresses a solution as \( g(f(x)) \) where \( g \) is \( Ei \) (page 540), the classical exponential integral function. \( Ei \) does not have a known closed-form inverse, so a solution cannot be explicitly expressed as \( f(x) \) equaling a function of \( x \). Instead, `dsolve` returns an implicit solution.

When `dsolve` returns an implicit solution, extracting the right-hand side of the returned equality will not give an explicitly expression for the function to be solved for, here \( f(x) \). So before extracting an expression for the function to be solved for, check that `dsolve` was able to solve for the function explicitly.

**Extract the Result for Multiple Function-Solution Pairs**

If you are solving a system of equations with multiple unknown functions, the form of the output of `dsolve()` (page 807) depends on whether there is one or multiple solutions.
If There is One Solution Set

If there is only one solution set to a system of equations with multiple unknown functions, `dsolve()` (page 807) will return a non-nested list containing an equality. You can extract the solution expression using a single loop or comprehension:

```python
>>> from sympy import symbols, Eq, Function, dsolve
>>> y, z = symbols("y z", cls=Function)
>>> x = symbols("x")
>>> eqs_one_soln_set = [Eq(y(x).diff(x), z(x)**2), Eq(z(x).diff(x), z(x))]
>>> solutions_one_soln_set = dsolve(eqs_one_soln_set, [y(x), z(x)])
>>> solutions_one_soln_set
[Eq(y(x), C1 + C2**2*exp(2*x)/2), Eq(z(x), C2*exp(x))]
>>> # Loop through list approach
>>> solution_one_soln_set_dict = {}
>>> for fn in solutions_one_soln_set:
...    solution_one_soln_set_dict.update({fn.lhs: fn.rhs})
>>> solution_one_soln_set_dict
{y(x): C1 + C2**2*exp(2*x)/2, z(x): C2*exp(x)}
>>> # List comprehension approach
>>> solution_one_soln_set_dict = 
{fn.lhs:fn.rhs for fn in solutions_one_soln_set}
>>> solution_one_soln_set_dict
{y(x): C1 + C2**2*exp(2*x)/2, z(x): C2*exp(x)}
>>> # Extract expression for y(x)
>>> solution_one_soln_set_dict[y(x)]
C1 + C2**2*exp(2*x)/2
```

If There are Multiple Solution Sets

If there are multiple solution sets to a system of equations with multiple unknown functions, `dsolve()` (page 807) will return a nested list of equalities, the outer list representing each solution and the inner list representing each function. While you can extract results by specifying the index of each function, we recommend an approach which is robust with respect to function ordering. The following converts each solution into a dictionary so you can easily extract the result for the desired function. It uses standard Python techniques such as loops or comprehensions, in a nested fashion.

```python
>>> from sympy import symbols, Eq, Function, dsolve
>>> y, z = symbols("y z", cls=Function)
>>> x = symbols("x")
>>> eqs = [Eq(y(x).diff(x)**2, z(x)**2), Eq(z(x).diff(x), z(x))]
>>> solutions = dsolve(eqs, [y(x), z(x)])
>>> solutions
[[Eq(y(x), C1 - C2*exp(x)), Eq(z(x), C2*exp(x))], [Eq(y(x), C1 + C2*exp(x)), Eq(z(x), C2*exp(x))]]
>>> # Nested list approach
>>> solutions_list = []
>>> for solution in solutions:
...    solution_dict = {}
...    for fn in solution:
...        solution_dict.update({fn.lhs: fn.rhs})
>>> solutions_list
[[{y(x): C1 - C2*exp(x), z(x): C2*exp(x)}], [{y(x): C1 + C2*exp(x), z(x): C2*exp(x)}]]
```
Work With Arbitrary Constants

You can manipulate arbitrary constants such as \( C_1 \), \( C_2 \), and \( C_3 \), which are generated automatically by \texttt{dsolve()} (page 807), by creating them as symbols. For example, if you want to assign values to arbitrary constants, you can create them as symbols and then substitute in their values using \texttt{subs()} (page 993):

```python
>>> from sympy import Function, dsolve, Derivative, symbols, pi
>>> y = Function('y')
>>> x, C1, C2 = symbols("x, C1, C2")
>>> result = dsolve(Derivative(y(x), x, x) + 9*y(x), y(x)).rhs
>>> result
C1*sin(3*x) + C2*cos(3*x)
>>> result.subs({C1: 7, C2: pi})
7*sin(3*x) + pi*cos(3*x)
```

Numerically Solve an ODE in SciPy

A common workflow which leverages SciPy’s fast numerical ODE solving is

1. set up an ODE in SymPy
2. convert it to a numerical function using \texttt{lambdify()} (page 2173)
3. solve the initial value problem by numerically integrating the ODE using SciPy’s \texttt{solve_ivp}.

Here is an example from the field of chemical kinetics where the nonlinear ordinary differen-
Partial differential equations take this form:

\[ r_f = k_f y_0(t)^2 y_1(t) \]
\[ r_b = k_b y_2(t)^2 \]
\[ \frac{dy_0(t)}{dt} = 2(r_b - r_f) \]
\[ \frac{dy_1(t)}{dt} = r_b - r_f \]
\[ \frac{dy_2(t)}{dt} = 2(r_f - r_b) \]

and

\[ \ddot{y}(t) = \begin{bmatrix} y_0(t) \\ y_1(t) \\ y_2(t) \end{bmatrix} \]

```python
>>> from sympy import symbols, lambdify
>>> import numpy as np
>>> import scipy.integrate
>>> import matplotlib.pyplot as plt
>>> # Create symbols y0, y1, and y2
>>> y = symbols('y:3')
>>> kf, kb = symbols('kf kb')
>>> rf = kf * y[0]**2 * y[1]
>>> rb = kb * y[2]**2
>>> # Derivative of the function y(t); values for the three chemical species
>>> # for input values y, kf, and kb
>>> ydot = [2*(rb - rf), rb - rf, 2*(rf - rb)]
>>> t = symbols('t') # not used in this case
>>> # Convert the SymPy symbolic expression for ydot into a form that
>>> # SciPy can evaluate numerically, f
>>> f = lambdify((t, y, kf, kb), ydot)
>>> k_vals = np.array([0.42, 0.17]) # arbitrary in this case
>>> y0 = [1, 1, 0] # initial condition (initial values)
>>> t_eval = np.linspace(0, 10, 50) # evaluate integral from t = 0-10 for 50 points
>>> # Call SciPy's ODE initial value problem solver solve_ivp by passing it
>>> # the function f,
>>> # the interval of integration,
>>> # the initial state, and
>>> # the arguments to pass to the function f
>>> solution = scipy.integrate.solve_ivp(f, (0, 10), y0, t_eval=t_eval, args=k_vals)
>>> # Extract the y (concentration) values from SciPy solution result
>>> y = solution.y
>>> # Plot the result graphically using matplotlib
>>> plt.plot(t_eval, y.T)
>>> # Add title, legend, and axis labels to the plot
>>> plt.title('Chemical Kinetics')
```

(continues on next page)
SciPy's `solve_ivp` returns a result containing \( y \) (numerical function result, here, concentration) values for each of the three chemical species, corresponding to the time points \( t_{\text{eval}} \).

### Ordinary Differential Equation Solving Hints

#### Return Unevaluated Integrals

By default, `dsolve()` (page 807) attempts to evaluate the integrals it produces to solve your ordinary differential equation. You can disable evaluation of the integrals by using `Hint Functions` (page 818) ending with `_Integral`, for example `separable_Integral`. This is useful because `integrate()` (page 1016) is an expensive routine. SymPy may hang (appear to never complete the operation) because of a difficult or impossible integral, so using an `_Integral` hint will at least return an (unintegrated) result, which you can then consider. The simplest way to disable integration is with the `all_Integral` hint because you do not need to know
which hint to supply: for any hint with a corresponding _Integral hint, all_Integral only returns the _Integral hint.

**Select a Specific Solver**

You may wish to select a specific solver using a hint for a couple of reasons:

- educational purposes: for example if you are learning about a specific method to solve ODEs and want to get a result that exactly matches that method
- form of the result: sometimes an ODE can be solved by many different solvers, and they can return different results. They will be mathematically equivalent, though the arbitrary constants may not be. *dsolve()* (page 807) by default tries to use the “best” solvers first, which are most likely to return the most usable output, but it is not a perfect heuristic. For example, the “best” solver may produce a result with an integral that SymPy cannot solve, but another solver may produce a different integral that SymPy can solve. So if the solution isn’t in a form you like, you can try other hints to check whether they give a preferable result.

**Not All Equations Can Be Solved**

**Equations With No Solution**

Not all differential equations can be solved, for example:

```python
>>> from sympy import Function, dsolve, Derivative, symbols
>>> y = Function('y')
>>> x, C1, C2 = symbols("x, C1, C2")
>>> dsolve(Derivative(y(x), x, 3) - (y(x)**2), y(x)).rhs
Traceback (most recent call last):
... NotImplementedError: solve: Cannot solve -y(x)**2 + Derivative(y(x), (x, 3))
```

**Equations With No Closed-Form Solution**

As noted above, *Some ODEs Cannot Be Solved Explicitly, Only Implicitly* (page 154).

Also, some systems of differential equations have no closed-form solution because they are chaotic, for example the Lorenz system or a double pendulum described by these two differential equations (simplified from *ScienceWorld*):

\[
2\dot{\theta}_1''(t) + \theta_2''(t) \cos(\theta_1 - \theta_2) + \theta_2''(t) \sin(\theta_1 - \theta_2) + 2g \sin(\theta_1) = 0
\]

\[
\theta_2''(t) + \theta_1''(t) \cos(\theta_1 - \theta_2) - \theta_2''(t) \sin(\theta_1 - \theta_2) + g \sin(\theta_2) = 0
\]

```python
>>> from sympy import symbols, Function, cos, sin, dsolve
>>> theta1, theta2 = symbols('thetal theta2', cls=Function)
>>> g, t = symbols('g t')
>>> eq1 = 2*theta1(t).diff(t, t) + theta2(t).diff(t, t)*cos(theta1(t) - theta2(t)) + 2*theta1(t).diff(t)*sin(theta1(t) - theta2(t)) + 2*g*sin(theta1(t))
>>> eq2 = theta2(t).diff(t, t) + theta1(t).diff(t, t)*cos(theta1(t) - theta2(t)) - theta2(t).diff(t)*sin(theta1(t) - theta2(t)) + g*sin(theta2(t))
```

(continues on next page)
... \( \sin(\theta_1(t)) \)

>>> eq2 = theta2(t).diff(t, t) + theta1(t).diff(t)**2 * sin(theta1(t) - theta2(t))

>>> dsolve([eq1, eq2], [theta1(t), theta2(t)])
Traceback (most recent call last):
... 
NotImplementedError

For such cases, you can solve the equations numerically as mentioned in *Alternatives to Consider* (page 150).

**Report a Bug**

If you find a bug with *dsolve()* (page 807), please post the problem on the SymPy mailing list. Until the issue is resolved, you can use a different method listed in *Alternatives to Consider* (page 150).

### 3.4.6 Find the Roots of a Polynomial Algebraically or Numerically

Use SymPy to find the roots of a univariate polynomial algebraically. For example, finding the roots of \( ax^2 + bx + c \) for \( x \) yields \( x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} \).

**Alternatives to Consider**

- If you need a numeric (rather than algebraic) solution, you can use either
  - NumPy’s *roots()
  - SciPy’s *root()
- If you need to solve systems of polynomial equations algebraically, use *solve()* (page 882)

**Example of Finding the Roots of a Polynomial Algebraically**

Here is an example of finding the roots of a polynomial algebraically:

>>> from sympy import roots
>>> from sympy.abc import x, a, b, c
>>> roots(a*x**2 + b*x + c, x)
{-b/(2*a) - sqrt(-4*a*c + b**2)/(2*a): 1, 
  -b/(2*a) + sqrt(-4*a*c + b**2)/(2*a): 1}

This example reproduces the quadratic formula.
Functions to Find the Roots of a Polynomial

There are several functions that you can use to find the roots of a polynomial:

- `solve()` (page 882) is a general solving function which can find roots, though is less efficient than `all_roots()` (page 2456) and is the only function in this list that does not convey the multiplicity of roots; `solve()` (page 882) also works on non-polynomial equations (page 137) and systems of non-polynomial equations (page 143)

- `roots()` (page 2512) computes the symbolic roots of a univariate polynomial; will fail for most high-degree polynomials (five or greater)

- `nroots()` (page 2450) computes numerical approximations of the roots of any polynomial whose coefficients can be numerically evaluated, whether the coefficients are rational or irrational

- `RootOf()` (page 2507) can represent all the roots exactly of a polynomial of arbitrarily large degree, as long as the coefficients are rational numbers. `RootOf()` (page 2507) can avoid both ill-conditioning and returning spurious complex parts because it uses a more exact, but much slower, numerical algorithm based on isolating intervals. The following two functions use `RootOf()` (page 2507) so they have the same properties:
  - `real_roots()` (page 2449) can find all the real roots exactly of a polynomial of arbitrarily large degree; because it finds only the real roots, it can be more efficient than functions that find all roots.
  - `all_roots()` (page 2456) can find all the roots exactly of a polynomial of arbitrarily large degree

- `factor()` (page 2447) factors a polynomial into irreducibles and can reveal that roots lie in the coefficient ring

Each will be used on this page.

Guidance

Refer to Include the Variable to be Solved for in the Function Call (page 134) and Use Exact Values (page 134).

Find the Roots of a Polynomial

You can find the roots of a polynomial algebraically in several ways. The one to use depends on whether you

- want an algebraic or numeric answer

- want the multiplicity of each root (how many times each root is a solution). In the expression below representing \((x + 2)^2(x - 3)\), the root -2 has a multiplicity of two because \(x + 2\) is squared, whereas 3 has a multiplicity of one because \(x - 3\) has no exponent. Similarly, for the symbolic expression, the root \(-a\) has a multiplicity of two and the root \(b\) has a multiplicity of one.

```python
>>> from sympy import solve, roots, real_roots, factor, nroots, RootOf, expand
>>> from sympy import Poly
>>> expression = (x+2)**2 * (x-3)
>>> symbolic = (x+a)**2 * (x-b)```
Algebraic Solution Without Root Multiplicities

You can use SymPy’s standard `solve()` (page 882) function, though it will not return the multiplicity of roots:

```python
>>> solve(expression, x, dict=True)
[{x: -2}, {x: 3}]
>>> solve(symbolic, x, dict=True)
[{x: -a}, {x: b}]
```

`solve()` (page 882) will first try using `roots()` (page 2512); if that doesn’t work, it will try using `all_roots()` (page 2456). For cubics (third-degree polynomials) and quartics (fourth-degree polynomials), that means that `solve()` (page 882) will use radical formulae from roots rather than `RootOf()` (page 2507) even if RootOf is possible. The cubic and quartic formulae often give very complex expressions that are not useful in practice. As a result, you may want to set the `solve()` (page 882) parameter cubics or quartics to False to return `RootOf()` (page 2507) results:

```python
>>> from sympy import solve
>>> from sympy.abc import x

>>> # By default, solve() uses the radical formula, yielding very complex terms
>>> solve(x**4 - x + 1, x)
[-sqrt(2/(3*(1/16 + sqrt(687)*I/144)**(1/3)) + 2*(1/16 + sqrt(687)*I/144)**(1/3))/2 - sqrt(-2*(1/16 + sqrt(687)*I/144)**(1/3) - 2/sqrt(2/(3*(1/16 + sqrt(687)*I/144)**(1/3)) + 2*(1/16 + sqrt(687)*I/144)**(1/3)) - 2/(3*(1/16 + sqrt(687)*I/144)**(1/3)))/2, 
  sqrt(2/(3*(1/16 + sqrt(687)*I/144)**(1/3)) + 2*(1/16 + sqrt(687)*I/144)**(1/3)) - 2/sqrt(2/(3*(1/16 + sqrt(687)*I/144)**(1/3)) + 2*(1/16 + sqrt(687)*I/144)**(1/3)) - 2/(3*(1/16 + sqrt(687)*I/144)**(1/3)))/2, 
  sqrt(-2*(1/16 + sqrt(687)*I/144)**(1/3) + 2/(3*(1/16 + sqrt(687)*I/144)**(1/3)) + sqrt(-2*(1/16 + sqrt(687)*I/144)**(1/3))/(3*(1/16 + sqrt(687)*I/144)**(1/3)))/2 - sqrt(2/(3*(1/16 + sqrt(687)*I/144)**(1/3)) - 2/sqrt(2/(3*(1/16 + sqrt(687)*I/144)**(1/3)) + 2*(1/16 + sqrt(687)*I/144)**(1/3)) - 2/(3*(1/16 + sqrt(687)*I/144)**(1/3)))/2]
```

```python
>>> # If you set quartics=False, solve() uses RootOf()
>>> solve(x**4 - x + 1, x, quartics=False)
[CRootOf(x**4 + x + 1, 0), 
  CRootOf(x**4 + x + 1, 1), 
  CRootOf(x**4 + x + 1, 2), 
  CRootOf(x**4 + x + 1, 3)]
```

Writing the first root from `solve()` (page 882) in standard mathematical notation emphasizes how complex it is:

\[
\sqrt[3]{\frac{2}{3\sqrt[3]{\frac{1}{16} + \frac{\sqrt{687}}{144}}}} + 2\sqrt[3]{\frac{1}{16} + \frac{\sqrt{687}}{144}} - \sqrt[3]{\frac{-2\sqrt[3]{\frac{1}{16} + \frac{\sqrt{687}}{144}} - \frac{2}{3\sqrt[3]{\frac{1}{16} + \frac{\sqrt{687}}{144}}} + 2\sqrt[3]{\frac{1}{16} + \frac{\sqrt{687}}{144}}}{3\sqrt[3]{\frac{1}{16} + \frac{\sqrt{687}}{144}}}}
\]

Further, there is no general radical formula for quintics (fifth degree) or higher polynomials,
so their `RootOf()` (page 2507) representations may be the best option.

Refer to *Solve an Equation Algebraically* (page 137) for more about using `solve()` (page 882).

### Algebraic Solution With Root Multiplicities

**roots**

`roots()` (page 2512) can give explicit expressions for the roots of polynomials that have symbolic coefficients (that is, if there are symbols in the coefficients) if `factor()` (page 2447) does not reveal them. However, it may fail for some polynomials. Here are examples of `roots()` (page 2512):

```python
>>> roots(expression, x)
{-2: 2, 3: 1}
>>> roots(symbolic, x)
{-a: 2, b: 1}
```

It returns results as a dictionary, where the key is the root (for example, -2) and the value is the multiplicity of that root (for example, 2).

`roots()` (page 2512) function uses a combination of techniques (factorization, decomposition, radical formulae) to find expressions in radicals if possible for the roots. When it can find some radical expressions for the roots, it returns them along with their multiplicity. This function will fail for most high-degree polynomials (five or greater) because they do not have radical solutions, and there is no guarantee that they have closed-form solutions at all, as explained by the *Abel-Ruffini theorem*.

### Factor the Equation

A different approach is to factor a polynomial using `factor()` (page 2447), which does not give the roots directly but can give you simpler expressions:

```python
>>> expression_expanded = expand(expression)
>>> expression_expanded
x**3 + x**2 - 8*x - 12
>>> factor(expression_expanded)
(x - 3)*(x + 2)**2
>>> symbolic_expanded = expand(symbolic)
>>> symbolic_expanded
-a**2*b + a**2*x - 2*a*b*x + 2*a*x**2 - b*x**2 + x**3
>>> factor(symbolic_expanded)
(a + x)**2*(-b + x)
```

`factor()` (page 2447) can also factorize a polynomial in a given *polynomial ring* (page 2417) which can reveal roots lie in the coefficient ring. For example, if the polynomial has rational coefficients, then `factor()` (page 2447) will reveal any rational roots. If the coefficients are polynomials involving, for example, symbol `a` with rational coefficients then any roots that are polynomial functions of `a` with rational coefficients will be revealed. In this example, `factor()` (page 2447) reveals that \(x = a^2\) and \(x = -a^3 - a\) are roots.
>>> from sympy import expand, factor
>>> from sympy.abc import x, a
>>> p = expand((x - a**2)*(x + a + a**3))
>>> p
-a**5 + a**3*x - a**3 - a**2*x + a*x + x**2
>>> factor(p)
(-a**2 + x)*(a**3 + a + x)

**Exact Numeric Solution With Root Multiplicities**

`real_roots`

If the roots to your polynomial are real, using `real_roots()` (page 2449) ensures that only real (not complex or imaginary) roots will be returned.

```python
>>> from sympy import real_roots
>>> from sympy.abc import x
>>> cubed = x**3 - 1
>>> # roots() returns real and complex roots
>>> roots(cubed)
{1: 1, -1/2 - sqrt(3)*I/2: 1, -1/2 + sqrt(3)*I/2: 1}
>>> # real_roots() returns only real roots
>>> real_roots(cubed)[1]
[1]
```

`real_roots()` (page 2449) calls `RootOf()` (page 2507), so for equations whose roots are all real, you can get the same results by iterating over the number of roots of your equation:

```python
>>> [RootOf(expression, n) for n in range(3)]
[-2, -2, 3]
```

**Approximate Numeric Solution With Root Multiplicities**

`nroots`

`nroots()` (page 2450) gives an approximate numerical approximation to the roots of a polynomial. This example demonstrates that it can include numerical noise, for example a (negligible) imaginary component in what should be a real root:

```python
>>> nroots(expression)
[3.0, -2.0 - 4.18482169793536e-14*I, -2.0 + 4.55872552179222e-14*I]
```

If you want numeric approximations of the real roots, but you want to know exactly which roots are real, then the best method is `real_roots()` (page 2449) with `evalf()` (page 1111):

```python
>>> [r.n(2) for r in real_roots(expression)]
[-2.0, -2.0, 3.0]
>>> [r.is_real for r in real_roots(expression)]
[True, True, True]
```
nroots() (page 2450) is analogous to NumPy’s roots() function. Usually the difference between these two is that nroots() (page 2450) is more accurate but slower.

A major advantage of nroots() (page 2450) is that it can compute numerical approximations of the roots of any polynomial whose coefficients can be numerically evaluated with evalf() (page 1111) (that is, they do not have free symbols). Contrarily, symbolic solutions may not be possible for higher-order (fifth or greater) polynomials as explained by the Abel-Ruffini theorem. Even if closed-form solutions are available, they may have so many terms that they are not useful in practice. You may therefore want to use nroots() (page 2450) to find approximate numeric solutions even if closed-form symbolic solutions are available. For example, the closed-form roots of a fourth-order (quartic) polynomial may be rather complicated:

```plaintext
>>> rq0, rq1, rq2, rq3 = roots(x**4 + 3*x**2 + 2*x + 1)
>>> rq0
sqrt(-4 - 2*(-1/8 + sqrt(237)*I/36)**(1/3) + 4/sqrt(-2 + 7/(6*(-1/8 + sqrt(237)*I/36)**(1/3)) + 2*(-1/8 + sqrt(237)*I/36)**(1/3)) - 7/(6*(-1/8 + sqrt(237)*I/36)**(1/3)) + 2*(-1/8 + sqrt(237)*I/36)**(1/3))/2 - sqrt(-2 + 7/(6*(-1/8 + sqrt(237)*I/36)**(1/3)) + 2*(-1/8 + sqrt(237)*I/36)**(1/3))/2
```

so you may prefer an approximate numerical solution:

```plaintext
>>> rq0.n()
-0.349745826211722 - 0.438990337475312*I
```

nroots() (page 2450) can fail sometimes for polynomials that are numerically ill conditioned, for example Wilkinson’s polynomial. Using RootOf() (page 2507) and evalf() (page 1111) as described in Numerically Evaluate CRootOf Roots (page 168) can avoid both ill-conditioning and returning spurious complex parts because it uses a more exact, but much slower, numerical algorithm based on isolating intervals.

**Complex Roots**

For complex roots, similar functions can be used, for example solve() (page 882):

```plaintext
>>> from sympy import solve, roots, nroots, real_roots, expand, RootOf, CRootOf, Symbol
>>> from sympy import Poly
>>> from sympy.abc import x
>>> expression_complex = (x**2+4)**2 * (x-3)
>>> solve(expression_complex, x, dict=True)

{{x: 3}, {x: -2*I}, {x: 2*I}}
```

If the constants are symbolic, you may need to specify their domain for SymPy to recognize that the solutions are not real. For example, specifying that a is positive leads to imaginary roots:

```plaintext
>>> a = Symbol("a", positive=True)
>>> symbolic_complex = (x**2+a)**2 * (x-3)
>>> solve(symbolic_complex, x, dict=True)

{{x: 3}, {x: -I*sqrt(a)}, {x: I*sqrt(a)}}
```

roots() (page 2512) will also find imaginary or complex roots:
```python
>>> roots(expression_complex, x)
{3: 1, -2*I: 2, 2*I: 2}
```

*RootOf()* (page 2507) will also return complex roots:

```python
>>> [RootOf(expression_complex, n) for n in range(0, 3)]
[3, -2*I, -2*I]
```

*real_roots()* (page 2449) will return only the real roots.

```python
>>> real_roots(expression_complex)
[3]
```

An advantage of *real_roots()* (page 2449) is that it can be more efficient than generating all the roots: *RootOf()* (page 2507) can be slow for complex roots.

If you make the expression into a polynomial class *Poly* (page 2453), you can use its *all_roots()* (page 2456) method to find the roots:

```python
>>> expression_complex_poly = Poly(expression_complex)
>>> expression_complex_poly.all_roots()
```

Use the Solution Result

The way to extract solutions from the result depends on the form of the result.

**List (all_roots, real_roots, nroots)**

You can use standard Python list traversal techniques such as looping. Here, we substitute each root into the expression to verify that the result is 0:

```python
>>> expression = (x+2)**2 * (x-3)
>>> my_real_roots = real_roots(expression)
>>> my_real_roots
[-2, -2, 3]
>>> for root in my_real_roots:
...     print(f"expression({root}) = {expression.subs(x, root)}")
expression(-2) = 0
expression(-2) = 0
expression(3) = 0
```
List of dictionaries (solve)

Refer to Use the Solution Result (page 140).

Dictionary (roots)

You can use standard Python list traversal techniques such as looping through the keys and values in a dictionary. Here we print the value and multiplicity of each root:

```python
>>> my_roots = roots(expression)
>>> my_roots
{-2: 2, 3: 1}
>>> for root, multiplicity in my_roots.items():
...     print(f"Root {root} has multiplicity of {multiplicity}"")
Root -2 has multiplicity of 1
Root -2 has multiplicity of 2
```

Expression (factor)

You can manipulate an algebraic expression using various SymPy techniques, for example substituting in a symbolic or numeric value for $x$:

```python
>>> from sympy.abc import y
>>> factored = factor(expression_expanded)
>>> factored
(x - 3)*(x + 2)**2
>>> factored.subs(x, 2*y)
(2*y - 3)*(2*y + 2)**2
>>> factored.subs(x, 7)
324
```

Tradeoffs

Mathematical Exactness, Completeness of List of Roots, and Speed

Consider the high-order polynomial $x^5 - x + 1 = 0$. `nroots()` (page 2450) returns numerical approximations to all five roots:

```python
>>> from sympy import roots, solve, real_roots, nroots
>>> from sympy.abc import x
>>> fifth_order = x**5 - x + 1
>>> nroots(fifth_order)
[-1.16730397826142, -0.181232444469875 - 1.08395410131771*I, -0.181232444469875 + 1.08395410131771*I, 0.764884433600585 - 0.352471546031726*I, 0.764884433600585 + 0.352471546031726*I]
```

`roots()` (page 2512) can sometimes return only a subset of the roots or nothing if it can’t express any roots in radicals. In this case, it returns no roots (an empty set):
But if you set the flag \texttt{strict=True}, \texttt{roots()} will inform you that all roots cannot be returned:

```
>>> roots(x**5 - x + 1, x, strict=True)
Traceback (most recent call last):
...  
sympy.polys.polyerrors.UnsolvableFactorError: Strict mode: some factors cannot be solved in radicals, so a complete list of solutions cannot be returned. Call roots with strict=False to get solutions expressible in radicals (if there are any).
```

**Get All Roots, Perhaps Implicitly**

\texttt{solve()} will return all five roots as \texttt{CRootOf} (\texttt{ComplexRootOf}) class members:

```
>>> fifth_order_solved = solve(fifth_order, x, dict=True)
>>> fifth_order_solved
[{{x: CRootOf(x**5 - x + 1, 0)}},
 {x: CRootOf(x**5 - x + 1, 1)},
 {x: CRootOf(x**5 - x + 1, 2)},
 {x: CRootOf(x**5 - x + 1, 3)},
 {x: CRootOf(x**5 - x + 1, 4)}]
```

where the second argument in each \texttt{CRootOf} is the index of the root.

**Numerically Evaluate \texttt{CRootOf} Roots**

You can then numerically evaluate those \texttt{CRootOf} roots using \texttt{n from evalf()}:

```
>>> for root in fifth_order_solved:
...         print(root[x].n(10))
-1.167303978
-0.1812324445 - 1.083954101*I
-0.1812324445 + 1.083954101*I
0.7648844336 - 0.352471546*I
0.7648844336 + 0.352471546*I
```

If you are only interested in the sole real root, it is faster to use \texttt{real_roots()} because it will not attempt to find the complex roots:

```
>>> real_root = real_roots(fifth_order, x)
>>> real_root
[CRootOf(x**5 - x + 1, 0)]
>>> real_root[0].n(10)
-1.167303978
```
Representing Roots

RootOf() (page 2507), real_roots() (page 2449), and all_roots() (page 2456) can find all the roots exactly of a polynomial of arbitrarily large degree despite the Abel-Ruffini theorem. Those functions allow the roots to be categorized precisely and manipulated symbolically.

```python
>>> from sympy import init_printing
>>> init_printing()

>>> real_roots(fifth_order)

\[ 5 \]
\[ \text{CRootOf}(x - x + 1, 0) \]

```Poly(fifth_order, x).all_roots()

\[ 5 \]
\[ \text{CRootOf}(x - x + 1, 0), \text{CRootOf}(x - x + 1, 1), \text{CRootOf}(x - x + 1, 2), \text{CRootOf}(x - x + 1, 3), \text{CRootOf}(x - x + 1, 4) \]

```r0, r1, r2, r3, r4 = Poly(fifth_order, x).all_roots()

```r0

\[ 5 \]
\[ \text{CRootOf}(x - x + 1, 0) \]

```r1

\[ 5 \]
\[ \text{CRootOf}(x - x + 1, 1) \]

```r1.conjugate()

\[ 5 \]
\[ \text{CRootOf}(x - x + 1, 2) \]

```r1.is_real

False

Now that the roots have been found exactly, their properties can be determined free of numerical noise. For example, we can tell whether roots are real or not. If we request the conjugate() (page 1012) (same real part and imaginary part with opposite sign) of a root, for example r1, and that is exactly equal to another root r2, that root r2 will be returned:

```python
>>> r0.n()
-1.16730397826142
>>> r0.is_real
True
>>> r1.n()
-0.181232444469875 - 1.08395410131771*I
>>> r2.n()
-0.181232444469875 + 1.08395410131771*I
>>> r1

\[ 5 \]
\[ \text{CRootOf}(x - x + 1, 1) \]

```r1.conjugate()

\[ 5 \]
\[ \text{CRootOf}(x - x + 1, 2) \]

```r1.is_real

False

solve() (page 882) will also give the complex roots where possible but it is less efficient than using all_roots() (page 2456) directly.

RootOf() (page 2507) exactly represents the root in a way that can be manipulated symbolically, and computed to arbitrary precision. The RootOf() (page 2507) representation makes it possible to precisely:

- Compute all roots of a polynomial with exact rational coefficients.
- Decide exactly the multiplicity of every root.
- Determine exactly whether roots are real or not.

3.4. Solve Equations 169
• Order the real and complex roots precisely.
• Know which roots are complex conjugate pairs of each other.
• Determine precisely which roots are rational vs irrational.
• Represent every possible algebraic number exactly.

The other numerical methods such NumPy’s roots(), nroots() (page 2450), and nsolve() (page 895) cannot do any of these things robustly, if at all. Similarly, when numerically evaluated using evalf() (page 1111), the radical expressions returned by solve() (page 882) or roots() (page 2512) cannot do these things robustly.

Not All Equations Can Be Solved

Equations With No Closed-Form Solution

As mentioned above, higher-order polynomials (fifth or greater) are unlikely to have closed-form solutions, so you may have to represent them using, for example, RootOf as described above (page 169), or use a numerical method such as nroots as described above (page 164).

Report a Bug

If you encounter a bug with these commands, please post the problem on the SymPy mailing list. Until the issue is resolved, you can use another of the Functions to Find the Roots of a Polynomial (page 161) or try one of the Alternatives to Consider (page 160).

3.4.7 Solve a Matrix Equation Algebraically

Use SymPy to solve a matrix (linear) equation. For example, solving \[
\begin{bmatrix}
c & d \\
1 & -c \\
\end{bmatrix}
\begin{bmatrix}
x \\
y \\
\end{bmatrix} = 
\begin{bmatrix}
2 \\
0 \\
\end{bmatrix}
\]
yields \[
\begin{bmatrix}
x \\
y \\
\end{bmatrix} = 
\begin{bmatrix}
\frac{2c}{ce^2 + d} \\
\frac{2}{ce + d} \\
\end{bmatrix}
\].

Alternatives to Consider

• If your matrix and constant vector contain only numbers, not symbols, for example \[
\begin{bmatrix}
1 & 2 \\
3 & 4 \\
\end{bmatrix}
\begin{bmatrix}
x \\
y \\
\end{bmatrix} = 
\begin{bmatrix}
2 \\
0 \\
\end{bmatrix}
\], you can use one of these other free and open-source packages instead of SymPy:
  - NumPy’s numpy.linalg.solve()
  - SciPy’s scipy.linalg.solve()
  - mpmath’s lu_solve()

• Solving a matrix equation is equivalent to solving a system of linear equations, so if you prefer you can Solve a System of Equations Algebraically (page 143)

• If you formulated your problem as a system of linear equations, and want to convert it to matrix form, you can use linear_eq_to_matrix() (page 917) and then follow the procedures in this guide.
Solve a Matrix Equation

Here is an example of solving a matrix equation with SymPy’s \texttt{sympy.matrices.matrices.MatrixBase.solve()} (page 1353). We use the standard matrix equation formulation $Ax = b$ where

- $A$ is the matrix representing the coefficients in the linear equations
- $x$ is the column vector of unknowns to be solved for
- $b$ is the column vector of constants, where each row is the value of an equation

```python
>>> from sympy import init_printing
>>> init_printing(use_unicode=True)
```

```python
>>> from sympy import symbols
>>> from sympy.matrices import Matrix

>>> c, d, e = symbols("c, d, e")
>>> A = Matrix([[c,d], [1, -e]])
```

```latex
\begin{bmatrix}
c & d \\
1 & -e 
\end{bmatrix}
```

```python
>>> b = Matrix([2, 0])
>>> b
```

```latex
\begin{bmatrix}
2 \\
0 
\end{bmatrix}
```

```python
>>> A.solve(b)
```

```latex
\begin{bmatrix}
\frac{2 \cdot e}{c \cdot e + d} \\
\frac{2}{c \cdot e + d}
\end{bmatrix}
```

Guidance

Matrix Usually Must Be Square

The matrix $A$ usually must be square to represent a system of linear equations with the same number of unknowns as equations. If not, SymPy will give the error \texttt{ShapeError: `self` and `rhs` must have the same number of rows}.

The exception to the requirement that a matrix be square comes from SymPy’s use of the Moore-Penrose pseudoinverse (page 1346).
Methods for Solving Matrix Equations

SymPy’s matrix solving method, `sympy.matrices.matrices.MatrixBase.solve()` (page 1353), can use several different methods, which are listed at that API reference link. Depending on the nature of the matrix, a given method may be more efficient. By default, Gauss-Jordan elimination will be used.

Specifying a method in `solve` is equivalent to using a specialized solving function. For example, using `solve` with `method='LU'` calls `LUsolve()` (page 1328).

Solving Several Matrix Equations With the Same Matrix

If you need to repeatedly solve matrix equations with the same matrix $A$ but different constant vectors $b$, it is more efficient to use one of the following methods.

You can use LU decomposition via `LUsolve()` (page 1328):

```python
>>> from sympy import symbols, Matrix, eye, simplify
>>> c, d, e = symbols("c, d, e")
>>> A = Matrix([[c, d], [1, -e]])
>>> A
\begin{bmatrix}
c & d \\
1 & -e
\end{bmatrix}
>>> b = Matrix([2, 0])
>>> b
\begin{bmatrix}
2 \\
0
\end{bmatrix}
>>> solution = A.LUsolve(b)
>>> solution
\begin{bmatrix}
2⋅e \\
\frac{c⋅e + d}{c⋅e + d}
\end{bmatrix}
>>> # Demonstrate that solution is correct
>>> simplify(A * solution)
\begin{bmatrix}
2 \\
0
\end{bmatrix}
>>> b2 = Matrix([4, 0])
>>> b2
\begin{bmatrix}
4 \\
0
\end{bmatrix}
>>> solution2 = A.LUsolve(b2)
>>> solution2
\begin{bmatrix}
4⋅e \\
\end{bmatrix}
```

(continues on next page)
Another approach is to compute the inverse matrix, but this is almost always slower, and significantly slower for larger matrices. If efficient computation is not a priority, you can use `inv()` (page 1340):

```python
>>> from sympy import symbols, Matrix, simplify
>>> c, d, e = symbols("c, d, e")
>>> A = Matrix([[c, d], [1, -e]])
>>> b = Matrix([2, 0])
>>> b
[2]
[0]
>>> b2 = Matrix([4, 0])
>>> b2
[4]
[0]
>>> inv = A.inv()
```
Determining the inverse of a large symbolic matrix may not be computationally tractable.

### Work With Symbolic Matrices

The computational complexity of manipulating symbolic matrices can increase rapidly with matrix size. For example, the number of terms in the determinant of a symbolic matrix increases with the factorial of the matrix dimension. As a result, the maximum dimensionality of matrices that can be solved is more limited than for numerical matrices. For example, the determinant of this 4x4 symbolic matrix has 24 terms with four elements in each term:

```python
>>> from sympy import MatrixSymbol
>>> A = MatrixSymbol('A', 4, 4).as_explicit()
>>> A
\[
\begin{bmatrix}
A_{00} & A_{01} & A_{02} & A_{03} \\
A_{10} & A_{11} & A_{12} & A_{13} \\
A_{20} & A_{21} & A_{22} & A_{23} \\
A_{30} & A_{31} & A_{32} & A_{33}
\end{bmatrix}
\]
```

and solving a matrix equation of it takes about a minute, whereas the analogous 3x3 matrix takes less than one second. The more unrelated, symbolic entries in a matrix, the more likely it is to be slow to manipulate. This example, finding a general solution to a matrix where all
elements are independent symbols, is the extreme case and thus the slowest for a matrix of its size.

**Speed up Solving Matrix Equations**

Here are some suggestions:

- If matrix elements are zero, ensure that they are recognized as zero. You can do this by either making them zero or by applying *assumptions* (page 244).
- Selecting a solve method suited to the properties of the matrix, for example hermitian, symmetric, or triangular. Refer to *Methods for Solving Matrix Equations* (page 172).
- Use the *DomainMatrix* (page 2753) class, which can be faster to operate on because it limits the domain of matrix elements.

**Use the Solution Result**

**Use the Solution as a Vector**

You can use the solution result as a vector. For example, to prove that the solution $x$ is correct, you can multiply it the matrix $A$ and verify that it produces the constants vector $b$:

```python
>>> from sympy import symbols, simplify
>>> from sympy.matrices import Matrix
>>> c, d, e = symbols("c, d, e")
>>> A = Matrix([[c,d], [1, -e]])
>>> b = Matrix([2, 0])
>>> solution = A.solve(b)

>>> solution
```

```plaintext
[ 2⋅e
 c⋅e + d
 2
 c⋅e + d]
```

```python
>>> # Not immediately obvious whether this result is a zeroes vector
>>> (A * solution) - b
```

```plaintext
[2⋅c⋅e 2⋅d]
[c⋅e + d c⋅e + d]

[0]
```

```python
>>> # simplify reveals that this result is a zeroes vector
>>> simplify((A * solution) - b)
```

```plaintext
[0]
```

Note that we had to use `simplify()` (page 719) to make SymPy simplify the expression in a matrix element to make it immediately obvious that the solution is correct.
Extract Elements From the Solution

Because you can iterate through the elements in a column vector, you can extract its elements using standard Python techniques. For example, you can create a list of the elements using list comprehension:

```python
>>> [element for element in solution]
```

or you can extract individual elements by subscripting:

```python
>>> solution[0]
```

Equations With No Solution

If the determinant of a matrix is zero, matrix equations with it have no solution:

```python
>>> from sympy import symbols
>>> from sympy.matrices import Matrix
>>> c, d, e = symbols("c, d, e")
>>> A = Matrix([[c*e**2, d*e], [c*e, d]])
>>> A
```

```python
>>> b = Matrix([2, 0])
>>> A.LUsolve(b)
Traceback (most recent call last):
... NonInvertibleMatrixError: Matrix det == 0; not invertible.
```

Report a Bug

If you find a bug with matrix-solving functions, please post the problem on the SymPy mailing list. Until the issue is resolved, you can use a different method listed in Alternatives to Consider (page 170).
3.4.8 Reduce One or a System of Inequalities for a Single Variable Algebraically

Use SymPy to reduce one or a system of inequalities for a single variable algebraically. For example, reducing $x^2 < \pi$, $x > 0$ yields $0 < x < \sqrt{\pi}$.

**Note:** SymPy can currently reduce for only one symbol (variable) in an inequality.

SymPy can reduce a system containing more than one symbol, if there is only one symbol per inequality.

**Alternatives to Consider**

- To reduce for more than one symbol in an inequality, try SciPy’s `linprog()`
- To reduce Boolean expressions, use `as_set` (page 1207)

**Examples**

**Reducing a System of Inequalities for a Single Variable Algebraically**

`reduce_inequalities()` (page 805) accepts a list or tuple of inequalities to be reduced as a system:

```python
>>> from sympy import symbols, reduce_inequalities, pi
>>> x = symbols('x')
>>> reduce_inequalities([x >= 0, x**2 <= pi], x)
(0 <= x) & (x <= sqrt(pi))
```

**Note:** While `solve()` (page 882) currently accomplishes the same thing (by calling `reduce_inequalities()` (page 805) internally), that functionality may be deprecated or removed from `solve()` (page 882). We thus recommend using `reduce_inequalities()` (page 805).

`reduce_inequalities()` (page 805) is the top-level inequality-reducing function which will internally call any other lower-level inequality-reducing functions (page 803) as needed.

**Reducing One Inequality for a Single Variable Algebraically**

If you have only one inequality, you can optionally exclude the list construct and simply pass `reduce_inequalities()` (page 805) the inequality as an expression:

```python
>>> from sympy import symbols, reduce_inequalities, pi
>>> x = symbols('x')
>>> reduce_inequalities(x**2 <= pi, x)
(x <= sqrt(pi)) & (-sqrt(pi) <= x)
```
Guidance

Include the Variable to Be Reduced for in the Function Call

We recommend you include the variable to be reduced for as the second argument for `reduce_inequalities()` (page 805) to ensure that it reduces for the desired variable.

Reduce a System of Inequalities Algebraically

You can create your inequalities, then reduce the system as a list:

```python
>>> from sympy import symbols, reduce_inequalities, pi
>>> x = symbols('x')
>>> reduce_inequalities([3*x >= 1, x**2 <= pi], x)
(1/3 <= x) & (x <= sqrt(pi))
```

Use the Result

A common way to use the result is to extract the bounds for the symbol (variable). For example, for a solution of $0 < x < \sqrt{\pi}$, you might want to extract 0 and $\sqrt{\pi}$.

Extract a List of Decomposed Relations

You can decompose a set of relations which is joined by ^ (Or (page 1211)) or & (And (page 1210)) into individual relations using relational atoms. Using `canonical` (page 1068) will put order each relation so the symbol is on the left, so you can take the right-hand side `rhs` (page 1070) to extract the constants:

```python
>>> from sympy import symbols, reduce_inequalities, pi
>>> from sympy.core.relational import Relational
>>> x = symbols('x')
>>> eq = reduce_inequalities([3*x >= 1, x**2 <= pi], x); eq
(1/3 <= x) & (x <= sqrt(pi))
>>> relations = [(i.lhs, i.rel_op, i.rhs) for i in eq if i.canonical]
>>> relations_sorted = sorted(relations, key=lambda x: float(x[2])) # Sorting
>>> relations_sorted
[(x, '>=', 1/3), (x, '<=', sqrt(pi))]
```
Extract a Tuple of Relations

The args (page 980) (arguments) of reduced relations are the individual relations, so you can extract the constants from the left- or right-hand side of the args:

```python
>>> from sympy import symbols, reduce_inequalities, pi
>>> x = symbols('x')
>>> eq = reduce_inequalities([3*x >= 1, x**2 <= pi], x);
eq
(1/3 <= x) & (x <= sqrt(pi))
>>> eq.args
(1/3 <= x, x <= sqrt(pi))
>>> constants = []
>>> for arg in eq.args:
...    if arg.lhs == x:
...        constants.append(arg.rhs)
...    else:
...        constants.append(arg.lhs)
>>> constants
[1/3, sqrt(pi)]
```

Limitations of Inequality Reduction Using SymPy

SymPy Can Reduce for Only One Symbol of Interest Per Inequality

SymPy can currently reduce for only one symbol (variable) of interest in a given inequality.

```python
>>> from sympy import reduce_inequalities, symbols
>>> x, y = symbols("x y")
>>> reduce_inequalities([x + y > 1, y > 0], [x, y])
Traceback (most recent call last):
... NotImplementedError: inequality has more than one symbol of interest.
```

You can use SciPy's linprog() to reduce this system of inequalities.

SymPy can reduce for more than one symbol in a system, if there is only one symbol of interest per inequality. For example, the following system of inequalities has two variables, \(x\) and \(y\). SymPy can reduce for \(x\), and gives the constraints on \(y\).

```python
>>> from sympy import reduce_inequalities, symbols
>>> x, y = symbols("x y")
>>> reduce_inequalities([x + y > 1, y > 0], x)
(0 < y) & (1 < x) & (x < oo) & (y < oo)
```

(oo is Infinity (page 1048).)

If each inequality contains only one symbol to be reduced for, SymPy can reduce the set of inequalities for multiple symbols:

```python
>>> from sympy import reduce_inequalities, symbols
>>> x, y = symbols("x y")
>>> x_y_reduced = reduce_inequalities([x > 1, y > 0], [x, y]); x_y_reduced
(0 < y) & (1 < x) & (x < oo) & (y < oo)
```

3.4. Solve Equations
Note that this provides no mathematical insight beyond reducing the inequalities separately:

```python
>>> from sympy import And
>>> x_reduced = reduce_inequalities(x > 1, x); x_reduced
(1 < x) & (x < oo)
>>> y_reduced = reduce_inequalities(y > 0, y); y_reduced
(0 < y) & (y < oo)
>>> And(x_reduced, y_reduced) == x_y_reduced
True
```

so the benefit of solving such inequalities as a set maybe only convenience.

**Limitations on Types of Inequalities That SymPy Can Solve**

`reduce_inequalities()` (page 805) can solve a system of inequalities involving a power of the symbol to be reduced for, or involving another symbol, but not both:

```python
>>> from sympy import reduce_inequalities
>>> from sympy.abc import x, y
>>> reduce_inequalities([x**2 < 4, x > 0], x)
(0 < x) & (x < 2)
>>> reduce_inequalities([x < y, x > 0], x)
(0 < x) & (x < oo) & (x < y)
>>> reduce_inequalities([x**2 - y < 4, x > 0], x)
Traceback (most recent call last):
  ... NotImplementedError: The inequality, -y + x**2 - 4 < 0, cannot be solved using solve_univariante_inequality.
```

**Not All Results Are Returned for Periodic Functions**

The results returned for trigonometric inequalities are restricted in its periodic interval. `reduce_inequalities()` (page 805) tries to return just enough solutions so that all (infinitely many) solutions can generated from the returned solutions by adding integer multiples of the `periodicity()` (page 304) of the equation, here 2π.

```python
>>> from sympy import reduce_inequalities, cos
>>> from sympy.abc import x, y
>>> from sympy.calculus.util import periodicity
>>> reduce_inequalities([2*cos(x) < 1, x > 0], x)
(0 < x) & (x < oo) & (pi/3 < x) & (x < 5*pi/3)
>>> periodicity(2*cos(x), x)
2*pi
```
Not All Systems of Inequalities Can Be Reduced

Systems of Inequalities Which Cannot Be Satisfied

If the system of inequalities has incompatible conditions, for example \( x < 0 \) and \( x > \pi \), SymPy will return False:

```python
>>> from sympy import symbols, reduce_inequalities, pi
>>> x = symbols('x')
>>> reduce_inequalities([x < 0, x > pi], x)
False
```

Systems of Inequalities That Cannot Be Reduced Analytically

SymPy may reflect that your system of inequalities has no solutions that can be expressed algebraically (symbolically) by returning an error such as `NotImplementedError`:

```python
>>> from sympy import symbols, reduce_inequalities, cos
>>> x = symbols('x')
>>> reduce_inequalities([cos(x) - x > 0, x > 0], x)
Traceback (most recent call last):
  ...  
NotImplementedError: The inequality, \(-x + \cos(x) > 0\), cannot be solved using
  _solve_univariate_inequality.
```

so you may have to reduce your inequalities numerically instead using SciPy’s `linprog()`.

Inequalities Which Can Be Reduced Analytically, and SymPy Cannot Reduce

Refer to *Limitations of Inequality Reduction Using SymPy* (page 179) above.

Report a Bug

If you find a bug with `diophantine()` (page 775), please post the problem on the SymPy mailing list. Until the issue is resolved, you can use a different method listed in *Alternatives to Consider* (page 177).

### 3.4.9 Solve a Diophantine Equation Algebraically

Use SymPy to solve a Diophantine equation (find integer solutions to a polynomial equation) algebraically, returning a parameterized general solution if possible. For example, solving the Pythagorean equation \( a^2 + b^2 = c^2 \) yields \( (a = 2pq, b = p^2 - q^2, c = p^2 + q^2) \). Here, \( p \) and \( q \) are new parameters introduced in the solution. \( p \) and \( q \) can take on any integer value to parameterize the full set of solutions. More formally, \( p, q \in \mathbb{Z} \) parameterize the infinite set of Pythagorean triples.
Alternatives to Consider

There are few alternatives for finding a parameterized general solution for a Diophantine equation.

- **Numerical alternatives:**
  - Sage’s EllipticCurve command may be able to find a set of relative numerical values for each variable.
  - You can test explicit integer values, for example using a nested for loop of ranges of values. This is inefficient, but fine if you are only interested in solutions that are relatively small.

- `solve()` (page 882) treats the variables as real or complex numbers, and simply solves for one variable in terms of the others, which produces a different type of solution. For example, attempting to solve \( a^2 + b^2 = c^2 \) for \( a, b, \) and \( c \) can only reveal that \( a = \pm \sqrt{c^2 - b^2} \).

Example of Solving a Diophantine Equation

Here is an example of solving a Diophantine equation, specifically \( a^2 + b^2 = c^2 \), using `diophantine()` (page 775):

```python
>>> from sympy.solvers.diophantine import diophantine
>>> from sympy import symbols, Eq
>>> a, b, c = symbols("a, b, c", integer=True)
>>> my_syms = (a, b, c)
>>> pythag_eq = Eq(a**2 + b**2, c**2)
>>> # Solve Diophantine equation
>>> d = diophantine(pythag_eq, syms=my_syms)
>>> d
{(2*p*q, p**2 - q**2, p**2 + q**2)}
```

Refer to the [Diophantine API reference](page 769) for more examples of solving various types of Diophantine equations.

Guidance

Diophantine Equation Can be Expressed as Expression That Equals Zero

If you already have an expression that equals zero, you can solve that expression. For example, expressing the Pythagorean equation as \( a^2 + b^2 - c^2 \) is also valid:

```python
>>> from sympy.solvers.diophantine import diophantine
>>> from sympy import symbols
>>> a, b, c = symbols("a, b, c", integer=True)
>>> my_syms = (a, b, c)
>>> pythag = a**2 + b**2 - c**2
>>> diophantine(pythag, syms=my_syms)
{(2*p*q, p**2 - q**2, p**2 + q**2)}
```
Specify the Order of Symbols in the Result

We recommend you specify the order of symbols in the result to avoid confusion. Use the `syms` parameter and pass it a tuple or list of symbols to ensure the result will be in that order, for example `syms=my_syms`, as in the examples on this page.

Limitations

Currently, following five types of Diophantine equations can be solved using `diophantine()` (page 775) and other helper functions of the Diophantine module.

- **Linear Diophantine equations**: \(a_1x_1 + a_2x_2 + \ldots + a_nx_n = b\)
- **General binary quadratic equation**: \(ax^2 + bxy + cy^2 + dx + ey + f = 0\)
- **Homogeneous ternary quadratic equation**: \(ax^2 + by^2 + cz^2 + dxy + eyz + fzx = 0\)
- **Extended Pythagorean equation**: \(a_1x_1^2 + a_2x_2^2 + \ldots + a_nx_n^2 = a_{n+1}x_{n+1}^2\)
- **General sum of squares**: \(x_1^2 + x_2^2 + \ldots + x_n^2 = k\)

Use the Solution Result

Extract Expressions From the Result

`diophantine()` (page 775) returns results as a set of tuples, where each element in a tuple is an expression for a variable in your equation. For example, for the Pythagorean equation, the result is a set containing one tuple where the expressions correspond to \((a, b, c)\). That is, the tuple represents \(a = 2pq, \ b = p^2 - q^2, \ c = p^2 - q^2\). Because you cannot extract an element (here, a tuple) from a set by subscripting the set, you can create a dictionary of symbol-expression pairs to extract an expression by its symbol:

```
>>> from sympy.solvers.diophantine import diophantine
>>> from sympy import symbols
>>> a, b, c = symbols("a, b, c", integer=True)
>>> my_syms = (a, b, c)
>>> pythag = a**2 + b**2 - c**2
>>> solution, = diophantine(pythag, syms=my_syms)
>>> solution
(2*p*q, p**2 - q**2, p**2 + q**2)
>>> # Convert set to list
>>> solution_dict = dict(zip(my_syms, solution))
>>> solution_dict
{a: 2*p*q, b: p**2 - q**2, c: p**2 + q**2}
>>> # Extract an expression for one variable using its symbol, here a
>>> solution_dict[a]
2*p*q
```

Less elegantly, you can convert the set to a list, and then subscript the list. It is a common mistake to forget the order of parameters, so this method is more prone to errors:

```
>>> from sympy.solvers.diophantine import diophantine
>>> from sympy import symbols
```

(continues on next page)
>>> a, b, c, p, q = symbols(“a, b, c, p, q”, integer=True)
>>> my_syms = (a, b, c)
>>> pythag = a**2 + b**2 - c**2
>>> d = diophantine(pythag, syms=my_syms)
>>> d
{(2*p*q, p**2 - q**2, p**2 + q**2)}

Work With Parameters

You can manipulate parameters such as p and q, which are generated automatically by `diophantine()` (page 775), by creating them as symbols. For example, to find a particular set of values that satisfies the Diophantine equation, you can substitute in values for the parameters by

1. creating the parameters as symbols
2. substituting in their values using `subs()` (page 993).

Here, we express the set of values as a dictionary to associate each variable (a, b, c) with its example value:

>>> from sympy.solvers.diophantine import diophantine
>>> from sympy import symbols
>>> my_syms = (a, b, c)
>>> pythag = a**2 + b**2 - c**2
>>> d = diophantine(pythag, syms=my_syms)
>>> solution_list = list(d)
>>> solution_list
[(2*p*q, p**2 - q**2, p**2 + q**2)]
>>> p, q = symbols(“p, q”, integer=True)

Note that you need to include the integer=True assumption for the generated parameters (p and q) to substitute numerical values for them. Conversely, you do not need to include the integer=True assumption for the symbols in the original equation (a, b, and c), although it is a good practice.
To iterate the set of solutions, you can iterate over value of the parameters (p and q) in a nested loop:

```python
>>> from sympy.solvers.diophantine import diophantine
>>> from sympy import symbols
>>> a, b, c, p, q = symbols("a, b, c, p, q", integer=True)
>>> my_syms = (a, b, c)
>>> pythag = a**2 + b**2 - c**2
>>> d = diophantine(pythag, syms=my_syms)
>>> solution_list = list(d)
>>> # Iterate over the value of parameters p and q
>>> for p_val in range(-1, 2):
...     for q_val in range(-1, 2):
...         # Substitute in the values of p and q
...         pythag_vals = dict(zip(my_syms, [var.subs({p:p_val, q:q_val}) for var in solution_list[0]]))
...         # Print out the values of the generated parameters, and the Pythagorean triple a, b, c
...         print(f"p: {p_val}, q: {q_val} -> {pythag_vals}"")
```

Verify a Solution

You can verify a solution is correct by substituting its integer values back into the original equation (expression which equals zero) and checking that the result is zero, either by using the dictionary approach from Work With Parameters (page 184), or by manually substituting in values determined by any procedure:

```python
>>> from sympy.solvers.diophantine import diophantine
>>> from sympy import symbols
>>> a, b, c, p, q = symbols("a, b, c, p, q", integer=True)
>>> my_syms = (a, b, c)
>>> pythag = a**2 + b**2 - c**2
>>> d = diophantine(pythag, syms=my_syms)
>>> solution_list = list(d)
>>> solution_p4q3 = dict(zip(my_syms, [var.subs({p:4, q:3}) for var in solution_list[0]]))
>>> # Substitute values in using a dictionary
>>> pythag.subs({a: solution_p4q3[a], b: solution_p4q3[b], c: solution_p4q3[c]})
0
>>> # Manually substitute in values
>>> pythag.subs({a: 24, b: 7, c: 25})
0
```
Programmatically Extract Parameter Symbols

If you want to programmatically obtain the set of auto-generated parameters for one solution, you can use the following code:

```python
>>> from sympy.solvers.diophantine import diophantine
>>> from sympy import symbols

>>> a, b, c, p, q = symbols("a, b, c, p, q", integer=True)
>>> my_syms = (a, b, c)
>>> pythag = a**2 + b**2 - c**2
>>> # Solve Diophantine equation
>>> solution, = diophantine(pythag, syms=my_syms)
>>> solution
(2*p*q, p**2 - q**2, p**2 + q**2)
>>> # Extract parameter symbols
>>> set().union(*(s.free_symbols for s in solution))
{p, q}
```

Not All Equations Can Be Solved

Equations With No Solution

Some Diophantine equations have no solution, in which case `diophantine()` (page 775) will return an empty set, set(). For example, in the expression $2x + 4y - 3$ (which we will try to set to zero), the coefficients are both even (2 and 4), so the sum of the terms $(2x + 4y)$ can only be even. However, the constant 3 is odd, so there is no solution.

```python
>>> from sympy.solvers.diophantine import diophantine
>>> from sympy import symbols

>>> x, y = symbols("x, y", integer=True)
>>> diophantine(2*x + 4*y - 3, syms=(x, y))
set()
```

Report a Bug

If you find a bug with `diophantine()` (page 775), please post the problem on the SymPy mailing list. Until the issue is resolved, you can use a different method listed in Alternatives to Consider (page 182).

3.5 Citing SymPy

To cite SymPy in publications use

symbolic computing in Python. *PeerJ Computer Science* 3:e103
https://doi.org/10.7717/peerj-cs.103

A BibTeX entry for LaTeX users is

SymPy is BSD licensed, so you are free to use it however you like, be it academic, commercial, creating forks or derivatives, as long as you copy the BSD statement if you redistribute it (see the LICENSE file for details). That said, although not required by the SymPy license, if it is convenient for you, please cite SymPy when using it in your work and also consider contributing all your changes back, so that we can incorporate it and all of us will benefit in the end.

The SymPy development team members are listed in the AUTHORS file on GitHub.

A list of papers citing SymPy can be found on Zotero.
Explanations provide in-depth discussions about select SymPy features. These topic guides talk about things like the motivation behind design decisions, technical implementation details, and opinionated recommendations.

Content

4.1 Gotchas and Pitfalls

4.1.1 Introduction

SymPy runs under the Python Programming Language, so there are some things that may behave differently than they do in other, independent computer algebra systems like Maple or Mathematica. These are some of the gotchas and pitfalls that you may encounter when using SymPy. See also the FAQ, the introductory tutorial (page 5), the remainder of the SymPy Docs, and the official Python Tutorial.

If you are already familiar with C or Java, you might also want to look at this 4 minute Python tutorial.

Ignore #doctest: +SKIP in the examples. That has to do with internal testing of the examples.

4.1.2 Equals Signs (=)

Single Equals Sign

The equals sign (=) is the assignment operator, not equality. If you want to do \( x = y \), use Eq(x, y) for equality. Alternatively, all expressions are assumed to equal zero, so you can just subtract one side and use \( x - y \).

The proper use of the equals sign is to assign expressions to variables.

For example:

```python
>>> from sympy.abc import x, y
>>> a = x - y
>>> print(a)
x - y
```
Double Equals Signs

Double equals signs (==) are used to test equality. However, this tests expressions exactly, not symbolically. For example:

```python
>>> (x + 1)**2 == x**2 + 2*x + 1
False
>>> (x + 1)**2 == (x + 1)**2
True
```

If you want to test for symbolic equality, one way is to subtract one expression from the other and run it through functions like `expand()` (page 1099), `simplify()` (page 719), and `trigsimp()` (page 735) and see if the equation reduces to 0.

```python
>>> from sympy import simplify, cos, sin, expand
>>> simplify((x + 1)**2 - (x**2 + 2*x + 1))
0
>>> eq = sin(2*x) - 2*sin(x)*cos(x)
>>> simplify(eq)
0
>>> expand(eq, trig=True)
0
```

Note: See also Why does SymPy say that two equal expressions are unequal? in the FAQ.

4.1.3 Variables

Variables Assignment does not Create a Relation Between Expressions

When you use = to do assignment, remember that in Python, as in most programming languages, the variable does not change if you change the value you assigned to it. The equations you are typing use the values present at the time of creation to “fill in” values, just like regular Python definitions. They are not altered by changes made afterwards. Consider the following:

```python
>>> from sympy import Symbol
>>> a = Symbol('a')  # Symbol, ‘a’, stored as variable “a”
>>> b = a + 1        # an expression involving ‘a’ stored as variable “b”
>>> print(b)
a + 1
>>> a = 4            # “a” now points to literal integer 4, not Symbol('a')
>>> print(a)
4
>>> print(b)         # “b” is still pointing at the expression involving ‘a’
a + 1
```

Changing quantity a does not change b; you are not working with a set of simultaneous equations. It might be helpful to remember that the string that gets printed when you print a variable referring to a SymPy object is the string that was given to it when it was created; that string does not have to be the same as the variable that you assign it to.
If you need variables that have dependence on each other, you can define functions. Use the `def` operator. Indent the body of the function. See the Python docs for more information on defining functions.

```
>>> c, d = var('c d')
>>> print(c)
c
>>> print(d)
d
>>> def ctimesd():
...     return c*d
...     
>>> c timesd()
c*d
>>> c = 2
>>> print(c)
2
>>> c timesd()
2*d
```

If you define a circular relationship, you will get a `RuntimeError`.

```
>>> def a():
...     return b()
...
>>> def b():
...     return a()
...
>>> a()
Traceback (most recent call last):
  File "...", line ..., in ...
    compileflags, 1) in test.globs
  File "<...>", line 1, in <module>
    a()
  File "<...>", line 2, in a
    return b()
  File "<...>", line 2, in b
```
Symbols

Symbols are variables, and like all other variables, they need to be assigned before you can use them. For example:

```python
>>> import sympy
>>> z**2  # z is not defined yet
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
NameError: name 'z' is not defined
>>> sympy.var('z')  # This is the easiest way to define z as a standard symbol
z
>>> z**2
z**2
```

If you use `isympy`, it runs the following commands for you, giving you some default Symbols and Functions.

```python
>>> from __future__ import division
>>> from sympy import *
>>> x, y, z, t = symbols('x y z t')
>>> k, m, n = symbols('k m n', integer=True)
>>> f, g, h = symbols('f g h', cls=Function)
```

You can also import common symbol names from `sympy.abc` (page 931).

```python
>>> from sympy.abc import w
>>> w
```

---

Note: See also Why doesn’t changing one variable change another that depends on it? in the FAQ.
If you want control over the assumptions of the variables, use `Symbol` (page 1028) and `symbols()` (page 1030). See `Keyword Arguments` (page 201) below.

Lastly, it is recommended that you not use `I` (page 1050), `E` (page 3045), `S` (page 1914), `N` (page 1113), `C`, `O` (page 686), or `Q` (page 249) for variable or symbol names, as those are used for the imaginary unit (`i`), the base of the natural logarithm (`e`), the `sympify()` (page 970) function (see `Symbolic Expressions` (page 194) below), numeric evaluation (`N()` (page 1113) is equivalent to `evalf()` (page 1139)), the big O order symbol (as in `O(n log n)`), and the assumptions object that holds a list of supported ask keys (such as `Q.real`), respectively. You can use the mnemonic OSINEQ to remember what Symbols are defined by default in SymPy. Or better yet, always use lowercase letters for Symbol names. Python will not prevent you from overriding default SymPy names or functions, so be careful.

```python
>>> cos(pi)  # cos and pi are a built-in sympy names.
-1
>>> pi = 3  # Notice that there is no warning for overriding pi.
>>> cos(pi)
\cos(3)
>>> def cos(x):
    # No warning for overriding built-in functions either.
    ...
    return 5*x
    ...
>>> cos(pi)
15
>>> from sympy import cos  # reimport to restore normal behavior
```

To get a full list of all default names in SymPy do:

```python
>>> import sympy
>>> dir(sympy)
# A big list of all default sympy names and functions follows.
# Ignore everything that starts and ends with __.
```

If you have IPython installed and use `isympy`, you can also press the TAB key to get a list of all built-in names and to autocomplete. Also, see this page for a trick for getting tab completion in the regular Python console.

**Note:** See also What is the best way to create symbols? in the FAQ.

### Functions

A function like `f(x)` can be created by defining the Function and the variable:

```python
>>> from sympy import Function
>>> f = Function('f')
>>> x = Symbol('x')
>>> f(x)
f(x)
```

If you assign `f(x)` to a Python variable `f` you will lose your ability to copy and paste that function or to create a function with a different argument: `Function('f')` is callable, but `Function('f')(x)` is not:
4.1.4 Symbolic Expressions

Python numbers vs. SymPy Numbers

SymPy uses its own classes for integers, rational numbers, and floating point numbers instead of the default Python int and float types because it allows for more control. But you have to be careful. If you type an expression that just has numbers in it, it will default to a Python expression. Use the `sympify()` (page 970) function, or just `S` (page 1914), to ensure that something is a SymPy expression.

```python
>>> 6.2  # Python float. Notice the floating point accuracy problems.
6.2000000000000002
>>> type(6.2)  # <type 'float'> in Python 2.x, <class 'float'> in Py3k
<... 'float'>
>>> S(6.2)  # SymPy Float has no such problems because of arbitrary precision.
6.2000000000000
>>> type(S(6.2))
<class 'sympy.core.numbers.Float'>
```

If you include numbers in a SymPy expression, they will be sympified automatically, but there is one gotcha you should be aware of. If you do `<number>/<number>` inside of a SymPy expression, Python will evaluate the two numbers before SymPy has a chance to get to them. The solution is to `sympify()` (page 970) one of the numbers, or use `Rational` (page 1036).

```python
>>> x**(1/2)  # evaluates to x**0 or x**0.5
x**0.5
>>> x**(S(1)/2)  # sympify one of the ints
sqrt(x)
>>> x**Rational(1, 2)  # use the Rational class
sqrt(x)
```

With a power of 1/2 you can also use `sqrt` shorthand:

```python
>>> sqrt(x) == x**Rational(1, 2)
True
```
If the two integers are not directly separated by a division sign then you don’t have to worry about this problem:

```python
>>> x**(2*x/3)
```

Note: A common mistake is copying an expression that is printed and reusing it. If the expression has a `Rational` (page 1036) (i.e., `<number>/<number>`) in it, you will not get the same result, obtaining the Python result for the division rather than a SymPy Rational.

```python
>>> x = Symbol('x')
>>> print(solve(7*x - 22, x))
[22/7]
>>> 22/7  # If we just copy and paste we get int 3 or a float
3.142857142857143
>>> # One solution is to just assign the expression to a variable
>>> # If we need to use it again.
>>> a = solve(7*x - 22, x)[0]
>>> a
22/7

The other solution is to put quotes around the expression and run it through S() (i.e., sympify it):

```python
>>> S("22/7")
22/7
```

Also, if you do not use `isympy`, you could use from `__future__` import division to prevent the / sign from performing integer division.

```python
>>> from __future__ import division
>>> 1/2  # With division imported it evaluates to a python float
0.5
>>> 1//2  # You can still achieve integer division with //
0
```

But be careful: you will now receive floats where you might have desired a Rational:

```python
>>> x**(1/2)
```

`Rational` (page 1036) only works for number/number and is only meant for rational numbers. If you want a fraction with symbols or expressions in it, just use /. If you do number/expression or expression/number, then the number will automatically be converted into a SymPy Number. You only need to be careful with number/number.

```python
>>> Rational(2, x)
Traceback (most recent call last):
  ...TypeError: invalid input: x
>>> 2/x
2/x
```
Evaluating Expressions with Floats and Rationals

SymPy keeps track of the precision of Float objects. The default precision is 15 digits. When an expression involving a Float is evaluated, the result will be expressed to 15 digits of precision but those digits (depending on the numbers involved with the calculation) may not all be significant.

The first issue to keep in mind is how the Float is created: it is created with a value and a precision. The precision indicates how precise of a value to use when that Float (or an expression it appears in) is evaluated.

The values can be given as strings, integers, floats, or rationals.

- strings and integers are interpreted as exact
  ```python
  >>> Float(100)
  100.000000000000
  >>> Float('100', 5)
  100.0
  ```

- to have the precision match the number of digits, the null string can be used for the precision
  ```python
  >>> Float(100, '')
  100.
  >>> Float('12.34')
  12.3400000000000
  >>> Float('12.34', '')
  12.34
  ```

Next, notice that each of those values looks correct to 3 digits. But if we try to evaluate them to 20 digits, a difference will become apparent:

The 0.25 (with precision of 3) represents a number that has a non-repeating binary decimal; 1/7 is repeating in binary and decimal – it cannot be represented accurately too far past those first 3 digits (the correct decimal is a repeating 142857):

```python
>>> s, r = [Float(j, 3) for j in ('0.25', Rational(1, 7))]
>>> for f in [s, r]:
...     print(f)
0.250
0.143
``` 

It is important to realize that although a Float is being displayed in decimal at arbitrary precision, it is actually stored in binary. Once the Float is created, its binary information is set at the given precision. The accuracy of that value cannot be subsequently changed; so 1/7, at a precision of 3 digits, can be padded with binary zeros, but these will not make it a more accurate value of 1/7.

If inexact, low-precision numbers are involved in a calculation with higher precision values, the evalf engine will increase the precision of the low precision values and inexact results will be obtained. This is feature of calculations with limited precision:
Although the `evalf` engine tried to maintain 10 digits of precision (since that was the highest precision represented) the 3-digit precision used limits the accuracy to about 4 digits - not all the digits you see are significant. `evalf` doesn’t try to keep track of the number of significant digits.

That very simple expression involving the addition of two numbers with different precisions will hopefully be instructive in helping you understand why more complicated expressions (like trig expressions that may not be simplified) will not evaluate to an exact zero even though, with the right simplification, they should be zero. Consider this unsimplified trig identity, multiplied by a big number:

```python
big = 12345678901234567890
big_trig_identity = big*cos(x)**2 + big*sin(x)**2 - big*1
abs(big_trig_identity.subs(x, .1).n(2)) > 1000
```

When the cos and sin terms were evaluated to 15 digits of precision and multiplied by the big number, they gave a large number that was only precise to 15 digits (approximately) and when the 20 digit big number was subtracted the result was not zero.

There are three things that will help you obtain more precise numerical values for expressions:

1) Pass the desired substitutions with the call to evaluate. By doing the subs first, the `Float` values cannot be updated as necessary. By passing the desired substitutions with the call to `evalf` the ability to re-evaluate as necessary is gained and the results are impressively better:

```python
big_trig_identity.n(2, {x: 0.1})
```

2) Use Rationals, not Floats. During the evaluation process, the Rational can be computed to an arbitrary precision while the Float, once created - at a default of 15 digits - cannot. Compare the value of -1.4e+3 above with the nearly zero value obtained when replacing x with a Rational representing 1/10 - before the call to evaluate:

```python
big_trig_identity.subs(x, S('1/10')).n(2)
```

3) Try to simplify the expression. In this case, SymPy will recognize the trig identity and simplify it to zero so you don’t even have to evaluate it numerically:
Immutability of Expressions

Expressions in SymPy are immutable, and cannot be modified by an in-place operation. This means that a function will always return an object, and the original expression will not be modified. The following example snippet demonstrates how this works:

```python
def main():
    var('x y a b')
    expr = 3*x + 4*y
    print('original =', expr)
    expr_modified = expr.subs({x: a, y: b})
    print('modified =', expr_modified)

if __name__ == '__main__':
    main()
```

The output shows that the `subs()` function has replaced variable x with variable a, and variable y with variable b:

```
original = 3*x + 4*y
modified = 3*a + 4*b
```

The `subs()` function does not modify the original expression `expr`. Rather, a modified copy of the expression is returned. This returned object is stored in the variable `expr_modified`. Note that unlike C/C++ and other high-level languages, Python does not require you to declare a variable before it is used.

Mathematical Operators

SymPy uses the same default operators as Python. Most of these, like */+-, are standard. Aside from integer division discussed in Python numbers vs. SymPy Numbers (page 194) above, you should also be aware that implied multiplication is not allowed. You need to use * whenever you wish to multiply something. Also, to raise something to a power, use **, not ^ as many computer algebra systems use. Parentheses () change operator precedence as you would normally expect.

In isympy, with the ipython shell:

```
>>> 2*x
Traceback (most recent call last):
  ...
SyntaxError: invalid syntax
>>> 2*x
2*x
>>> (x + 1)^2  # This is not power. Use ** instead.
Traceback (most recent call last):
  ...
TypeError: unsupported operand type(s) for ^: 'Add' and 'int'
>>> (x + 1)**2
(x + 1)**2
>>> pprint(3 - x**2/(x + 1))
    2*x
    x
```

(continues on next page)
Inverse Trig Functions

SymPy uses different names for some functions than most computer algebra systems. In particular, the inverse trig functions use the python names of \texttt{asin} (page 454), \texttt{acos} (page 455) and so on instead of the usual \texttt{arcsin} and \texttt{arccos}. Use the methods described in \textit{Symbols} (page 192) above to see the names of all SymPy functions.

\textbf{Sqrt is not a Function}

There is no \texttt{sqrt} function in the same way that there is an exponential function (\texttt{exp}). \texttt{sqrt(x)} is used to represent \texttt{Pow(x, S(1)/2)} so if you want to know if an expression has any square roots in it, \texttt{expr.has(sqrt)} will not work. You must look for \texttt{Pow} with an exponent of one half (or negative one half if it is in a denominator; e.g.

\begin{verbatim}
>>> (y + sqrt(x)).find(Wild('w')**S.Half)
{sqrt(x)}
>>> (y + 1/sqrt(x)).find(Wild('w')**-S.Half)
{1/sqrt(x)}
\end{verbatim}

If you are interested in any power of the \texttt{sqrt} then the following pattern would be appropriate

\begin{verbatim}
>>> sq = lambda s: s.is_Pow and s.exp.is_Rational and s.exp.q == 2
>>> (y + sqrt(x)**3).find(sq)
{x**(3/2)}
\end{verbatim}

4.1.5 Special Symbols

The symbols [], {}, =, and () have special meanings in Python, and thus in SymPy. See the Python docs linked to above for additional information.

Lists

Square brackets [] denote a list. A list is a container that holds any number of different objects. A list can contain anything, including items of different types. Lists are mutable, which means that you can change the elements of a list after it has been created. You access the items of a list also using square brackets, placing them after the list or list variable. Items are numbered using the space before the item.

\textbf{Note:} List indexes begin at 0.

Example:
>>> a = [x, 1] # A simple list of two items
>>> a
[x, 1]
>>> a[0] # This is the first item
x
>>> a[0] = 2 # You can change values of lists after they have been created
>>> print(a)
[2, 1]
>>> print(solve(x**2 + 2*x - 1, x)) # Some functions return lists
[-1 + sqrt(2), -sqrt(2) - 1]

Note: See the Python docs for more information on lists and the square bracket notation for accessing elements of a list.

Dictionaries

Curly brackets {} denote a dictionary, or a dict for short. A dictionary is an unordered list of non-duplicate keys and values. The syntax is {key: value}. You can access values of keys using square bracket notation.

>>> d = {'a': 1, 'b': 2} # A dictionary.
>>> d
{'a': 1, 'b': 2}
>>> d['a'] # How to access items in a dict
1
>>> roots((x - 1)**2*(x - 2), x) # Some functions return dicts
{1: 2, 2: 1}
>>> # Some SymPy functions return dictionaries. For example,
>>> # roots returns a dictionary of root:multiplicity items.
>>> roots((x - 5)**2*(x + 3), x)
{3: 1, 5: 2}
>>> # This means that the root -3 occurs once and the root 5 occurs twice.

Note: See the Python docs for more information on dictionaries.

Tuples

Parentheses (), aside from changing operator precedence and their use in function calls, (like cos(x)), are also used for tuples. A tuple is identical to a list (page 199), except that it is not mutable. That means that you cannot change their values after they have been created. In general, you will not need tuples in SymPy, but sometimes it can be more convenient to type parentheses instead of square brackets.

>>> t = (1, 2, x) # Tuples are like lists
>>> t
(1, 2, x)
>>> t[0]
Single element tuples, unlike lists, must have a comma in them:

```python
>>> (x,)
(x,)
```

Without the comma, a single expression without a comma is not a tuple:

```python
>>> (x)
x
```

integrate takes a sequence as the second argument if you want to integrate with limits (and a tuple or list will work):

```python
>>> integrate(x**2, (x, 0, 1))
1/3
>>> integrate(x**2, [x, 0, 1])
1/3
```

**Note:** See the Python docs for more information on tuples.

### Keyword Arguments

Aside from the usage described *above* (page 189), equals signs (=) are also used to give named arguments to functions. Any function that has key=value in its parameters list (see below on how to find this out), then key is set to value by default. You can change the value of the key by supplying your own value using the equals sign in the function call. Also, functions that have ** followed by a name in the parameters list (usually **kwargs or **assumptions) allow you to add any number of key=value pairs that you want, and they will all be evaluated according to the function.

sqrt(x**2) doesn’t auto simplify to x because x is assumed to be complex by default, and, for example, sqrt((-1)**2) == sqrt(1) == 1 != -1:

```python
>>> sqrt(x**2)
sqrt(x**2)
```

Giving assumptions to Symbols is an example of using the keyword argument:

```python
>>> x = Symbol('x', positive=True)
```

The square root will now simplify since it knows that x >= 0:

```python
>>> sqrt(x**2)
x
```
powsimp has a default argument of combine='all':

```
>>> pprint(powsimp(x**n*x**m*y**n*y**m))
  m + n
(x*y)
```

Setting combine to the default value is the same as not setting it.

```
>>> pprint(powsimp(x**n*x**m*y**n*y**m, combine='all'))
  m + n
(x*y)
```

The non-default options are 'exp', which combines exponents...

```
>>> pprint(powsimp(x**n*x**m*y**n*y**m, combine='exp'))
  m + n
x * y
```

...and 'base', which combines bases.

```
>>> pprint(powsimp(x**n*x**m*y**n*y**m, combine='base'))
  m * n
(x*y) * (x*y)
```

**Note:** See the Python docs for more information on function parameters.

### 4.1.6 Getting help from within SymPy

`help()`

Although all docs are available at [docs.sympy.org](https://docs.sympy.org) or on the SymPy Wiki, you can also get info on functions from within the Python interpreter that runs SymPy. The easiest way to do this is to do `help(function), or function? if you are using ipython:

```
In [1]: help(powsimp)  # help() works everywhere
In [2]: # But in ipython, you can also use ?, which is better because it
In [3]: # it gives you more information
In [4]: powsimp?
```

These will give you the function parameters and docstring for `powsimp()` (page 736). The output will look something like this:

```
sympy.simplify.simplify.powsimp(expr, deep=False, combine='all', force=False,
measure=<function count_ops>)
```

Reduce expression by combining powers with similar bases and exponents.
Explanation

If deep is True then powsimp() will also simplify arguments of functions. By default deep is set to False.

If force is True then bases will be combined without checking for assumptions, e.g. \(\sqrt{x} \cdot \sqrt{y} \rightarrow \sqrt{x \cdot y}\) which is not true if \(x\) and \(y\) are both negative.

You can make powsimp() only combine bases or only combine exponents by changing combine='base' or combine='exp'. By default, combine='all', which does both. combine='base' will only combine:

\[
\begin{align*}
\text{a a a} & \rightarrow (x^y) \quad \text{as well as things like} \quad 2 \rightarrow 4
\end{align*}
\]

and combine='exp' will only combine

\[
\begin{align*}
\text{a b} \rightarrow (a + b) \\
x \cdot x & \rightarrow x
\end{align*}
\]

combine='exp' will strictly only combine exponents in the way that used to be automatic. Also use deep=True if you need the old behavior.

When combine='all', 'exp' is evaluated first. Consider the first example below for when there could be an ambiguity relating to this. This is done so things like the second example can be completely combined. If you want 'base' combined first, do something like powsimp(powsimp(expr, combine='base'), combine='exp').

Examples

```python
>>> from sympy import powsimp, exp, log, symbols
>>> from sympy.abc import x, y, z, n

>>> powsimp(x**y*x**z*y**z, combine='all')
(x**(y + z)*y**z)

>>> powsimp(x**y*x**z*y**z, combine='exp')
(x**(y + z)*y**z)

>>> powsimp(x**y*x**z*y**z, combine='base', force=True)
(x**(y + z)*y**z)

>>> powsimp(x**z*x**y*n**z*n**y, combine='all', force=True)
(n*x)**(y + z)

>>> powsimp(x**z*x**y*n**z*n**y, combine='exp')
n**(y + z)*x**(y + z)

>>> powsimp(x**z*x**y*n**z*n**y, combine='base', force=True)
(n*x)**y*(n*x)**z

>>> x, y = symbols('x y', positive=True)

>>> powsimp(log(exp(x)*exp(y)))
log(exp(x)*exp(y))

>>> powsimp(log(exp(x)*exp(y)), deep=True)
x + y
```

Radicals with Mul bases will be combined if combine='exp'
Two radicals are automatically joined through Mul:

```python
>>> a = sqrt(x * sqrt(y))
>>> a * a**3 == a**4
True
```

But if an integer power of that radical has been autoexpanded then Mul does not join the resulting factors:

```python
>>> a**4  # auto expands to a Mul, no longer a Pow
x**2*y
>>> a  # so Mul doesn't combine them
x**2*y*sqrt(x*sqrt(y))
>>> powsimp(_))  # but powsimp will
(x*sqrt(y))**(5/2)
>>> powsimp(x**y*a)  # but won't when doing so would violate assumptions
x*y*sqrt(x*sqrt(y))
```

### 4.2 Solve Output by Type

The output of the `solve()` function can seem very unwieldy since it may appear to arbitrarily return one of six different types of output (in addition to raising errors). The reasons for this are historical and are biased toward human interaction rather than programmatic use. The type of output will depend on the type of equation(s) (and how they are entered) and the number of symbols that are provided (and how they are provided).

```python
>>> from sympy import sqrt, exp, solve, Symbol, Eq
>>> from sympy.abc import x, y, z, a, b
```

The `solve()` function attempts to find all values for as many symbols as possible that will make each expression given equal to zero. The format of the output can be controlled by using the `dict` or `set` keyword:

```python
>>> solve(x - 1, dict=True)
{x: 1}
>>> solve([x**2 - y, x + y - 6], set=True)
([x, y], {(-3, 9), (2, 4)})
```

The following discussion provides an explanation for the output obtained when not using those keywords.
4.2.1 Empty List

When there is no solution, an empty list is returned.

```python
>>> solve(sqrt(x) + 1)  # or solve(sqrt(x) + 1, dict=True)
[]
>>> solve(sqrt(x) + 1, set=True)
([x], set())
```

4.2.2 List Of Values

A list of values is given when the symbol to solve for was unambiguous in context because a) the equation was univariate or b) a single symbol was specified as being of interest.

```python
>>> solve(x**2 - 4)
[-2, 2]
>>> solve(x - y - 1, x)
[y + 1]
```

4.2.3 Single Dictionary

A single dictionary with keys being symbols and values being the solutions for those symbols is the result when equations are passed as a list and are all linear in the symbols given. Note: such a system is automatically generated for a single equation (not passed as a list) if there is an undetermined-coefficients solution for the symbols specified. If this is not what was intended, then pass the expression in a list.

```python
>>> solve([x + y - 2, x - y + 2], x, y)
{x: 0, y: 2}
>>> eq = a*x - 2*x + b - 5
>>> solve(eq, {a, b})  # undetermined coefficients
{a: 2, b: 5}
>>> solve([eq], {a, b})  # algebraic
{a: -b/x + (2*x + 5)/x}
```

4.2.4 List of Tuples

Each tuple in the list gives a solution for the symbols in the order they were given. This format is used when a) a list of equations contains at least one nonlinear equation or b) a list of symbols is given in a well defined order. (This is also the format for the tuples in the set returned when using the flag set=True.)

```python
>>> solve(x - 1, x, y)  # more than one symbol
[(1, y)]
>>> solve([x**2], x)  # list with nonlinear equation
[(0,)]
>>> solve([x**2 - 1], x)
[(-1,), (1,)]
```

(continues on next page)
>>> solve([x**2 - y, x - 3], x, y)  # nonlinear and multiple symbols
[(3, 9)]

### 4.2.5 List of Dictionaries

The list of dictionaries is returned when the expression was not univariate or there was a nonlinear expression in a list and the order of symbols would otherwise be ambiguous because a) no symbols were passed or b) the symbols were passed as a set. (This is also the format selected with dict=True.)

```python
>>> solve(x - y)
[{x: y}]
>>> solve([exp(x) - 1, x*(x - 1)])
[\{x: 0\}]
>>> system = [x + y - z, x**2 - y + z, exp(z) + 1/x + 1/y - 2]
>>> sol = solve(system[:2]); sol
[{x: -1, y: z + 1}, {x: 0, y: z}]
```

The dictionaries only contain values that are distinct from the keys. In the last example above, there is no key for z in the dictionary since only two of the three equations were insufficient to determine its value. These solutions can be used to eliminate those variables from the third equation, however, to give a relationship in a single variable that can be solved (perhaps numerically) to obtain a full solution with the advantage of only needing to guess a single value instead of three.

```python
>>> from sympy import nsolve
>>> [system[-1].subs(s) for s in sol]
[exp(z) - 3 + 1/(z + 1), exp(z) + zoo + 1/z]
>>> z_eq = [0]
>>> zsol = nsolve(z_eq, 1); zsol
0.906425478894557
>>> sol0 = {k: v.subs(z, zsol) for k, v in sol[0].items()}
>>> sol0[z] = zsol; sol0
{x: -1, y: 1.90642547889456, z: 0.906425478894557}
```

### 4.2.6 Boolean or Relational

A boolean expression is returned when a relational expression other than an Equality (page 1071) is given as an expression to solve. A single Equality or a more complicated relational expression might be returned. The use of `solve()` (page 882) here is equivalent to passing the equation set and symbols to `reduce_inequalities()` (page 805) (and dict, set, and check flags are ignored).

```python
>>> solve([x**2 > 4, x > 0])
(2 < x) & (x < oo)
>>> from sympy import Unequality as Ne
>>> solve([x**2 - 4, Ne(x, -2)])
Eq(x, 2)
```
Any returned *Equality* can be converted to a dictionary:

```python
>>> {_.lhs: _.rhs}
{x: 2}
```

## 4.3 SymPy Special Topics

The purpose of this collection of documents is to provide users of SymPy with topics which are not strictly tutorial or are longer than tutorials and tests. The documents will hopefully fill a gap as SymPy matures and users find more ways to show how SymPy can be used in more advanced topics.

### 4.3.1 Finite Difference Approximations to Derivatives

**Introduction**

Finite difference approximations to derivatives is quite important in numerical analysis and in computational physics. In this tutorial we show how to use SymPy to compute approximations of varying accuracy. The hope is that these notes could be useful for the practicing researcher who is developing code in some language and needs to be able to efficiently generate finite difference formulae for various approximations.

In order to establish notation, we first state that we envision that there exists a continuous function $F$ of a single variable $x$, with $F$ having as many derivatives as desired. We sample $x$ values uniformly at points along the real line separated by $h$. In most cases we want $h$ to be small in some sense. $F(x)$ may be expanded about some point $x_0$ via the usual Taylor series expansion. Let $x = x_0 + h$. Then the Taylor expansion is

$$
F(x_0 + h) = F(x_0) + \left( \frac{dF}{dx} \right)_{x_0} h + \frac{1}{2!} \left( \frac{d^2F}{dx^2} \right)_{x_0} h^2 + \frac{1}{3!} \left( \frac{d^3F}{dx^3} \right)_{x_0} h^3 + \cdots
$$

In order to simplify the notation, we now define a set of coefficients $c_n$, where

$$
c_n := \frac{1}{n!} \left( \frac{d^n F}{dx^n} \right)_{x_0}.
$$

So now our series has the form:

$$
F(x_0 + h) = F(x_0) + c_1 h + c_2 h^2 + c_3 h^3 + \cdots
$$

In the following we will only use a finite grid of values $x_i$ with $i$ running from 1,...,$N$ and the corresponding values of our function $F$ at these grid points denoted by $F_i$. So the problem is how to generate approximate values for the derivatives of $F$ with the constraint that we use a subset of the finite set of pairs $(x_i, F_i)$ of size $N$.

What follows are manipulations using SymPy to formulate approximations for derivatives of a given order and to assess its accuracy. First, we use SymPy to derive the approximations by using a rather brute force method frequently covered in introductory treatments. Later we shall make use of other SymPy functions which get the job done with more efficiency.
A Direct Method Using SymPy Matrices

If we let \( x_0 = x_i \), evaluate the series at \( x_i + 1 = x_i + h \) and truncate all terms above \( O(h^1) \) we can solve for the single coefficient \( c_1 \) and obtain an approximation to the first derivative:

\[
\left( \frac{dF}{dx} \right)_{x_0} \approx \frac{F_{i+1} - F_i}{h} + O(h)
\]

where the \( O(h) \) refers to the lowest order term in the series in \( h \). This establishes that the derivative approximation is of first order accuracy. Put another way, if we decide that we can only use the two pairs \((x_i, F_i)\) and \((x_{i+1}, F_{i+1})\) we obtain a “first order accurate” derivative.

In addition to \((x_i, F_i)\) we next use the two points \((x_{i+1}, F_{i+1})\) and \((x_{i+2}, F_{i+2})\). Then we have two equations:

\[
F_{i+1} = F_i + c_1 \cdot h + \frac{1}{2} \cdot c_2 \cdot h^2 + \frac{1}{3!} \cdot c_3 \cdot h^3 + \ldots
\]

\[
F_{i+2} = F_i + c_1 \cdot (2h) + \frac{1}{2} \cdot c_2 \cdot (2h)^2 + \frac{1}{3!} \cdot c_3 \cdot (2h)^3 + \ldots
\]

If we again want to find the first derivative \((c_1)\), we can do that by eliminating the term involving \( c_2 \) from the two equations. We show how to do it using SymPy.

```python
>>> from __future__ import print_function
>>> from sympy import *
>>> x, x0, h = symbols('x, x_0, h')
>>> Fi, Fip1, Fip2 = symbols('F_{i}, F_{i+1}, F_{i+2}')
>>> n = 3  # there are the coefficients c_0=F_i, c_1=dF/dx, c_2=d**2F/dx**2
>>> c = symbols('c:3')
>>> def P(x, x0, c, n):
...     return sum(((1/factorial(i))*c[i] * (x-x0)**i for i in range(n)) )

Vector of right hand sides:

```python
>>> R = Matrix([[Fi], [Fip1], [Fip2]])
```

Now we make a matrix consisting of the coefficients of the \( c_i \) in the nth degree polynomial \( P \).

Coefficient of \( c_i \) evaluated at \( x_i \):

```python
>>> m11 = P(x0 , x0, c, n).diff(c[0])
>>> m12 = P(x0 , x0, c, n).diff(c[1])
>>> m13 = P(x0 , x0, c, n).diff(c[2])
```

Coefficient of \( c_i \) evaluated at \( x_i + h \):

```python
>>> m21 = P(x0+h, x0, c, n).diff(c[0])
>>> m22 = P(x0+h, x0, c, n).diff(c[1])
>>> m23 = P(x0+h, x0, c, n).diff(c[2])
```

Coefficient of \( c_i \) evaluated at \( x_i + 2 \cdot h \):

```python
>>> m31 = P(x0+2*h, x0, c, n).diff(c[0])
>>> m32 = P(x0+2*h, x0, c, n).diff(c[1])
>>> m33 = P(x0+2*h, x0, c, n).diff(c[2])
```

Matrix of the coefficients is 3x3 in this case:
Matrix form of the three equations for the $c_i$ is $M \times X = R$:

The solution is obtained by directly inverting the 3x3 matrix $M$:

```python
>>> X = M.inv() * R
```

Note that all three coefficients make up the solution. The desired first derivative is coefficient $c_1$ which is $X[1]$.

```python
>>> print(together(X[1]))
(4*F_{i+1} - F_{i+2} - 3*F_{i})/(2*h)
```

It is instructive to compute another three-point approximation to the first derivative, except centering the approximation at $x_i$, and thus using points at $x_{i-1}$, $x_i$, and $x_{i+1}$. So here is how this can be done using the ‘brute force’ method:

```python
from __future__ import print_function
from sympy import *

x, x0, h = symbols('x, x_i, h')
Fi, Fim1, Fip1 = symbols('F_{i}, F_{i-1}, F_{i+1}')
n = 3 # there are the coefficients c_0=F_i, c_1=dF/h, c_2=d^2F/h^2

c = symbols('c:3')
# define a polynomial of degree n
# coefficients of c_i evaluated at x_i
m11 = P(x0 , x0, c, n).diff(c[0])
m12 = P(x0 , x0, c, n).diff(c[1])
m13 = P(x0 , x0, c, n).diff(c[2])
# coefficients of c_i evaluated at x_i - h
m21 = P(x0-h, x0, c, n).diff(c[0])
m22 = P(x0-h, x0, c, n).diff(c[1])
m23 = P(x0-h, x0, c, n).diff(c[2])
# coefficients of c_i evaluated at x_i + h
m31 = P(x0+h, x0, c, n).diff(c[0])
m32 = P(x0+h, x0, c, n).diff(c[1])
m33 = P(x0+h, x0, c, n).diff(c[2])
# matrix of the coefficients is 3x3 in this case
M = Matrix([[m11, m12, m13], [m21, m22, m23], [m31, m32, m33]])

Now that we have the matrix of coefficients we next form the right-hand-side and solve by inverting $M$:

```python
>>> R = Matrix([[Fi], [Fim1], [Fip1]])
# matrix form of the three equations for the c_i is M*X = R
# solution directly inverting the 3x3 matrix M:
X = M.inv() * R
# note that all three coefficients make up the solution
# the first derivative is coefficient c_1 which is X[1].
```
The second-order accurate approximation for the first derivative is:

\[
\frac{F_{i+1} - F_{i-1}}{2h}
\]

These two examples serve to show how one can directly find second order accurate first derivatives using SymPy. The first example uses values of \(x\) and \(F\) at all three points \(x_i, x_{i+1},\) and \(x_{i+2}\) whereas the second example only uses values of \(x\) at the two points \(x_{i-1}\) and \(x_{i+1}\) and thus is a bit more efficient.

From these two simple examples a general rule is that if one wants a first derivative to be accurate to \(O(h^n)\) then one needs \(n+1\) function values in the approximating polynomial (here provided via the function \(P(x, x_0, c, n)\)).

Now let’s assess the question of the accuracy of the centered difference result to see how we determine that it is really second order. To do this we take the result for \(dF/dx\) and substitute in the polynomial expansion for a higher order polynomial and see what we get. To this end, we make a set of eight coefficients \(d\) and use them to perform the check:

\[
\text{dfdxcheck} = \frac{P(x_0 + h, x_0, d, 8) - P(x_0 - h, x_0, d, 8)}{2h}
\]

Thus we see that indeed the derivative is \(c_1\) with the next term in the series of order \(h^2\).

However, it can quickly become rather tedious to generalize the direct method as presented above when attempting to generate a derivative approximation to high order, such as 6 or 8 although the method certainly works and using the present method is certainly less tedious than performing the calculations by hand.

As we have seen in the discussion above, the simple centered approximation for the first derivative only uses two point values of the \((x_i, F_i)\) pairs. This works fine until one encounters the last point in the domain, say at \(i = N\). Since our centered derivative approximation would use data at the point \((x_{N+1}, F_{N+1})\) we see that the derivative formula will not work. So, what to do? Well, a simple way to handle this is to devise a different formula for this last point which uses points for which we do have values. This is the so-called backward difference formula. To obtain it, we can use the same direct approach, except now we the three points \((x_N, F_N)\), \((x_{N-1}, F_{N-1})\), and \((x_{N-2}, F_{N-2})\) and center the approximation at \((x_N, F_N)\). Here is how it can be done using SymPy:

```python
>>> from __future__ import print_function
>>> from symy import *
>>> x, xN, h = symbols('x, x_N, h')
>>> FN, FNm1, FNm2 = symbols('F_{N}, F_{N-1}, F_{N-2}')
>>> n = 8 # there are the coefficients c_0=F1, c_1=dF/h, c_2=d**2F/h**2
>>> c = symbols('c:8')
>>> # define a polynomial of degree d
>>> def P(x, x0, c, n):
...     return sum(((i/factorial(i))*c[i] * (x-x0)**i for i in range(n)) )
```

Now we make a matrix consisting of the coefficients of the \(c_i\) in the dth degree polynomial \(P\) coefficients of \(c_i\) evaluated at \(x_i, x_{i-1},\) and \(x_{i+1}\):
Next we construct the $3 \times 3$ matrix of the coefficients:

```python
>>> M = Matrix([[m11, m12, m13], [m21, m22, m23], [m31, m32, m33]])
```

Then we invert $M$ and write the solution to the $3 \times 3$ system.

The matrix form of the three equations for the $c_i$ is $M \cdot C = R$. The solution is obtained by directly inverting $M$:

```python
>>> X = M.inv() * R
```

The first derivative is coefficient $c_1$ which is $X[1]$. Thus the second order accurate approximation for the first derivative is:

```python
>>> print("The first derivative centered at the last point on the right is:"))
```

```python
>>> print(together(X[1]))
```

```python
(-4*F_{N-1} + F_{N-2} + 3*F_{N})/(2*h)
```

Of course, we can devise a similar formula for the value of the derivative at the left end of the set of points at $(x_1, F_1)$ in terms of values at $(x_2, F_2)$ and $(x_3, F_3)$.

Also, we note that output of formats appropriate to Fortran, C, etc. may be done in the examples given above.

Next we show how to perform these and many other discretizations of derivatives, but using a much more efficient approach originally due to Bengt Fornberg and now incorporated into SymPy.

**Finite differences** (page 46)

**Finite difference weights** (page 294)
4.3.2 Classification of SymPy objects

There are several ways of how SymPy object is classified.

class

Like any other object in Python, SymPy expression is an instance of class. You can get the class of the object with built-in \texttt{type()} function, and check it with \texttt{isinstance()} function.

```
>>> from sympy import Add
>>> from sympy.abc import x,y
>>> type(x + y)
<class 'sympy.core.add.Add'>
>>> isinstance(x + y, Add)
True
```

Classes represent only the programmatic structures of the objects, and does not distinguish the mathematical difference between them. For example, the integral of number and the integral of matrix both have the class \texttt{Integral}, although the former is number and the latter is matrix.

```
>>> from sympy import MatrixSymbol, Integral
>>> A = MatrixSymbol('A', 2, 2)
>>> type(Integral(1, x))
<class 'sympy.integrals.integrals.Integral'>
>>> type(Integral(A, x))
<class 'sympy.integrals.integrals.Integral'>
```

kind

Kind indicates what mathematical object does the expression represent. You can retrieve the kind of expression with \texttt{kind} property.

```
>>> Integral(1, x).kind
NumberKind
>>> Integral(A, x).kind
MatrixKind(NumberKind)
```

This result shows that \texttt{Integral(1,x)} is number, and \texttt{Integral(A,x)} is matrix with number element.

Since the class cannot guarantee to catch this difference, kind of the object is very important. For example, if you are building a function or class that is designed to work only for numbers, you should consider filtering the arguments with \texttt{NumberKind} so that the user does not naively pass unsupported objects such as \texttt{Integral(A,x)}.

For the performance, set theory is not implemented in kind system. For example, \texttt{NumberKind} does not distinguish the real number and complex number.

```
>>> from sympy import pi, I
>>> pi.kind
NumberKind
```
SymPy’s `Set` and `kind` are not compatible.

```python
>>> from sympy import S
>>> from sympy.core.kind import NumberKind
>>> S.Reals.is_subset(S.Complexes)
True
>>> S.Reals.is_subset(NumberKind)
Traceback (most recent call last):
... ValueError: Unknown argument 'NumberKind'
```

### sets and assumptions

If you want to classify the object in strictly mathematical way, you may need SymPy’s `sets` and `assumptions`.

```python
>>> from sympy import ask, Q
>>> S.One in S.Reals
True
>>> ask(Q.even(2*x), Q.odd(x))
True
```

See `assumptions` module and `sets` module for more information.

### func

`func` is the head of the object, and it is used to recurse over the expression tree.

```python
>>> Add(x + y).func
<class 'sympy.core.add.Add'>
>>> Add(x + x).func
<class 'sympy.core.mul.Mul'>
>>> Q.even(x).func
<class 'sympy.assumptions.assume.AppliedPredicate'>
```

As you can see, resulting head may be a class or another SymPy object. Keep this in mind when you classify the object with this attribute. See `Advanced Expression Manipulation` (page 61) for detailed information.
4.4 List of active deprecations

This page lists all active deprecations in the SymPy codebase. See the *Deprecation Policy* (page 3101) page for a description of SymPy's deprecation policy, as well as instructions for contributors on how to deprecate things.

In particular, the deprecation policy for SymPy is for deprecations to last at least 1 year after the first major release that includes the deprecation. After that period, the deprecated functionality may be removed from SymPy, and code will need to be updated to use the replacement feature to continue working.

During the deprecation period, a `SymPyDeprecationWarning` message will be printed whenever the deprecated functionality is used. It is recommended for users to update their code so that it does not use deprecated functionality, as described below for each given deprecation.

4.4.1 Silencing SymPy Deprecation Warnings

To silence SymPy deprecation warnings, add a filter using the `warnings` module. For example:

```python
import warnings
from sympy.utilities.exceptions import SymPyDeprecationWarning

warnings.filterwarnings(
    # replace "ignore" with "error" to make the warning raise an exception.
    # This useful if you want to test you aren't using deprecated code.
    "ignore",

    # message may be omitted to filter all SymPyDeprecationWarnings
    message=r"(?s).*<regex matching the warning message>",

    category=SymPyDeprecationWarning,
    module=r"<regex matching your module>"
)
```

Here (?s).*<regex matching the warning message> is a regular expression matching the warning message. For example, to filter a warning about `sympy.printing`, you might use `message=r"(?s).*sympy\.printing"`. The leading (?s).* is there because the warnings module matches `message` against the start of the warning message, and because typical warning messages span multiple lines.

<regex matching your module> should be a regular expression matching your module that uses the deprecated code. It is recommended to include this so that you don't also silence the same warning for unrelated modules.

This same pattern may be used to instead turn `SymPyDeprecationWarning` into an error so that you can test that you aren't using deprecated code. To do this, replace "ignore" with "error" in the above example. You may also omit `message` to make this apply to all `SymPyDeprecationWarning` warnings.

If you are using pytest, you can use the `pytest warnings filtering capabilities` to either ignore `SymPyDeprecationWarning` or turn them into errors.

**Note:** The Python `-W` flag and `PYTHONWARNINGS` environment variable will NOT work to filter SymPy deprecation warnings (see this blog post by Ned Batchelder and this SymPy issue for
details on why). You will need to either add a warnings filter as above or use pytest to filter SymPy deprecation warnings.

4.4.2 Version 1.12

The ManagedProperties metaclass

The ManagedProperties metaclass was previously the metaclass for Basic. Now Basic does not use metaclasses and so its metaclass is just type. Any code that previously subclassed Basic and wanted to do anything with metaclasses would have needed to subclass ManagedProperties to make the relevant metaclass. The only relevant method of ManagedProperties has been moved to Basic.__init_subclass__. Since ManagedProperties is not used as the metaclass for Basic any more and no longer does anything useful it should be possible for such code to just subclass type instead for any metaclass.

New Joint coordinate format

The format, i.e. type and auto generated name, of the generalized coordinates and generalized speeds of the joints in the sympy.physics.mechanics module has changed. The data type has changed from list to Matrix, which is the same as the type for the generalized coordinates within the KanesMethod. The auto naming of the generalized coordinates and generalized speeds of the PinJoint and PrismaticJoint have also changed to q_<joint.name> and u_<joint.name>. Previously each of those joints had an unique template for auto generating these names.

New Joint intermediate frames

The definition of the joint axis in the sympy.physics.mechanics module has changed. Instead of using the arguments parent_axis and child_axis to automatically determine the joint axis and an intermediate reference frame, the joints now use an intermediate frame argument for both the parent and the child body, i.e. parent_interframe and child_interframe. This means that you can now fully define the joint attachment, consisting of a point and frame, for both bodies. Furthermore, if a joint like the PinJoint has a specific joint axis, e.g. the axis about which the rotation occurs, then this axis can be specified using the joint_axis argument. An advantage of this setup is that one can more accurately define the transformation from the parent body to the child body.

For example, suppose you want a PinJoint that rotates the child body about the parent.z axis and -child.z axis. The previous way to specify this joint was:

```python
>>> from sympy.physics.mechanics import Body, PinJoint
>>> parent, child = Body('parent'), Body('child')
>>> pin = PinJoint('pin', parent, child, parent_axis=parent.z,
...                child_axis=-child.z)
>>> parent.dcm(child)
Matrix(
    [[-cos(q_pin(t)), -sin(q_pin(t)), 0],
     [-sin(q_pin(t)), cos(q_pin(t)), 0],
     [ 0, 0, -1]])
```
When inspecting this matrix you will notice that for \( \theta_{\text{pin}} = 0 \) the child body is rotated \( \pi \) rad about the parent.y axis. In the new definition you can see that we get the same result, but this time we have also specified this exact rotation:

```python
>>> from sympy import pi
>>> from sympy.physics.mechanics import Body, PinJoint, ReferenceFrame
>>> parent, child, = Body('parent'), Body('child')
>>> int_frame = ReferenceFrame('int_frame')
>>> int_frame.orient_axis(child.frame, child.y, pi)
>>> pin = PinJoint('pin', parent, child, joint_axis=parent.z, child_interframe=int_frame)
>>> parent.dcm(child)
Matrix([[-cos(q_pin(t)), -sin(q_pin(t)), 0],
       [-sin(q_pin(t)), cos(q_pin(t)), 0],
       [ 0, 0, -1]])
```

However if you liked the fact that the deprecated arguments aligned the frames for you, then you can still make use of this feature by providing vectors to `parent_interframe` and `child_interframe`, which are then oriented such that the joint axis expressed in the intermediate frame is aligned with the given vector:

```python
>>> from sympy.physics.mechanics import Body, PinJoint
>>> parent, child, = Body('parent'), Body('child')
>>> pin = PinJoint('pin', parent, child, parent_interframe=parent.z, child_interframe=-child.z)
>>> parent.dcm(child)
Matrix([[-cos(q_pin(t)), -sin(q_pin(t)), 0],
       [-sin(q_pin(t)), cos(q_pin(t)), 0],
       [ 0, 0, -1]])
```

### Change in joint attachment point argument

The argument names for specifying the attachment points of a joint in `sympy.physics.mechanics`, i.e. `parent_joint_pos` and `child_joint_pos`, have been changed to `parent_point` and `child_point`. This is because these arguments can now also be `Point` objects, so they can be exactly the same as the `parent_point` and `child_point` attributes.

For example, suppose you want a PinJoint in the parent to be positioned at `parent.frame.x` with respect to the mass center, and in the child at `-child.frame.x`. The previous way to specify this was:

```python
>>> from sympy.physics.mechanics import Body, PinJoint
>>> parent, child, = Body('parent'), Body('child')
>>> pin = PinJoint('pin', parent, child, parent_joint_pos=parent.frame.x,
...               child_joint_pos=-child.frame.x)
>>> pin.parent_point.pos_from(parent.masscenter)
parent_frame.x
>>> pin.child_point.pos_from(child.masscenter)
- child_frame.x
```

Now you can do the same with either
>>> from sympy.physics.mechanics import Body, PinJoint
>>> parent, child = Body('parent'), Body('child')
>>> pin = PinJoint('pin', parent, child, parent_point=parent.frame.x,
...                child_point=-child.frame.x)
>>> pin.parent_point.pos_from(parent.masscenter)
parent_frame.x
>>> pin.child_point.pos_from(child.masscenter)
- child_frame.x

Or

>>> from sympy.physics.mechanics import Body, PinJoint, Point
>>> parent, child = Body('parent'), Body('child')
>>> parent_point = parent.masscenter.locatenew('parent_point', parent.frame.x)
>>> child_point = child.masscenter.locatenew('child_point', -child.frame.x)
>>> pin = PinJoint('pin', parent, child, parent_point=parent_point,
...                child_point=child_point)
>>> pin.parent_point.pos_from(parent.masscenter)
parent_frame.x
>>> pin.child_point.pos_from(child.masscenter)
- child_frame.x

4.4.3 Version 1.11

Modules sympy.tensor.array.expressions.conv_* renamed to sympy.tensor.array.expressions.from_*

In order to avoid possible naming and tab-completion conflicts with functions with similar names to the names of the modules, all modules whose name starts with conv_* in sympy.tensor.array.expressions have been renamed to from_*.

New Mathematica code parser

The old mathematica code parser defined in the module sympy.parsing.mathematica in the function mathematica is deprecated. The function parse_mathematica with a new and more comprehensive parser should be used instead.

The additional_translations parameter for the Mathematica parser is not available in parse_mathematica. Additional translation rules to convert Mathematica expressions into SymPy ones should be specified after the conversion using SymPy's .replace() or .subs() methods on the output expression. If the translator fails to recognize the logical meaning of a Mathematica expression, a form similar to Mathematica's full form will be returned, using SymPy's Function object to encode the nodes of the syntax tree.

For example, suppose you want F to be a function that returns the maximum value multiplied by the minimum value, the previous way to specify this conversion was:

>>> from sympy.parsing.mathematica import mathematica
>>> mathematica('F[7,5,3]', {'F[*x]': 'Max(*x)*Min(*x)'}
21

Now you can do the same with

4.4. List of active deprecations
from sympy.parsing.mathematica import parse_mathematica
from sympy import Function, Max, Min
>>> parse_mathematica("F[7,5,3]").replace(Function("F"), lambda *x: Max(*x)*Min(*x))
21

Redundant static methods in carmichael

A number of static methods in ~.carmichael are just wrappers around other functions. Instead of carmichael.is_perfect_square use sympy.ntheory.primetest.is_square and instead of carmichael.is_prime use ~.isprime. Finally, carmichael.divides can be replaced by instead checking

n % p == 0

The check argument to HadamardProduct, MatAdd and MatMul

This argument can be used to pass incorrect values to ~.HadamardProduct, ~.MatAdd, and ~.MatMul leading to later problems. The check argument will be removed and the arguments will always be checked for correctness, i.e., the arguments are matrices or matrix symbols.

4.4.4 Version 1.10

Some traversal functions have been moved

Some traversal functions have moved. Specifically, the functions

• bottom_up
• interactive_traversal
• postorder_traversal
• preorder_traversal
• use

have moved to different SymPy submodules.

These functions should be used from the top-level sympy namespace, like

sympy.preorder_traversal

or

from sympy import preorder_traversal

In general, end-users should use the top-level sympy namespace for any functions present there. If a name is in the top-level namespace, its specific SymPy submodule should not be relied on, as functions may move around due to internal refactorings.
**sympy.core.trace**

The trace object `sympy.core.trace.Tr()` was moved to `sympy.physics.quantum.trace.Tr()`. This was because it was only used in the `sympy.physics.quantum` submodule, so it was better to have it there than in the core.

**The sympy.core.compatibility submodule**

The `sympy.core.compatibility` submodule is deprecated.

This submodule was only ever intended for internal use. Now that SymPy no longer supports Python 2, this module is no longer necessary, and the remaining helper functions have been moved to more convenient places in the SymPy codebase.

Some of the functions that were in this module are available from the top-level SymPy namespace, i.e.,

```python
sympy.ordered
sympy.default_sort_key
```

or

```python
from sympy import ordered, default_sort_key
```

In general, end-users should use the top-level `sympy` namespace for any functions present there. If a name is in the top-level namespace, its specific SymPy submodule should not be relied on, as functions may move around due to internal refactorings.

The remaining functions in `sympy.core.compatibility` were only intended for internal SymPy use and should not be used by user code.

Additionally, these two functions, `ordered` and `default_sort_key`, also used to be in `sympy.utilities.iterables` but have been moved from there as well.

### 4.4.5 Version 1.9

**expr_free_symbols**

The `expr_free_symbols` attribute of various SymPy objects is deprecated.

`expr_free_symbols` was meant to represent indexed objects such as `MatrixElement` and `Indexed` (page 1449) as free symbols. This was intended to make derivatives of free symbols work. However, this now works without making use of the method:

```python
>>> from sympy import Indexed, MatrixSymbol, diff
>>> a = Indexed("A", 0)
>>> diff(a**2, a)
2*A[0]
>>> X = MatrixSymbol("X", 3, 3)
>>> diff(X[0, 0]**2, X[0, 0])
2*X[0, 0]
```

This was a general property that was added to solve a very specific problem but it added a layer of abstraction that is not necessary in general.
1. objects that have structural “non-expression” nodes already allow one to focus on the expression node if desired, e.g.

```python
>>> from sympy import Derivative, symbols, Function
>>> x = symbols('x')
>>> f = Function('f')
>>> Derivative(f(x), x).expr
f(x)
```

introduction of this property encourages imprecise thinking when requesting free_symbols since it allows one to get symbols from a specific node of an object without specifying the node

2. the property was incorrectly added to AtomicExpr so numbers are returned as expr_free_symbols:

```python
>>> S(2).expr_free_symbols
2
```

3. the application of the concept was misapplied to define Subs.expr_free_symbols: it added in expr_free_symbols of the point but the point is a Tuple so nothing was added

4. it was not used anywhere else in the codebase except in the context of differentiating a Subs object, which suggested that it was not something of general use, this is also confirmed by the fact that,

5. it was added without specific tests except for test of the derivatives of the Subs object for which it was introduced

See issue #21494 for more discussion.

**sympy.stats.sample(numsamples=n)**

The numsamples parameter to `sympy.stats.sample()` (page 3055) is deprecated. numsamples makes sample() return a list of size numsamples, like

```python
>>> from sympy.stats import Die, sample
>>> X = Die('X', 6)
>>> sample(X, numsamples=3)
[3, 2, 3]
```

However, this functionality can be easily implemented by the user with a list comprehension

```python
>>> [sample(X) for i in range(3)]
[5, 4, 3]
```

Additionally, it is redundant with the size parameter, which makes sample return a NumPy array with the given shape.

```python
>>> sample(X, size=(3,))
array([6, 6, 1])
```

Historically, sample was changed in SymPy 1.7 so it returned an iterator instead of sample value. Since an iterator was returned, a numsamples parameter was added to specify the length of the iterator.
However, this new behavior was considered confusing, as discussed in issue #21563, so it was reverted. Now, sample_iter should be used if a iterator is needed. Consequently, the numsamples parameter is no longer needed for sample().

**sympy.polys.solvers.RawMatrix**

The RawMatrix class is deprecated. The RawMatrix class was a subclass of Matrix that used domain elements instead of Expr as the elements of the matrix. This breaks a key internal invariant of Matrix and this kind of subclassing limits improvements to the Matrix class.

The only part of SymPy that documented the use of the RawMatrix class was the Smith normal form code, and that has now been changed to use DomainMatrix instead. It is recommended that anyone using RawMatrix with the previous Smith Normal Form code should switch to using DomainMatrix as shown in issue #21402. A better API for the Smith normal form will be added later.

**Non-Expr objects in a Matrix**

In SymPy 1.8 and earlier versions it was possible to put non-Expr elements in a Matrix and the matrix elements could be any arbitrary Python object:

```python
>>> M = Matrix([[1, 2], {'dict': None}])
```

This is not useful and does not really work, e.g.:

```python
>>> M + M
Traceback (most recent call last):
...    TypeError: unsupported operand type(s) for +: 'Dict' and 'Dict'
```

The main reason for making this possible was that there were a number of Matrix subclasses in the SymPy codebase that wanted to work with objects from the polys module, e.g.

1. RawMatrix (see above) was used in solve_lin_sys which was part of heurisch and was also used by smith_normal_form. The NewMatrix class used domain elements as the elements of the Matrix rather than Expr.

2. NewMatrix was used in the holonomic module and also used domain elements as matrix elements

3. PolyMatrix used a mix of Poly and Expr as the matrix elements and was used by risch.

All of these matrix subclasses were broken in different ways and the introduction of DomainMatrix provides a better solution for all cases. Previous PRs have removed the dependence of these other use cases on Matrix (#21441, #21427, #21402) and now #21496 has deprecated having non-Expr in a Matrix.

This change makes it possible to improve the internals of the Matrix class but it potentially impacts on some downstream use cases that might be similar to the uses of Matrix with non-Expr elements that were in the SymPy codebase. A potential replacement for code that used Matrix with non-Expr elements is DomainMatrix if the elements are something like domain elements and a domain object can be provided for them. Alternatively if the goal is just printing support then perhaps TableForm can be used.
It isn’t clear what to advise as a replacement here without knowing more about the use case. If you are unclear how to update your code, please open an issue or write to our mailing list so we can discuss it.

The `get_segments` attribute of plotting objects

The `get_segments` method implemented in `Line2DBaseSeries` (page 2949) is used to convert two list of coordinates, x and y, into a list of segments used by Matplotlib’s LineCollection to plot a line.

Since the list of segments is only required by Matplotlib (for example, Bokeh, Plotly, Mayavi, K3D only require lists of coordinates), this has been moved inside the MatplotlibBackend class.

Note that previously, the method `get_points()` (page 2950) always returned uniformly sampled points, which meant that some functions were not plotted correctly when using `get_points()` to plot with Matplotlib.

To avoid this problem, the method `get_segments()` could be used, which used adaptive sampling and which could be used with Matplotlib’s LineCollection. However, this has been changed, and now `get_points()` can also use adaptive sampling. The `get_data()` (page 2950) method can also be used.

The `mdft` function in `sympy.physics.matrices`

The `sympy.physics.matrices.mdft()` function is deprecated. It can be replaced with the DFT class in `sympy.matrices.expressions.fourier`.

In particular, replace `mdft(n)` with `DFT(n).as_explicit()`. For example:

```python
>>> from sympy.physics.matrices import mdft
>>> mdft(3) # DEPRECATED
Matrix([[sqrt(3)/3, sqrt(3)/3, sqrt(3)/3],
        [sqrt(3)/3, sqrt(3)*exp(-2*I*pi/3)/3, sqrt(3)*exp(2*I*pi/3)/3],
        [sqrt(3)/3, sqrt(3)*exp(2*I*pi/3)/3, sqrt(3)*exp(-2*I*pi/3)/3]])
```

```python
>>> from sympy.matrices.expressions.fourier import DFT
>>> DFT(3)
DFT(3)
>>> DFT(3).as_explicit()
Matrix([[sqrt(3)/3, sqrt(3)/3, sqrt(3)/3],
        [sqrt(3)/3, sqrt(3)*exp(-2*I*pi/3)/3, sqrt(3)*exp(2*I*pi/3)/3],
        [sqrt(3)/3, sqrt(3)*exp(2*I*pi/3)/3, sqrt(3)*exp(-2*I*pi/3)/3]])
```

This was changed because the sympy.physics submodule is supposed to only contain things that are specific to physics, but the discrete Fourier transform matrix is a more general mathematical concept, so it is better located in the sympy.matrices module. Furthermore, the DFT class is a matrix expression (page 1414), meaning it can be unevaluated and support symbolic shape.
The private SparseMatrix._smat and DenseMatrix._mat attributes

The .mat attribute of Matrix (page 1406) and the ._smat attribute of SparseMatrix (page 1409) are deprecated.

The internal representation of Matrix and SparseMatrix was changed to be a DomainMatrix (page 2753) in #21626 so that it is no longer possible to expose a mutable list/dict as a way of mutating a Matrix. Instead of .mat the new .flat() method can be used, which returns a new list that cannot be used to mutate the Matrix itself. Instead of ._smat the .todok() method can be used which returns a new dict.

Note that these attributes are already changed in SymPy 1.9 to return read-only copies, so that any code that relied on mutating them will be broken. Also these attributes were technically always private (they started with an underscore), so user code should not really have been using them in the first place.

laplace_transform of a Matrix with noconds=False

Prior to version 1.9, calling laplace_transform() (page 635) on a Matrix (page 1406) with noconds=False (which is the default), resulted in a Matrix of tuples:

```python
>>> from sympy import laplace_transform, symbols, eye
>>> t, z = symbols('t z')
>>> laplace_transform(eye(2), t, z)
Matrix([[(1/z, 0, True), (0, 0, True)],
       [(0, 0, True), (1/z, 0, True)]])
```

However, Matrix is only designed to work with Expr objects (see Non-Expr objects in a Matrix (page 221) above).

To avoid this, either use noconds=True to remove the convergence conditions

```python
>>> laplace_transform(eye(2), t, z, noconds=True)
Matrix([ [1/z, 0],
       [0, 1/z]])
```

or use legacy_matrix=False to return the new behavior, which will be to return a single tuple with the Matrix in the first argument and the convergence conditions combined into a single condition for the whole matrix.

```python
>>> laplace_transform(eye(2), t, z, legacy_matrix=False)
(Matrix([ [1/z, 0],
         [0, 1/z]]), 0, True)
```

When this deprecation is removed the legacy_matrix=False behavior will become the default, but the flag will be left intact for compatibility.
4.4.6 Version 1.8

sympy.printing.theanocode

Theano has been discontinued, and forked into a new project called Aesara. The sympy.printing.theanocode module has been renamed to sympy.printing.aesaracode (page 2241), and all the corresponding functions have been renamed (e.g., theano_code has been renamed to aesara_code() (page 2242), TheanoPrinter has been renamed to AesaraPrinter (page 2241), and so on).

sympy.assumptions.handlers.AskHandler and related methods

Predicate has experienced a big design change. Previously, its handler was a list of AskHandler classes and registration was done by add_handler() and remove_handler() functions. Now, its handler is a multipledispatch instance and registration is done by register() or register_many() methods. Users must define a predicate class to introduce a new one.

Previously, handlers were defined and registered this way:

```python
class AskPrimeHandler(AskHandler):
    @staticmethod
    def Integer(expr, assumptions):
        return expr.is_prime

register_handler('prime', AskPrimeHandler)
```

It should be changed to this:

```python
# Predicate definition.
# Not needed if you are registering the handler to existing predicate.
class PrimePredicate(Predicate):
    name = 'prime'
Q.prime = PrimePredicate()

# Handler registration
@Q.prime.register(Integer)
def _(expr, assumptions):
    return expr.is_prime
```

See GitHub issue #20209.

4.4.7 Version 1.7.1

Calling sympy.stats.StochasticProcess.distribution with RandomIndexedSymbol

The distribution method of sympy.stats stochastic processes (page 3028) used to accept a RandomIndexedSymbol (that is, a stochastic process indexed with a timestamp), but should now only be called with the timestamp.

For example, if you have
from sympy import symbols
from sympy.stats import WienerProcess
W = WienerProcess('W')
t = symbols('t', positive=True)

Previously this would work
W.distribution(W(t)) # DEPRECATED

It should now be called like
>>> W.distribution(t)
NormalDistribution(0, sqrt(t))

This was change was made as part of a change to store only Basic objects in sympy.stats.args. See issue #20078 for details.

4.4.8 Version 1.7

sympy.stats.DiscreteMarkovChain.absorbing_probabilites()

The absorbing_probabilites method name was misspelled. The correct spelling absorbing_probabilities() (page 3030) ("absorbing probabilities") should be used instead.

sympy.utilities.misc.find_executable()

The function sympy.utilities.misc.find_executable() is deprecated. Instead use the standard library shutil.which() function, which has been in the standard library since Python 3.3 and is more powerful.

Mutable attributes in sympy.diffgeom

Several parts of sympy.diffgeom (page 2883) have been updated to no longer be mutable, which better matches the immutable design used in the rest of SymPy.

• Passing strings for symbol names in CoordSystem (page 2885) is deprecated. Instead you should be explicit and pass symbols with the appropriate assumptions, for instance, instead of

CoordSystem(name, patch, ['x', 'y']) # DEPRECATED

use

CoordSystem(name, patch, symbols('x y', real=True))

• Similarly, the names keyword argument has been renamed to symbols, which should be a list of symbols.

• The Manifold.patches attribute is deprecated. Patches should be tracked separately.

• The Patch.coord_systems attribute is deprecated. Coordinate systems should be tracked separately.

4.4. List of active deprecations
• The CoordSystem.transforms attribute, CoordSystem.connect_to() method, and CoordSystem.coord_tuple_transform_to() method are deprecated. Instead, use the relations keyword to the CoordSystem class constructor and the CoordSystem.transformation() (page 2889) and CoordSystem.transform() (page 2889) methods (see the docstring of CoordSystem (page 2885) for examples).

The unicode argument and attribute to sympy.printing.pretty.stringpict.prettyForm and the sympy.printing.pretty.pretty_symbology.xstr function

The sympy.printing.pretty.pretty_symbology.xstr function, and the unicode argument and attribute to sympy.printing.pretty.stringpict.prettyForm (page 2263) were both present to support the Unicode behavior of Python 2. Since Unicode strings are the default in Python 3, these are not needed any more. xstr() should be replaced with just str(), the unicode argument to prettyForm should be omitted, and the prettyForm.unicode attribute should be replaced with the prettyForm.s attribute.

Passing the arguments to lambdify as a set

Passing the function arguments to lambdify as a set is deprecated. Instead pass them as a list or tuple. For example, instead of

\[
\text{lambdify}({x, y}, x + 2*y) \ # \text{WRONG}
\]

use

\[
\text{lambdify}((x, y), x + 2*y) \ # \text{RIGHT}
\]

This is because sets are unordered. For instance, in the above example it would be impossible for lambdify to know if it was called with \{x, y\} or \{y, x\}. Thus, when passed the arguments as a set lambdify would have to guess their order, which would lead to an incorrect function if it guessed incorrectly.

Core operators no longer accept non-Expr args

The core operator classes Add (page 1062), Mul (page 1058), and Pow (page 1055) can no longer be constructed directly with objects that are not subclasses of Expr (page 999).

Expr (page 999) is the superclass of all SymPy classes that represent scalar numeric quantities. For example, sin (page 449), Symbol (page 1028), and Add (page 1062) are all subclasses of Expr (page 999). However, may objects in SymPy are not Expr (page 999) because they represent some other type of mathematical object. For example, Set (page 1229), Poly (page 2453), and Boolean (page 1207) are all non-Expr. These do not make mathematical sense inside of Add, Mul, and Pow, which are designed specifically to represent the addition, multiplication, and exponentiation of scalar complex numbers.

Manually constructing one of these classes with such an object is possible, but it will generally create something that will then break. For example

\[
\text{Mul}(1, \text{Tuple}(2)) \ # \text{This is deprecated}
\]

works and creates Tuple(2), but only because Mul is “tricked” by always treating \(1 \cdot x = x\). If instead you try
SymPy Documentation, Release 1.12.1

Mul(2, Tuple(2)) # This is deprecated

it fails with an exception

```
AttributeError: 'Tuple' object has no attribute 'as_coeff_Mul'
```

because it tries to call a method of Expr on the Tuple object, which does not have all the Expr methods (because it is not a subclass of Expr).

If you want to use the +, *, or ** operation on a non-Expr object, use the operator directly rather than using Mul, Add or Pow. If functional versions of these are desired, you can use a lambda or the operator module.

### 4.4.9 Version 1.6

Various sympy.utilities submodules have moved

The following submodules have been renamed.

- sympy.utilities.benchmarking → sympy.testing.benchmarking
- sympy.utilities.pytest → sympy.testing.pytest
- sympy.utilities.randtests → sympy.core.random
- sympy.utilities.runtests → sympy.testing.runtests
- sympy.utilities.tmpfiles → sympy.testing.tmpfiles

**sympy.testing.randtest**

sympy.testing.randtest is deprecated. The functions in it have been moved to sympy.core.random. The following functions have been moved.

- sympy.testing.randtest.random_complex_number → sympy.core.random.random_complex_number
- sympy.testing.randtest.verify_numerically → sympy.core.random.verify_numerically
- sympy.testing.randtest.test_derivative_numerically → sympy.core.random.test_derivative_numerically
- sympy.testing.randtest._randrange → sympy.core.random._randrange
- sympy.testing.randtest._randint → sympy.core.random._randint

4.4. List of active deprecations 227
Mixing Poly and non-polynomial expressions in binary operations

In previous versions of SymPy, Poly (page 2453) was a subclass of Expr (page 999), but it has been changed to only be a subclass of Basic (page 979). This means that some things that used to work with Poly are now deprecated because they are only designed to work with Expr (page 999) objects.

This includes combining Poly with Expr objects using binary operations, for example

```
Poly(x) * sin(x)  # DEPRECATED
```

To do this, either explicitly convert the non-Poly operand to a Poly using Expr.as_poly() (page 1007) or convert the Poly operand to an Expr (page 999) using Poly.as_expr() (page 2457), depending on which type you want the result to be.

The print_cyclic flag of sympy.combinatorics.Permutation

The print_cyclic attribute of sympy.combinatorics.Permutation (page 312) controls whether permutations print as cycles or arrays. This would be done by setting Permutation.print_cyclic = True or Permutation.print_cyclic = False. However, this method of controlling printing is bad because it is a global flag, but printing should not depend on global behavior.

Instead, users should use the perm_cyclic flag of the corresponding printer. The easiest way to configure this is to set the flag when calling init_printing() (page 2192), like

```python
>>> from sympy import init_printing
>>> init_printing(perm_cyclic=False)  # Makes Permutation print in array form
>>> from sympy.combinatorics import Permutation
>>> Permutation((1, 2)(3, 4))
(0 1 2 3 4)
(0 2 1 4 3)
```

The Permutation (page 312) docstring contains more details on the perm_cyclic flag.

Using integrate with Poly

In previous versions of SymPy, Poly (page 2453) was a subclass of Expr (page 999), but it has been changed to only be a subclass of Basic (page 979). This means that some things that used to work with Poly are now deprecated because they are only designed to work with Expr (page 999) objects.

This includes calling integrate() (page 657) or Integral (page 660) with Poly.

To integrate a Poly, use the Poly.integrate() (page 2473) method. To compute the integral as an Expr (page 999) object, call the Poly.as_expr() (page 2457) method first.

See also Mixing Poly and non-polynomial expressions in binary operations (page 228) above.
The string fallback in `sympify()`

The current behavior of `sympify()` (page 970) is that `sympify(expr)` tries various methods to try to convert `expr` into a SymPy objects. If all these methods fail, it takes `str(expr)` and tries to parse it using `parse_expr()` (page 2195). This string fallback feature is deprecated. It is problematic for a few reasons:

- It can affect performance in major ways. See for instance issues #18056 and #15416 where it caused up to 100x slowdowns. The issue is that SymPy functions automatically call `sympify` on their arguments. Whenever a function is passed something that `sympify` doesn’t know how to convert to a SymPy object, for instance, a Python function type, it passes the string to `parse_expr()` (page 2195). This is significantly slower than the direct conversions that happen by default. This occurs specifically whenever `sympify()` is used in library code instead of `_sympify()` (or equivalently `sympify(strict=True)`), but presently this is done a lot. Using `strict=True` will at some point be the default for all library code, but this is a harder change to make.

- It can cause security issues, since strings are evaled, and objects can return whatever string they want in their `__repr__`. See also https://github.com/sympy/sympy/pull/12524.

- It really isn’t very useful to begin with. Just because an object’s string form can be parsed into a SymPy expression doesn’t mean it should be parsed that way. This is usually correct for custom numeric types, but an object’s repr could be anything. For instance, if the string form of an object looks like a valid Python identifier, it will parse as a Symbol.

There are plenty of ways to make custom objects work inside of `sympify()` (page 970).

- Firstly, if an object is intended to work alongside other SymPy expressions, it should subclass from `Basic` (page 979) (or `Expr` (page 999)). If it does, `sympify()` (page 970) will just return it unchanged because it will already be a valid SymPy object.

- For objects that you control, you can add the `_sympy_` method. The `sympify` docstring (page 970) has an example of this.

- For objects that you don’t control, you can add a custom converter to the `sympy.core.sympify.converter` dictionary. The `sympify()` (page 970) docstring also has an example of this.

To silence this deprecation warning in all cases, you can pass `strict=True` to `sympify()`. However, note that this will also disable some other conversions such as conversion of strings (for converting strings to SymPy types, you can explicitly use `parse_expr()` (page 2195)).

Creating an indefinite Integral with an Eq argument

Passing an `Eq()` (page 1071) object to `integrate()` (page 657) is deprecated in the case where the integral is indefinite. This is because if \( f(x) = g(x) \), then \( \int f(x) \, dx = \int g(x) \, dx \) is not true in general, due to the arbitrary constants (which `integrate` does not include).

If you want to make an equality of indefinite integrals, use `Eq(integrate(f(x), x), integrate(g(x), x))` explicitly.

If you already have an equality object `eq`, you can use `Eq(integrate(eq.lhs, x), integrate(eq.rhs, x))`. 
4.4.10 Version 1.5

Tensor.fun_eval and Tensor.__call__

TensExpr.fun_eval and Tensor.__call__ (i.e., calling a tensor to evaluate it) are deprecated. The Tensor.substitute_indices() method should be used. This was changed because fun_eval was considered a confusing name and using function evaluation was considered both confusing and dangerous.

TensorType

The TensorType class is deprecated. Use tensor_heads() (page 1461) instead. The TensorType class had no purpose except shorter creation of TensorHead (page 1459) objects. See also The tensorhead() function (page 231) below.

The dummy_fmt argument to TensorIndexType

The dummy_fmt keyword argument to TensorIndexType (page 1457) is deprecated. Setting dummy_fmt='L' leads to _dummy_fmt='L_%d', which is confusing and uses obsolete string formatting. dummy_name should be used instead. This change was made because dummy_name is a clearer name.

The metric argument to TensorIndexType

The metric keyword argument to TensorIndexType (page 1457) is deprecated. The name “metric” was ambiguous because it meant “metric symmetry” in some places and “metric tensor” in others.

Either the metric_symmetry keyword or the TensorIndexType.set_metric() method should be used instead.

The get_kronecker_delta() and get_epsilon() methods of TensorIndexType

The get_kronecker_delta() and get_epsilon() methods of TensorIndexType (page 1457) are deprecated. Use the TensorIndexType.delta and TensorIndexType.epsilon properties instead, respectively.

The tensorsymmetry() function

The tensorsymmetry() function in symy.tensor is deprecated. Use the TensorSymmetry (page 1467) class constructor instead.

TensorSymmetry is preferred over tensorsymmetry() because the latter
  1. Does not have any extra functionality
  2. Involves obscure Young tableau
  3. Is not a member of the TensorSymmetry class
The tensorhead() function

The tensorhead() function is deprecated in favor of tensor_heads() (page 1461). tensor_heads() is more consistent with other SymPy names (i.e., Symbol and symbols() or TensorIndex and tensor_indices()). It also does not use Young tableau to denote symmetries.

The is_EmptySet attribute of sets

The is_EmptySet attribute of Set (page 1229) objects is deprecated. Instead either use

```
from sympy import S
s is S.EmptySet
```
or

```
s.is_empty
```
The difference is that s.is_empty may return None if it is unknown if the set is empty.

ProductSet(iterable)

Passing a single iterable as the first argument to ProductSet (page 1242) is deprecated. Creating a product set from an iterable should be done using ProductSet(*iterable), or as each individual argument. For example

```
>>> from sympy import ProductSet
>>> sets = [{i} for i in range(3)]
>>> ProductSet(*sets)
ProductSet({0}, {1}, {2})
>>> ProductSet({1, 2}, {1})
ProductSet({1, 2}, {1})
```
This is done because sets themselves can be iterables, and sets of sets are allowed. But the product set of a single set should mathematically be that set itself (or more exactly, the set of 1-tuples of elements of that set). Automatically denesting a single iterable makes it impossible to represent this object and makes ProductSet not generalize correctly when passed 1 argument. On the other hand, treating the first argument differently if it is a set than if it is another type of iterable (which is what is currently done in the deprecated code path) is confusing behavior.

The set_potential_energy method in sympy.physics.mechanics

The set_potential_energy() methods of sympy.physics.mechanics.particle.Particle (page 1790) and sympy.physics.mechanics.rigidbody.RigidBody (page 1793) are deprecated.

Instead one should set the Particle.potential_energy (page 1793) and RigidBody. potential_energy (page 1796) attributes to set the potential energy, like

```
P.potential_energy = scalar
```
This change was made to be more Pythonic, by using setters and getters of a @property method rather than an explicit set_method.

**Using a set for the condition in ConditionSet**

Using a set for the condition in ConditionSet is deprecated. A boolean should be used instead. This is because the condition is mathematically a boolean, and it is ambiguous what a set should mean in this context.

To fix this deprecation, replace

```python
ConditionSet(symbol, set_condition)
```

with

```python
ConditionSet(symbol, And(*[Eq(lhs, 0) for lhs in set_condition]))
```

For example,

```python
ConditionSet((x, y), {x + 1, x + y}, S.Reals) # DEPRECATED
```

would become

```python
ConditionSet((x, y), Eq(x + 1, 0) & Eq(x + y, 0), S.Reals)
```

**The max_degree and get_upper_degree properties of sympy.polys.multiivariate_resultants.DixonResultant**

The max_degree property and get_upper_degree() methods of DixonResultant are deprecated. See issue #17749 for details.

**Non-tuple iterable for the first argument to Lambda**

Using a non-tuple as the first argument to Lambda (page 1087) is deprecated. If you have a non-tuple, convert it to a tuple first, like Lambda(tuple(args), expr).

This was done so that Lambda could support general tuple unpacking, like

```python
from sympy import Lambda, symbols
x, y, z = symbols('x y z')
f = Lambda((x, (y, z)), x + y + z)
f(1, (2, 3))
6
```
The evaluate flag to differentiate_finite

The evaluate flag to differentiate_finite() (page 296) is deprecated.

differentiate_finite(expr, x, evaluate=True) expands the intermediate derivatives before computing differences. But this usually not what you want, as it does not satisfy the product rule.

If you really do want this behavior, you can emulate it with

```python
diff(expr, x).replace(
    lambda arg: arg.is_Derivative,
    lambda arg: arg.as_finite_difference())
```

See the discussion on issue #17881.

4.4.11 Version 1.4

TensorIndexType.data and related methods

The TensorIndexType.data property is deprecated, as well as several methods which made use of it including the get_matrix(), the __getitem__() (indexing), __iter__() (iteration), _components_data_full_destroy(), and __pow__() (** methods. Storing data on tensor objects was a design flaw and not consistent with how the rest of SymPy works.

Instead, the TensExpr.replace_with_arrays() (page 1461) method should be used.

4.5 Glossary

This page is a glossary for various terms used throughout the SymPy documentation. This glossary is primarily for terms that are specific to SymPy. For more general Python terms, refer to the Python glossary. Mathematical terms are only included here if they have a specific meaning in SymPy. For general mathematical definitions, refer to other sources such as Wikipedia or MathWorld, as well as the references in the documentation for the specific SymPy functions.

Antiderivative

An antiderivative of a function \(f(x)\) with respect to \(x\) is a function \(F(x)\) such that \(\frac{d}{dx} F(x) = f(x)\). It is also sometimes called an “indefinite integral” of \(f(x)\), and written as \(\int f(x) \, dx\). Antiderivatives in SymPy can be computed with integrate() (page 657).

Note some sources call this the “primitive” of \(f(x)\), but this terminology is not used in SymPy because it is not as universally used as “antiderivative”, and because “primitive” has other meanings in mathematics and in SymPy (page 2444).

args

The args property of a SymPy expression is a tuple of the top-level subexpressions used to create it. They are the arguments to the class used to create the expression. The args of any expression can be obtained by the .args attribute. For example, \((1 + x*y).args\) is \((1, x*y)\), because it equals Add(1, x*y). The args together with func completely define an expression. It is always possible to walk the expression tree and extract any subexpression of a SymPy expression by repeated use of .args. Every SymPy expression can be rebuilt exactly with func and args, that is, expr.func(*expr.args) == expr will
always be true of any SymPy expression expr. The args of an expression may be the empty tuple (), meaning the expression is an atom.

Assumptions

Assumptions are a set of predicates on a symbol or expression that define the set of possible values it can take. Some examples of assumptions are positive, real, and integer. Assumptions are related to one another logically, for example, an assumption of integer automatically implies real. Assumptions use a three-valued logic system where predicates are either True, False, or None.

Assumptions are either assumed or queried. For example, a symbol x might be assumed to be positive by defining it as x = symbols('x', positive=True). Then an assumption might be queried on the expression containing this symbol, like (x + 1).is_real, which in this case would return True.

If no assumptions are assumed on a symbol, then by default symbols are assumed to be general complex numbers. Setting assumptions is important because certain simplifications are only mathematically true in a restricted domain, for example, $\sqrt{x^2} = x$ is not true for general complex $x$ but it is true when $x$ is positive. SymPy functions will never perform an operation on an expression unless it is true for all values allowed by its assumptions.

SymPy has two separate assumptions systems, which are closely related to one another. In the first, which is sometimes called the “old assumptions” because it is older, assumptions are assumed on Symbol objects and queried with is_* attributes. In the second, which is sometimes called the “new assumptions”, assumptions are assumed using separate predicate objects like Q.positive and queried using the ask() (page 249) function. The newer assumptions system is able to support more complex queries, but is also not as well developed as the older one. Most users of SymPy should prefer the older assumptions system at this time.

See the assumptions guide (page 71) for more details on assumptions.

Atom

An atom is an expression whose args is the empty tuple (). Atoms are the leaves of the expression tree. For example, if a function uses recursion to walk an expression tree using args, the atomic expressions will be the base case of the recursion.

Note that the class Atom (page 996) is sometimes used as the base class of atomic expressions, but it is not a requirement for atomic expressions to subclass this class. The only requirement for an expression to be atomic is for its args to be empty.

Automatic Simplification

Automatic Simplification refers to any simplification that happens automatically inside of a class constructor. For example, x + x is automatically simplified to 2*x in the Add (page 1062) constructor. Unlike manual simplification, automatic simplification can only be disabled by setting evaluate=False (see Unevaluated). Automatic simplification is often done so that expressions become canonicalized. Excessive automatic simplification is discouraged, as it makes it impossible to represent the non-simplified form of the expression without using tricks like evaluate=False, and it can often be an expensive thing to do in a class constructor. Instead, manual simplification/canonicalization is generally preferred.

Basic (page 979)

Basic (page 979) is the superclass of all SymPy expressions. It defines the basic methods required for a SymPy expression, such as args, func, equality, immutability, and some useful expression manipulation functions such as substitution. Most SymPy classes will subclass a more specific Basic subclass such as Boolean, Expr, Function, or Matrix. An
object that is not a Basic instance typically cannot be used in SymPy functions, unless it can be turned into one via `sympify()`.

**Boolean** (page 1207)

Boolean (page 1207) is the base class for the classes in the logic (page 1204) module. Boolean instances represent logical predicates that are elements of a boolean algebra and can be thought of as having a “true” or “false” value (note that Boolean objects do not use the three-valued logic used by the assumptions).

**Bound symbols**

A symbol in an expression is bound if it is not free. A bound symbol can be replaced everywhere with a new symbol and the resulting expression will still be mathematically equivalent. Examples of bound symbols are integration variables in definite integrals and substituted variables in a Subs (page 1098). Bound symbols are sometimes represented by dummy symbols, but the are not always Dummy (page 1029) objects, and Dummy (page 1029) objects are not always bound symbols.

**Canonical Form**

**Canonicalize**

Often expressions can be written in multiple, mathematically equivalent ways. A canonical form is a single way of writing an expression, which all equivalent expressions can be transformed to. An expression that is put into a canonical form is said to be canonicalized. Often canonical forms are unique and have properties that make them easier to work with. For example, a common canonical form used for rational functions is $\frac{p}{q}$, where $p$ and $q$ are expanded polynomials with no common factors.

**Code Generation**

**Code generation** refers to the process of taking a SymPy expression and converting it into code for a language or library so that it can be evaluated numerically. SymPy supports code generation for dozens of languages (page 1153) and libraries including C, C++, Fortran, and NumPy.

**Core**

The core (page 970) is the submodule that contains the important functionality used by all SymPy objects. This includes the Basic and Expr base classes, classes like Add (page 1062), Mul (page 1058), and Pow (page 1055), and the assumptions.

**Dummy**

A dummy symbol is a symbol that is automatically unequal to any other dummy symbol other than itself, even if it has the same name. Dummy symbols are used when a function needs to return an expression with a new symbol, so that it cannot accidentally clash with a symbol of the same name. Dummy symbols can be created with Dummy (page 1029).

**Equation**

An equation is an expression that has an equals sign $\equal{}$. Equations in SymPy are represented using the Eq (page 1071) class. Equations are not created using the == operator. The == operator does a structural equality check between two expressions, and always returns True or False. To contrast, a symbolic equation may be unevaluated. Equations are considered booleans since they mathematically represent a predicate value that is either true or false.

**_eval_***

Various methods on Basic and Expr can be defined on subclasses using special _eval_* methods. For example, an object can define how it will be processed by the `diff()` (page 1094) function by defining a _eval_derivative method. _eval_* methods used are instead of overriding the method itself so that the method defined on the base class can do pre-processing before dispatching to the _eval_* method.
evalf

evalf (page 1111) is the method present on every Expr object that evaluates it to a floating-point numerical value, or converts the constant parts of the expression to a numerical value if it contains symbols. The \( .n() \) (page 1112) method and \( N() \) (page 1113) function are both shorthands for evalf. “evalf” stands for “evaluate floating-point”.
evalf uses mpmath under the hood to evaluate expressions to arbitrary precision.

Evaluate

Evaluate can refer to:

• The process of converting an expression into a numerical value (see evalf).
• The process of automatic simplification that occurs when creating an expression (see Unevaluated).
• The process of replacing one or more symbols in an expression with numeric values or with other expressions using substitution.

Expr (page 999)

Expr (page 999) is the superclass of all algebraic SymPy expressions. It is itself a subclass of Basic. SymPy expressions that can be in an Add (page 1062), Mul (page 1058), or Pow (page 1055) should be Expr subclasses. Not all SymPy classes are subclasses of Expr, for example, Boolean objects are Basic but not Expr, because boolean expressions do not make mathematical sense in classes like Add (page 1062) or Mul (page 1058).

Expression

Any SymPy object, that is, any instance of Basic, may be called an expression. Sometimes, the term “expression” is reserved for Expr objects, which are algebraic expressions. Expressions are not to be confused with equations, which are a specific types of expressions that represents mathematical equalities.

Expression Tree

An expression tree is a tree of expressions. Every expression is built up from smaller expressions as a tree. The nodes of an expression tree are expressions and the children of each node are the direct subexpressions that constitute that expression. Alternatively, one can view an expression tree as a tree where the non-leaf nodes are funcs and the leaf nodes are atoms. An example expression tree is shown in the tutorial (page 61). The expression tree of any SymPy expression can be obtained by recursing through args. Note that because SymPy expressions are immutable and are treated equal strictly by structural equality, one may also think of an expression tree as being a DAG, where identical subexpressions are only represented in the graph once.

Free symbols

A symbol in an expression is free if the expression mathematically depends on the value of that symbol. That is, if the symbol were replaced with a new symbol, the result would be a different expression. Symbols that are not free are bound. The free symbols of an expression can be accessed with the free_symbols (page 984) attribute.

func

The func property is the function of an expression, which can be obtained by expr. func. This is usually the same as type(expr), but may differ in some cases, so it should be preferred to use expr.func instead of type(expr) when rebuilding expressions with args. Every SymPy expression can be rebuilt exactly with func and args, that is, expr.func(*expr.args) == expr will always be true of any SymPy expression expr.

Function

Function may refer to:

• A mathematical function, that is, something which maps values from a domain to a
range. Sometimes an expression containing a symbol is colloquially called a “function” because the symbol can be replaced with a value using substitution, evaluating the expression. This usage is colloquial because one must use the subs (page 993) method to do this rather than the typical Python function calling syntax, and because it is not specific about what variable(s) the expression is a function of, so generally the term “expression” should be preferred unless something is an actual function. An expression can be converted into a function object that can be called using the Python \( f(x) \) syntax using \texttt{Lambda} (page 1087).

- An instance of the SymPy \texttt{Function} class.

- A Python function, i.e., a function defined using the \texttt{def} keyword. Python functions are not \texttt{symbolic}, since they must always return a value and thus cannot be \texttt{unevaluated}.

\textbf{Function (page 1096) (class)}

\texttt{Function} (page 1096) is the base class of symbolic functions in SymPy. This includes common functions like \texttt{sin()} (page 449) and \texttt{exp()} (page 468), special functions like \texttt{zeta()} (page 571) and \texttt{hyper()} (page 577), and integral functions like \texttt{primepi()} (page 1525) and \texttt{divisor_sigma()} (page 1547). Function classes are always \texttt{symbolic}, meaning that they typically remain \texttt{unevaluated} when passed a \texttt{symbol}, like \( f(x) \). Not every symbolic expression class is a Function subclass, for example, \texttt{core} classes like \texttt{Add} and \texttt{Mul} are not Function subclasses.

Function may also be used to create an \texttt{undefined function} by passing it a string name for the function, like \texttt{Function('f')}.

Not every function in SymPy is a symbolic Function class; some are just Python functions which always return a value. For example, most simplification functions like \texttt{simplify()} cannot be represented symbolically.

\textbf{Immutable}

In Python, objects are \texttt{immutable} if they cannot be modified in-place. In order to change an immutable object, a new object must be created. In SymPy, all \texttt{Basic} objects are immutable. This means that all functions that operate on \texttt{expressions} will return a new expression and leave the original unchanged. Performing an operation on an expression will never change other objects or expressions that reference that expression. This also means that any two objects that are \texttt{equal} are completely interchangeable and may be thought of as being the same object, even if they happen to be two different objects in memory. Immutability makes it easier to maintain a mental model of code, because there is no hidden state. SymPy objects being immutable also means that they are hashable, which allows them to be used as dictionary keys.

\textbf{Interactive}

\texttt{Interactive} usage refers to using SymPy in an interactive REPL environment such as the Python prompt, \texttt{isymy}, IPython, or the Jupyter notebook. When using SymPy interactively, all commands are typed in real time by the user and all intermediate results are shown. Interactive use is in contrast with \texttt{programmatic} use, which is where the code is written in a file which is either executed as a script or is part of a larger Python library. Some SymPy idioms are only recommended for interactive use and are considered anti-patterns when used programmatically. For example, running \texttt{from sympy import *} is convenient when using SymPy interactively, but is generally frowned upon for programmatic usage, where importing names explicitly just using \texttt{import sympy} is preferred.

\texttt{is_}

Attributes in SymPy that start with \texttt{is_} and use a \texttt{lowercase} name query the given \texttt{assumption} on that object (note: there are a few properties that are an exception to this because they do not use the assumptions system, see \texttt{the assumptions guide} (page 85)).
For example, `x.is_integer` will query the integer assumption on `x`. `is_*` attributes that use a `Capitalized` name test if an object is an instance of the given class. Sometimes the same name will exist for both the lowercase and `Capitalized` property, but they are different things. For example, `x.is_Integer` is only `True` if `x` is an instance of `Integer` (page 1038), whereas `x.is_integer` is `True` if `x` is integer in the assumptions system, such as `x = symbols('x', integer=True)`. In general, it is recommended to not use `is_Capitalized` properties. They exist for historical purposes, but they are unneeded because the same thing can be achieved with `isinstance()`. See also `Number`.

**isymy**

`isymy` is a command that ships with SymPy that starts an `interactive` session on the command line with all SymPy names imported and `printing` enabled. It uses IPython by default when it is installed.

**Kind**

The `kind` of a SymPy object represents what sort of mathematical object it represents. The kind of an object can be accessed with the `kind` attribute. Example kinds are `NumberKind` (page 1118), which represents complex numbers, `MatrixKind` (page 1405), which represents matrices of some other kind, and `BooleanKind` (page 1119), which represents boolean predicates. The kind of a SymPy object is distinct from its Python type, since sometimes a single Python type may represent many different kinds of objects. For example, `Matrix` could be a matrix of complex numbers or a matrix of objects from some other ring of values. See the *classification of SymPy objects* (page 212) page for more details about kinds in SymPy.

**Lamda**

“Lamda” is just an alternate spelling of the Greek letter “lambda”. It is used sometimes in SymPy because `lambda` is a reserved keyword in Python, so a symbol representing $\lambda$ must be named something else.

**lambdify() (page 2173)**

`lambdify()` (page 2173) is a function that converts a SymPy expression into a Python function that can be evaluated numerically, typically making use of a numeric library such as NumPy.

**Matrix**

`Matrix` refers to the set of classes used by SymPy to represent matrices. SymPy has several internal classes to represent matrices, depending on whether the matrix is symbolic (`MatrixExpr` (page 1414)) or explicit, mutable or immutable, dense or sparse, and what type the underlying elements are, but these are often all just called “Matrix”.

**mpmath**

`mpmath` is a pure Python library for arbitrary precision numerics. It is a hard dependency (page 3069) of SymPy. `mpmath` is capable of computing numerical functions to any given number of digits. `mpmath` is used under the hood whenever SymPy evaluates an expression numerically, such as when using `evalf`.

**Numeric**

A numeric representation or algorithm is one that operates directly on numeric inputs. It is in contrast with a symbolic representation or algorithm, which can work with objects in an unevaluated form. Often a numerical algorithm is quite different from a symbolic one. For example, numerically solving an ODE typically means evaluating the ODE using an algorithm like Runge–Kutta to find a set of numeric points given an initial condition, whereas symbolically solving an ODE (such as with SymPy’s `dsolve()` (page 807)) means mathematically manipulating the ODE to produce a symbolic equation that represents the solution. A symbolic ODE solution may including symbolic constants which can represent any numerical value. Numeric algorithms are typically designed around
issues caused by floating-point numbers such as loss of precision and numerical stability, whereas symbolic algorithms are not concerned with these things because they compute things exactly.

Most scientific libraries other than SymPy, such as NumPy or SciPy, are strictly numerical, meaning the functions in those libraries can only operate on specific numeric inputs. They will not work with SymPy expressions, because their algorithms are not designed to work with symbolic inputs. SymPy focuses on symbolic functions, leaving purely numerical code to other tools like NumPy. However, SymPy does interface with numerical libraries via tools like code generation and lambdify().

**Number**

*Number* can refer to two things in SymPy:

- The class *Number* (page 1033), which is the base class for explicit numbers (*Integer* (page 1038), *Rational* (page 1036), and *Float* (page 1033)). Symbolic numeric constants like *pi* (page 1050) are not instances of *Number*.
- Lowercase “number”, as in the *is_number* property, refers to any *expression* that can be *evalf* into an explicit *Number*. This includes symbolic constants like *pi* (page 1050). Note that *is_number* is not part of the *assumptions* system.

This distinction is important for the *is_Number* and *is_number* properties. *x.is_Number* will check if *x* is an instance of the class *Number* (page 1033).

**oo (page 1048)**

*oo* (page 1048) is the SymPy object representing positive infinity. It is spelled this way, as two lower case letter Os, because it resembles the symbol ∞ and is easy to type. See also *zoo*.

**Polys**

The *polys* refers to the *sympy.polys* (page 2435) submodule, which implements the basic data structures and algorithms for polynomial manipulation. The *polys* are a key part of SymPy (though not typically considered part of the *core*), because many basic symbolic manipulations can be represented as manipulations on polynomials. Many algorithms in SymPy make use of the *polys* under the hood. For example, *factor*() (page 2447) is a wrapper around the polynomial factorization algorithms that are implemented in the *polys*. The classes in the *polys* are implemented using efficient data structures, and are not subclasses of *Basic* like the other classes in SymPy.

**Printing**

*Printing* refers to the act of taking an *expression* and converting it into a form that can be viewed on screen. *Printing* is also often used to refer to *code generation*. SymPy has several printers which represent expressions using different formats. Some of the more common printers are the string printer (*str*()), the pretty printer (*pprint*()) (page 2212)) the LaTeX printer (*latex*()) (page 2245)), and code printers.

**Relational**

A *relational* is an *expression* that is a *symbolic equality* (like *a = b*), or a symbolic inequality like “less than” (*a < b*). Equality (=) and non-equality (≠) relationals are created with *Eq* (page 1071) and *Ne* (page 1079), respectively. For example, *Eq(x, 0)* represents *x = 0*. These should be used instead of == or !=, as these are used for *structural* rather than symbolic equality. Inequality relationals can be created directly using <, <=, >, and >=, like *x < 0*.

**S (page 998)**

The *S* (page 998) object in SymPy has two purposes:
• It holds all singleton classes as attributes. Some special classes in SymPy are singletonized, meaning that there is always exactly one instance of them. This is an optimization that allows saving memory. For instance, there is only ever one instance of `Integer(0)`, which is available as `S.Zero`.

• It serves as a shorthand for `sympify()`, that is $S(a)$ is the same as `sympify(a)`. This is useful for converting integers to SymPy Integers in expressions to avoid dividing Python ints (see the gotchas section of the tutorial (page 13)).

Simplification

Simplification (not to be confused with `sympify`) refers to the process of taking an expression and transforming it into another expression that is mathematically equivalent but which is somehow “simpler”. The adjective “simple” is actually not very well-defined. What counts as simpler depends on the specific use-case and personal aesthetics.

The SymPy function `simplify()` (page 719) heuristically tries various simplification algorithms to try to find a “simpler” form of an expression. If you aren’t particular about what you want from “simplify”, it may be a good fit. But if you have an idea about what sort of simplification you want to apply, it is generally better to use one or more of targeted simplification functions (page 719) which apply very specific mathematical manipulations to an expression.

Solve

Solvers

To solve an equation or system of equations means to find a set of expressions that make the equation(s) true when the given symbol(s) are substituted with them. For example, the solution to the equation $x^2 = 1$ with respect to $x$ would be the set $\{-1, 1\}$. Different types of equations can be solved by SymPy using different solvers (page 131) functions. For instance, algebraic equations can be solved with `solve()` (page 882), differential equations can be solved with `dsolve()` (page 807), and so on.

SymPy generally uses the word “solve” and “solvers” to mean equation solving in this sense. It is not used in the sense of “solving a problem”. For instance, one would generally prefer to say “compute an integral” or “evaluate an integral” rather than “solve an integral” to refer to symbolic integration using the function `integrate()` (page 657).

Structural Equality

Two SymPy objects are structurally equal if they are equal as expressions, that is, they have the same expression trees. Two structurally equal expressions are considered to be identical by SymPy, since all SymPy expressions are immutable. Structural equality can be checked with the $==$ operator, which always returns `True` or `False`. Symbolic equality can be represented using `Eq` (page 1071).

Typically, two expressions are structurally equal if they are the same class and (recursively) have the same `args`. Two expressions may be mathematically identical but not structurally equal. For example, $(x + 1)^2$ and $x^2 + 2x + 1$ are mathematically equal, but they are not structurally equal, because the first is a `Pow` (page 1055) whose `args` consist of an `Add` (page 1062) and an `Integer` (page 1038), and the second is an `Add` (page 1062) whose `args` consist of a `Pow` (page 1055), a `Mul` (page 1058), and an `Integer` (page 1038).

Two apparently different expressions may be structurally equal if they are canonicalized to the same thing by automatic simplification. For example, $x + y$ and $y + x$ are structurally equal because the `Add` (page 1062) constructor automatically sorts its arguments, making them both the same.

Subexpression

A subexpression is an expression that is contained within a larger expression. A subex-
expression appears somewhere in the expression tree. For Add and Mul terms, commutative and associative laws may be taken into account when determining what is a subexpression. For instance, $x + y$ may sometimes be considered a subexpression of $x + y + z$, even though the expression tree for $Add(x, y)$ is not a direct child of the expression tree for $Add(x, y, z)$.

**Substitution**

Substitution refers to the act of replacing a symbol or subexpression inside of an expression with another expression. There are different methods in SymPy for performing substitution, including `subs` (page 993), `replace` (page 989), and `xreplace` (page 995). The methods may differ depending on whether they perform substitution using only strict structural equality or by making use of mathematical knowledge when determining where a subexpression appears in an expression. Substitution is the standard way to treat an expression as a mathematical function and evaluate it at a point.

**Symbolic**

A symbolic representation of a mathematical object is a representation that is partially or completely unevaluated at runtime. It may include named symbolic constants in place of explicit numeric values. A symbolic representation is often contrasted with a numeric one. Symbolic representations are mathematically exact, to contrast with numeric representations which are typically rounded so they can fit within a floating-point value. Symbolic expressions representing mathematical objects may be aware of mathematical properties of these objects and be able to simplify to equivalent symbolic expressions using those properties. The goal of SymPy is to represent and manipulate symbolic expressions representing various mathematical objects.

Some sources use the phrases “analytic solution” or “closed-form” to refer to the concept of “symbolic”, but this terminology is not used in SymPy. If used in SymPy, “analytic” would refer to the property of being an analytic function, and in SymPy `solve` refers only to a certain type of symbolic operation. “Closed-form” in SymPy would typically refer to the mathematical sense of the term, whereas “symbolic” would generally refer to the implementation detail of how a mathematical concept is implemented, and be in contrast with a numeric implementation of the same mathematical concept.

**Symbol** (page 1028)

Symbol (page 1028) is the class for symbol objects. A symbol represents a single mathematical variable in an expression. The Symbol (page 1028) class is a subclass of Expr and is atomic. A Symbol contains a name, which is any string, and assumptions. Symbols are typically defined with the Symbol constructor or the `symbols()` (page 1030) function. Two Symbols with the same name and assumptions are considered equal. Symbols are implicitly assumed to be independent or constant with respect to one another. Constants, variables, and parameters are all represented by Symbols. The distinction is generally made in the way the Symbols are used in a given SymPy function.

**sympify()** (page 970)

`sympify()` (page 970) (not to be confused with `simplify()`) is a function that converts non-SymPy objects into SymPy objects. The result of `sympify()` will be an instance of Basic. Objects that can be sympified include native Python numeric types such as int and float, strings that are parsable as SymPy expressions, and iterables containing sympifiable objects (see the documentation for `sympify()` (page 970) for more information).

Since all SymPy expressions must be instances of Basic, all SymPy functions and operations will implicitly call `sympify()` on their inputs. For example, $x + 1$ implicitly calls `sympify(1)` to convert the 1 that is a Python int into a SymPy Integer (page 1038). Functions that accept SymPy expressions should typically call `sympify()` on their arguments so that they work even when the input is not a SymPy type.
Three-valued logic

Three-valued logic is a logic with three values, True, False, and None. It is also sometimes called fuzzy logic, although this term also has different meanings in the mathematical literature, so “three-valued logic” is preferred. True and False work the same as in the usual two-valued predicate logic. None is an additional term that represents “unknown”, “noncomputable”, or “could be either True or False” (philosophically these are distinct concepts, but logically they all function identically). The semantics of None are that it absorbs other terms in logical operations whenever the result would differ if it were replaced with True or False. For example, None OR False is None, but None OR True is True because the predicate is True whether the None “really” represents a value of True or False. One must be careful when using the usual Python logical operators like and, or and not on three-valued logic, since None is false. See the guide for symbolic and fuzzy bools (page 95) for more details on how to code with three-valued logic.

Three-valued logic is used by the assumptions system to represent assumptions that are not known. For instance, x.is_positive might be None if x could be positive or negative under its given assumptions. Note that the predicate logic defined by Boolean subclasses represents a standard two-valued logic, not three-valued logic.

Undefined Function

An undefined function is a Function that has no mathematical properties defined on it. It always remains unevaluated, like f(x). An undefined function can be created by passing a string name of the function to Function, like f = Function('f'). Undefined functions are commonly used when working with ODEs (page 807). Undefined functions are also the easiest way to make symbols that mathematically depend on other symbols. For example, if f = Function('f') and x = Symbol('x'), then SymPy will know that f(x) depends on x, meaning, for instance, that the derivative diff(f(x), x) will not be evaluated to 0.

Unevaluated

An expression is unevaluated if the automatic simplification that typically occurs when the expression is created is disabled. This is typically done by setting evaluate=False, using with evaluate(False), or using UnevaluatedExpr (page 1027). While unevaluated expressions are supported, they can sometimes lead to surprising behavior because the expressions are not properly canonicalized.

The term unevaluated is also sometimes used to denote the fact that an expression does not evaluate to a specific value when its arguments are symbolic.

zoo (page 1048)

zoo (page 1048) represents complex infinity, i.e., the north pole of the Riemann sphere. The reason it is spelled this way is that it is “z-oo”, where “z” is the symbol commonly used for complex variables, and oo is the symbol SymPy uses for real positive infinity.
This section contains a summary of SymPy modules, functions, classes, and methods. All functions and objects implemented in the sympy core subpackage are documented below.

5.1 Basics

Contains a description of operations for the basic modules. Subcategories include: absolute basics, manipulation, assumptions, functions, simplification, calculus, solvers, and some other subcategories.

5.2 Code Generation

Contains a description of methods for the generation of compilable and executable code.

5.3 Logic

Contains method details for the logic and sets modules.

5.4 Matrices

Discusses methods for the matrices, tensor and vector modules.
5.5 Number Theory

Documents methods for the Number theory module.

5.6 Physics

Contains documentation for Physics methods.

5.7 Utilities

Contains docstrings for methods of several utility modules. Subcategories include: Interactive, Parsing, Printing, Testing, Utilities.

5.8 Topics

5.8.1 Basics

Contents

Assumptions

A module to implement logical predicates and assumption system.

Predicate

class sympy.assumptions.assume.Predicate(*args, **kwargs)

Base class for mathematical predicates. It also serves as a constructor for undefined predicate objects.
Explanation

Predicate is a function that returns a boolean value [1].

Predicate function is object, and it is instance of predicate class. When a predicate is applied to arguments, AppliedPredicate instance is returned. This merely wraps the argument and remain unevaluated. To obtain the truth value of applied predicate, use the function ask.

Evaluation of predicate is done by multiple dispatching. You can register new handler to the predicate to support new types.

Every predicate in SymPy can be accessed via the property of Q. For example, Q.even returns the predicate which checks if the argument is even number.

To define a predicate which can be evaluated, you must subclass this class, make an instance of it, and register it to Q. After then, dispatch the handler by argument types.

If you directly construct predicate using this class, you will get UndefinedPredicate which cannot be dispatched. This is useful when you are building boolean expressions which do not need to be evaluated.

Examples

Applying and evaluating to boolean value:

```python
>>> from sympy import Q, ask
>>> ask(Q.prime(7))
True
```

You can define a new predicate by subclassing and dispatching. Here, we define a predicate for sexy primes [2] as an example.

```python
>>> from sympy import Predicate, Integer
>>> class SexyPrimePredicate(Predicate):
...    name = "sexyprime"
>>> Q.sexyprime = SexyPrimePredicate()
>>> @Q.sexyprime.register(Integer, Integer)
...    def _(int1, int2, assumptions):
...        args = sorted([int1, int2])
...        if not all(ask(Q.prime(a), assumptions) for a in args):
...            return False
...        return args[1] - args[0] == 6
>>> ask(Q.sexyprime(5, 11))
True
```

Direct constructing returns UndefinedPredicate, which can be applied but cannot be dispatched.

```python
>>> from sympy import Predicate, Integer
>>> Q.P = Predicate("P")
>>> type(Q.P)
<class 'sympy.assumptions.assume.UndefPredicate'>
>>> Q.P(1)
Q.P(1)
```

(continues on next page)
>>> Q.P.register(Integer)(lambda expr, assump: True)
Traceback (most recent call last):
  ...
TypeError: <class 'sympy.assumptions.assume.UndefinedPredicate'> cannot be dispatched.

References

[R7], [R8]

eval(args, assumptions=True)
   Evaluate self(*args) under the given assumptions.
   This uses only direct resolution methods, not logical inference.

handler = <dispatched AskPredicateHandler>

classmethod register(*types, **kwargs)
   Register the signature to the handler.

classmethod register_many(*types, **kwargs)
   Register multiple signatures to same handler.

class sympy.assumptions.assume.AppliedPredicate(predicate, *args)
   The class of expressions resulting from applying Predicate to the arguments.
   AppliedPredicate merely wraps its argument and remain unevaluated. To evaluate
   it, use the ask() function.

Examples

>>> from sympy import Q, ask
>>> Q.integer(1)
Q.integer(1)

The function attribute returns the predicate, and the arguments attribute returns the
tuple of arguments.

>>> type(Q.integer(1))
<class 'sympy.assumptions.assume.AppliedPredicate'>
>>> Q.integer(1).function
Q.integer
>>> Q.integer(1).arguments
(1,)

Applied predicates can be evaluated to a boolean value with ask:

>>> ask(Q.integer(1))
True

property arg
   Return the expression used by this assumption.
Examples

```python
>>> from sympy import Q, Symbol
>>> x = Symbol('x')
>>> a = Q.integer(x + 1)
>>> a.arg
x + 1
```

**property arguments**
Return the arguments which are applied to the predicate.

**property function**
Return the predicate.

Querying

Queries are used to ask information about expressions. Main method for this is `ask()`:

```python
sympy.assumptions.ask(proposition, assumptions=True, context={})
```

Function to evaluate the proposition with assumptions.

**Parameters**

- `proposition` : Boolean
  Proposition which will be evaluated to boolean value. If this is not AppliedPredicate, it will be wrapped by `Q.is_true`.

- `assumptions` : Boolean, optional
  Local assumptions to evaluate the `proposition`.

- `context` : AssumptionsContext, optional
  Default assumptions to evaluate the `proposition`. By default, this is `sympy.assumptions.global_assumptions` variable.

**Returns**

True, False, or None

**Raises**

- `TypeError` : `proposition` or `assumptions` is not valid logical expression.
- `ValueError` : assumptions are inconsistent.

**Explanation**

This function evaluates the proposition to True or False if the truth value can be determined. If not, it returns None.

It should be discerned from `refine()` (page 255) which, when applied to a proposition, simplifies the argument to symbolic Boolean instead of Python built-in True, False or None.

**Syntax**

- `ask(proposition)`
  Evaluate the `proposition` in global assumption context.
• `ask(proposition, assumptions)`

Evaluate the `proposition` with respect to `assumptions` in global assumption context.

**Examples**

```python
>>> from sympy import ask, Q, pi
>>> from sympy import x, y
>>> ask(Q.rational(pi))
False
>>> ask(Q.even(x*y), Q.even(x) & Q.integer(y))
True
>>> ask(Q.prime(4*x), Q.integer(x))
False
```

If the truth value cannot be determined, `None` will be returned.

```python
>>> print(ask(Q.odd(3*x)))  # cannot determine unless we know x
None
```

`ValueError` is raised if assumptions are inconsistent.

```python
>>> ask(Q.integer(x), Q.even(x) & Q.odd(x))
Traceback (most recent call last):
...
ValueError: inconsistent assumptions Q.even(x) & Q.odd(x)
```

**Notes**

Relations in assumptions are not implemented (yet), so the following will not give a meaningful result.

```python
>>> ask(Q.positive(x), x > 0)
```

It is however a work in progress.

**See also:**

`sympy.assumptions.refine.refine` (page 255)

Simplification using assumptions. Proposition is not reduced to `None` if the truth value cannot be determined.

`ask`'s optional second argument should be a boolean expression involving assumptions about objects in `expr`. Valid values include:

- `Q.integer(x)`
- `Q.positive(x)`
- `Q.integer(x) & Q.positive(x)`
- etc.
Q is an object holding known predicates.

See documentation for the logic module for a complete list of valid boolean expressions.

You can also define a context so you don’t have to pass that argument each time to function ask(). This is done by using the assuming context manager from module sympy.assumptions.

```python
from sympy import *
>>> x = Symbol('x')
>>> y = Symbol('y')
>>> facts = Q.positive(x), Q.positive(y)
>>> with assuming(*facts):
...    print(ask(Q.positive(2*x + y)))
True
```

## Contents

### Ask

Module for querying SymPy objects about assumptions.

```python
class sympy.assumptions.ask.AssumptionKeys
    This class contains all the supported keys by ask. It should be accessed via the instance sympy.Q.
```

```python
sympy.assumptions.ask.ask(proposition, assumptions=True, context={})
Function to evaluate the proposition with assumptions.
```

**Parameters**

- **proposition**: Boolean
  
  Proposition which will be evaluated to boolean value. If this is not AppliedPredicate, it will be wrapped by Q.is_true.

- **assumptions**: Boolean, optional
  
  Local assumptions to evaluate the `proposition`.

- **context**: AssumptionsContext, optional
  
  Default assumptions to evaluate the `proposition`. By default, this is sympy.assumptions.global_assumptions variable.

**Returns**

- True, False, or None

**Raises**

- **TypeError**: `proposition or assumptions` is not valid logical expression.

  - **ValueError**: assumptions are inconsistent.
Explanation

This function evaluates the proposition to True or False if the truth value can be determined. If not, it returns None.

It should be discerned from *refine()* (page 255) which, when applied to a proposition, simplifies the argument to symbolic Boolean instead of Python built-in True, False or None.

Syntax

- **ask(proposition)**
  Evaluate the *proposition* in global assumption context.

- **ask(proposition, assumptions)**
  Evaluate the *proposition* with respect to *assumptions* in global assumption context.

Examples

```python
from sympy import ask, Q, pi
from sympy.abc import x, y

>>> ask(Q.rational(pi))
False

>>> ask(Q.even(x*y), Q.even(x) & Q.integer(y))
True

>>> ask(Q.prime(4*x), Q.integer(x))
False
```

If the truth value cannot be determined, None will be returned.

```python
>>> print(ask(Q.odd(3*x)))  # cannot determine unless we know x
None
```

ValueError is raised if assumptions are inconsistent.

```python
>>> ask(Q.integer(x), Q.even(x) & Q.odd(x))
Traceback (most recent call last):
...
ValueError: inconsistent assumptions Q.even(x) & Q.odd(x)
```

Notes

Relations in assumptions are not implemented (yet), so the following will not give a meaningful result.

```python
>>> ask(Q.positive(x), x > 0)
```

It is however a work in progress.

See also:
**sympy.assumptions.refine.refine** *(page 255)*
Simplification using assumptions. Proposition is not reduced to None if the truth value cannot be determined.

**sympy.assumptions.ask.register_handler(key, handler)**
Register a handler in the ask system. key must be a string and handler a class inheriting from AskHandler.
Deprecation since version 1.8: Use multipledispatch handler instead. See `Predicate` (page 253).

**sympy.assumptions.ask.remove_handler(key, handler)**
Removes a handler from the ask system.
Deprecation since version 1.8: Use multipledispatch handler instead. See `Predicate` (page 253).

**Assume**
A module which implements predicates and assumption context.

**class** sympy.assumptions.assume.AppliedPredicate(predicate, *args)
The class of expressions resulting from applying Predicate to the arguments. AppliedPredicate merely wraps its argument and remain unevaluated. To evaluate it, use the ask() function.

**Examples**

```python
>>> from sympy import Q, ask
>>> Q.integer(1)
Q.integer(1)
```
The function attribute returns the predicate, and the arguments attribute returns the tuple of arguments.

```python
>>> type(Q.integer(1))
<class 'sympy.assumptions.assume.AppliedPredicate'>
>>> Q.integer(1).function
Q.integer
>>> Q.integer(1).arguments
(1,)
```

Applied predicates can be evaluated to a boolean value with ask:

```python
>>> ask(Q.integer(1))
True
```

**property** arg
Return the expression used by this assumption.
Examples

```python
>>> from sympy import Q, Symbol
>>> x = Symbol('x')
>>> a = Q.integer(x + 1)
>>> a.arg
x + 1
```

**property arguments**

Return the arguments which are applied to the predicate.

**property function**

Return the predicate.

**class** sympy.assumptions.assume.AssumptionsContext

Set containing default assumptions which are applied to the ask() function.

**Explanation**

This is used to represent global assumptions, but you can also use this class to create your own local assumptions contexts. It is basically a thin wrapper to Python’s set, so see its documentation for advanced usage.

**Examples**

The default assumption context is global_assumptions, which is initially empty:

```python
>>> from sympy import ask, Q
>>> from sympy.assumptions import global_assumptions
>>> global_assumptions
AssumptionsContext()
```

You can add default assumptions:

```python
>>> from sympy.abc import x
>>> global_assumptions.add(Q.real(x))
>>> global_assumptions
AssumptionsContext({Q.real(x)})
>>> ask(Q.real(x))
True
```

And remove them:

```python
>>> global_assumptions.remove(Q.real(x))
>>> print(ask(Q.real(x)))
None
```

The clear() method removes every assumption:

```python
>>> global_assumptions.add(Q.positive(x))
>>> global_assumptions
AssumptionsContext({Q.positive(x)})
```
See also:

assuming (page 255)

add(*assumptions)
Add assumptions.

class sympy.assumptions.assume.Predicate(*args, **kwargs)
Base class for mathematical predicates. It also serves as a constructor for undefined predicate objects.

Explanation

Predicate is a function that returns a boolean value [1].

Predicate function is object, and it is instance of predicate class. When a predicate is applied to arguments, AppliedPredicate instance is returned. This merely wraps the argument and remain unevaluated. To obtain the truth value of applied predicate, use the function ask.

Evaluation of predicate is done by multiple dispatching. You can register new handler to the predicate to support new types.

Every predicate in SymPy can be accessed via the property of Q. For example, Q.even returns the predicate which checks if the argument is even number.

To define a predicate which can be evaluated, you must subclass this class, make an instance of it, and register it to Q. After then, dispatch the handler by argument types.

If you directly construct predicate using this class, you will get UndefinedPredicate which cannot be dispatched. This is useful when you are building boolean expressions which do not need to be evaluated.

Examples

Applying and evaluating to boolean value:

```python
>>> from sympy import Q, ask
>>> ask(Q.prime(7))
True
```

You can define a new predicate by subclassing and dispatching. Here, we define a predicate for sexy primes [2] as an example.

```python
>>> from sympy import Predicate, Integer
>>> class SexyPrimePredicate(Predicate):
...     name = "sexyprime"
>>> Q.sexyprime = SexyPrimePredicate()
>>> @Q.sexyprime.register(Integer, Integer)
...     def _(int1, int2, assumptions):
```

(continues on next page)
...    args = sorted([int1, int2])
...    if not all(ask(Q.prime(a), assumptions) for a in args):
...        return False
...    return args[1] - args[0] == 6
>>> ask(Q.sexyprime(5, 11))
True

Direct constructing returns UndefinedPredicate, which can be applied but cannot be dispatched.

```python
>>> from sympy import Predicate, Integer
>>> Q.P = Predicate("P")
>>> type(Q.P)
<class 'sympy.assumptions.assume.UndefinedPredicate'>
>>> Q.P(1)
Q.P(1)
>>> Q.P.register(Integer)(lambda expr, assum: True)
Traceback (most recent call last):
...
TypeError: <class 'sympy.assumptions.assume.UndefinedPredicate'> cannot be dispatched.
```

References

[R5], [R6]

`eval(args, assumptions=True)`

Evaluate `self(*args)` under the given assumptions.

This uses only direct resolution methods, not logical inference.

```
handler = <dispatched AskPredicateHandler>
```

```
classmethod register(*types, **kwargs)
    Register the signature to the handler.

classmethod register_many(*types, **kwargs)
    Register multiple signatures to same handler.
```

```
class sympy.assumptions.assume.UndefinedPredicate(name, handlers=None)
    Predicate without handler.
```

Explanation

This predicate is generated by using Predicate directly for construction. It does not have a handler, and evaluating this with arguments is done by SAT solver.
Examples

```python
>>> from sympy import Predicate, Q
>>> Q.P = Predicate('P')
>>> Q.P.func
<class 'sympy.assumptions.assume.UndefinedPredicate'>
>>> Q.P.name
Str('P')
```

sympy.assumptions.assume.assuming(*assumptions)

Context manager for assumptions.

Examples

```python
>>> from sympy import assuming, Q, ask
>>> from sympy.abc import x, y

print(ask(Q.integer(x + y)))
None

>>> with assuming(Q.integer(x), Q.integer(y)):
...    print(ask(Q.integer(x + y)))
True
```

Refine

sympy.assumptions.refine.refine(expr, assumptions=True)

Simplify an expression using assumptions.

Explanation

Unlike simplify() (page 719) which performs structural simplification without any assumption, this function transforms the expression into the form which is only valid under certain assumptions. Note that simplify() is generally not done in refining process.

Refining boolean expression involves reducing it to S.true or S.false. Unlike ask() (page 249), the expression will not be reduced if the truth value cannot be determined.

Examples

```python
>>> from sympy import refine, sqrt, Q
>>> from sympy.abc import x

refine(sqrt(x**2), Q.real(x))
Abs(x)

refine(sqrt(x**2), Q.positive(x))
x
```
>>> refine(Q.real(x), Q.positive(x))
True
>>> refine(Q.positive(x), Q.real(x))
Q.positive(x)

See also:

sympy.simplify.simplify.simplify (page 719)
Structural simplification without assumptions.
sympy.assumptions.ask.ask (page 249)
Query for boolean expressions using assumptions.

sympy.assumptions.refine.refine_Pow(expr, assumptions)
Handler for instances of Pow.

Examples

>>> from sympy import Q
>>> from sympy.assumptions.refine import refine_Pow
>>> from sympy.abc import x, y, z
>>> refine_Pow((-1)**x, Q.real(x))
1
>>> refine_Pow((-1)**x, Q.even(x))
-1

For powers of -1, even parts of the exponent can be simplified:

>>> refine_Pow((-1)**(x+y), Q.even(x))
(-1)**y
>>> refine_Pow((-1)**(x+y+z), Q.odd(x) & Q.odd(z))
(-1)**y
>>> refine_Pow((-1)**(x+y+2), Q.odd(x))
(-1)**(y + 1)
>>> refine_Pow((-1)**(x+3), True)
(-1)**(x + 1)

sympy.assumptions.refine.refine_abs(expr, assumptions)
Handler for the absolute value.

Examples

>>> from sympy import Q, Abs
>>> from sympy.assumptions.refine import refine_abs
>>> from sympy.abc import x
>>> refine_abs(Abs(x), Q.real(x))
x
>>> refine_abs(Abs(x), Q.positive(x))
x
>>> refine_abs(Abs(x), Q.negative(x))
-x
**sympy.assumptions.refine**. **refine_arg**(expr, assumptions)

Handler for complex argument

**Explanation**

```python
>>> from sympy.assumptions.refine import refine_arg
>>> from sympy import Q, arg
>>> from sympy.abc import x
>>> refine_arg(arg(x), Q.positive(x))
0
>>> refine_arg(arg(x), Q.negative(x))
pi
```

**sympy.assumptions.refine**. **refine_atan2**(expr, assumptions)

Handler for the atan2 function.

**Examples**

```python
>>> from sympy import Q, atan2
>>> from sympy.assumptions.refine import refine_atan2
>>> from sympy.abc import x, y
>>> refine_atan2(atan2(y,x), Q.real(y) & Q.positive(x))
atan(y/x)
>>> refine_atan2(atan2(y,x), Q.negative(y) & Q.negative(x))
atan(y/x) - pi
>>> refine_atan2(atan2(y,x), Q.positive(y) & Q.negative(x))
atan(y/x) + pi
>>> refine_atan2(atan2(y,x), Q.zero(y) & Q.negative(x))
pi
>>> refine_atan2(atan2(y,x), Q.positive(y) & Q.zero(x))
pi/2
>>> refine_atan2(atan2(y,x), Q.negative(y) & Q.zero(x))
-pi/2
>>> refine_atan2(atan2(y,x), Q.zero(y) & Q.zero(x))
nan
```

**sympy.assumptions.refine**. **refine_im**(expr, assumptions)

Handler for imaginary part.

**Explanation**

```python
>>> from sympy.assumptions.refine import refine_im
>>> from sympy import Q, im
>>> from sympy.abc import x
>>> refine_im(im(x), Q.real(x))
0
>>> refine_im(im(x), Q.imaginary(x))
-I*x
```
**SymPy Documentation, Release 1.12.1**

`sympy.assumptions.refine.refine_matrixelement(expr, assumptions)`

Handler for symmetric part.

**Examples**

```python
>>> from sympy.assumptions.refine import refine_matrixelement
>>> from sympy import MatrixSymbol, Q
>>> X = MatrixSymbol('X', 3, 3)
>>> refine_matrixelement(X[0, 1], Q.symmetric(X))
X[0, 1]
>>> refine_matrixelement(X[1, 0], Q.symmetric(X))
X[0, 1]
```

`sympy.assumptions.refine.refine_re(expr, assumptions)`

Handler for real part.

**Examples**

```python
>>> from sympy.assumptions.refine import refine_re
>>> from sympy import Q, re
>>> from sympy.abc import x
>>> refine_re(re(x), Q.real(x))
x
>>> refine_re(re(x), Q.imaginary(x))
0
```

`sympy.assumptions.refine.refine_sign(expr, assumptions)`

Handler for sign.

**Examples**

```python
>>> from sympy.assumptions.refine import refine_sign
>>> from sympy import Symbol, Q, sign, im
>>> x = Symbol('x', real = True)
>>> expr = sign(x)
>>> refine_sign(expr, Q.positive(x) & Q.nonzero(x))
1
>>> refine_sign(expr, Q.negative(x) & Q.nonzero(x))
-1
>>> refine_sign(expr, Q.zero(x))
0
>>> y = Symbol('y', imaginary = True)
>>> expr = sign(y)
>>> refine_sign(expr, Q.positive(im(y)))
I
>>> refine_sign(expr, Q.negative(im(y)))
-I
```
Predicates

Common

class sympy.assumptions.predicates.common.IsTruePredicate(*args, **kwargs)
    Generic predicate.

Explanation

ask(Q.is_true(x)) is true iff x is true. This only makes sense if x is a boolean object.

Examples

>>> from sympy import ask, Q
>>> from sympy.abc import x, y
>>> ask(Q.is_true(True))
True

Wrapping another applied predicate just returns the applied predicate.

>>> Q.is_true(Q.even(x))
Q.even(x)

Wrapping binary relation classes in SymPy core returns applied binary relational predicates.

>>> from sympy import Eq, Gt
>>> Q.is_true(Eq(x, y))
Q.eq(x, y)
>>> Q.is_true(Gt(x, y))
Q.gt(x, y)

Notes

This class is designed to wrap the boolean objects so that they can behave as if they are applied predicates. Consequently, wrapping another applied predicate is unnecessary and thus it just returns the argument. Also, binary relation classes in SymPy core have binary predicates to represent themselves and thus wrapping them with Q.is_true converts them to these applied predicates.
Handler

Multiply dispatched method: IsTrueHandler
Wrapper allowing to query the truth value of a boolean expression.
handler = <dispatched IsTrueHandler>

class sympy.assumptions.predicates.common.CommutativePredicate(*args, **kwargs)
Commutative predicate.

Explanation

ask(Q.commutative(x)) is true iff x commutes with any other object with respect to multiplication operation.

Handler

Multiply dispatched method: CommutativeHandler
Handler for key ‘commutative’.
handler = <dispatched CommutativeHandler>

Calculus

class sympy.assumptions.predicates.calculus.FinitePredicate(*args, **kwargs)
Finite number predicate.

Explanation

Q.finite(x) is true if x is a number but neither an infinity nor a NaN. In other words, ask(Q.finite(x)) is true for all numerical x having a bounded absolute value.

Examples

>>> from sympy import Q, ask, S, oo, I, zoo
>>> from sympy.abc import x
>>> ask(Q.finite(oo))
False
>>> ask(Q.finite(-oo))
False
>>> ask(Q.finite(zoo))
False
>>> ask(Q.finite(1))
True
>>> ask(Q.finite(2 + 3*I))
True
>>> ask(Q.finite(x), Q.positive(x))

(continues on next page)
True
>>> print(ask(Q.finite(S.NaN)))
None

**Handler**

Multiply dispatched method: FiniteHandler
Handler for Q.finite. Test that an expression is bounded respect to all its variables.

**References**

[R9]

handler = <dispatched FiniteHandler>

```python
class sympy.assumptions.predicates.calculus.InfinitePredicate(*args, **kwargs)
```

Infinite number predicate.
Q.infinite(x) is true iff the absolute value of x is infinity.

**Handler**

Multiply dispatched method: InfiniteHandler
Handler for Q.infinite key.
handler = <dispatched InfiniteHandler>

**Matrix**

```python
class sympy.assumptions.predicates.matrices.SymmetricPredicate(*args, **kwargs)
```

Symmetric matrix predicate.

**Explanation**

Q.symmetric(x) is true iff x is a square matrix and is equal to its transpose. Every square diagonal matrix is a symmetric matrix.
Examples

```python
from sympy import Q, ask, MatrixSymbol

X = MatrixSymbol('X', 2, 2)
Y = MatrixSymbol('Y', 2, 3)
Z = MatrixSymbol('Z', 2, 2)
ask(Q.symmetric(X*Z), Q.symmetric(X) & Q.symmetric(Z))
True
ask(Q.symmetric(X + Z), Q.symmetric(X) & Q.symmetric(Z))
True
ask(Q.symmetric(Y))
False
```

Handler

Multiply dispatched method: SymmetricHandler
Handler for Q.symmetric.

References

[R10]

```python
class sympy.assumptions.predicates.matrices.InvertiblePredicate(*args,
                   **kwargs)
```

Invertible matrix predicate.

Explanation

Q.invertible(x) is true iff x is an invertible matrix. A square matrix is called invertible only if its determinant is 0.

Examples

```python
from sympy import Q, ask, MatrixSymbol

X = MatrixSymbol('X', 2, 2)
Y = MatrixSymbol('Y', 2, 3)
Z = MatrixSymbol('Z', 2, 2)
ask(Q.invertible(X*Y), Q.invertible(X))
False
ask(Q.invertible(X*Z), Q.invertible(X) & Q.invertible(Z))
True
ask(Q.invertible(X), Q.fullrank(X) & Q.square(X))
True
```
**Handler**

Multiply dispatched method: InvertibleHandler
Handler for Q.invertible.

**References**

[R11]

```python
definition = <dispatched InvertibleHandler>
```

**Explanation**

Q.orthogonal(x) is true iff x is an orthogonal matrix. A square matrix M is an orthogonal matrix if it satisfies $M^T M = M M^T = I$ where $M^T$ is the transpose matrix of $M$ and $I$ is an identity matrix. Note that an orthogonal matrix is necessarily invertible.

**Examples**

```python
>>> from sympy import Q, ask, MatrixSymbol, Identity
>>> X = MatrixSymbol('X', 2, 2)
>>> Y = MatrixSymbol('Y', 2, 3)
>>> Z = MatrixSymbol('Z', 2, 2)
>>> ask(Q.orthogonal(Y))
False
>>> ask(Q.orthogonal(X*Z*X), Q.orthogonal(X) & Q.orthogonal(Z))
True
>>> ask(Q.orthogonal(Identity(3)))
True
>>> ask(Q.invertible(X), Q.orthogonal(X))
True
```

**Handler**

Multiply dispatched method: OrthogonalHandler
Handler for key 'orthogonal'.
References

[R12]

handler = <dispatched OrthogonalHandler>

class sympy.assumptions.predicates.matrices.UnitaryPredicate(*args, **kwargs)

Unitary matrix predicate.

Explanation

Q.unitary(x) is true iff x is a unitary matrix. Unitary matrix is an analogue to orthogonal matrix. A square matrix \( M \) with complex elements is unitary if \( M^TM = MM^T = I \) where \( M^T \) is the conjugate transpose matrix of \( M \).

Examples

```python
>>> from sympy import Q, ask, MatrixSymbol, Identity
>>> X = MatrixSymbol('X', 2, 2)
>>> Y = MatrixSymbol('Y', 2, 3)
>>> Z = MatrixSymbol('Z', 2, 2)
>>> ask(Q.unitary(Y))
False
>>> ask(Q.unitary(X*Z*X), Q.unitary(X) & Q.unitary(Z))
True
>>> ask(Q.unitary(Identity(3)))
True
```

Handler

Multiply dispatched method: UnitaryHandler

Handler for key ‘unitary’.

References

[R13]

handler = <dispatched UnitaryHandler>

class sympy.assumptions.predicates.matrices.PositiveDefinitePredicate(*args, **kwargs)

Positive definite matrix predicate.
Explanation

If $M$ is a $n \times n$ symmetric real matrix, it is said to be positive definite if $Z^T M Z$ is positive for every non-zero column vector $Z$ of $n$ real numbers.

Examples

```python
>>> from sympy import Q, ask, MatrixSymbol, Identity
>>> X = MatrixSymbol('X', 2, 2)
>>> Y = MatrixSymbol('Y', 2, 3)
>>> Z = MatrixSymbol('Z', 2, 2)
>>> ask(Q.positive_definite(Y))
False
>>> ask(Q.positive_definite(Identity(3)))
True
>>> ask(Q.positive_definite(X + Z), Q.positive_definite(X) & ...
... Q.positive_definite(Z))
True
```

Handler

Multiply dispatched method: PositiveDefiniteHandler

Handler for key ‘positive_definite’.

References

[R14]

handler = <dispatched PositiveDefiniteHandler>

class sympy.assumptions.predicates.matrices.UpperTriangularPredicate(*args,
**kwargs)

Upper triangular matrix predicate.

Explanation

A matrix $M$ is called upper triangular matrix if $M_{ij} = 0$ for $i < j$.

Examples

```python
>>> from sympy import Q, ask, ZeroMatrix, Identity
>>> ask(Q.upper_triangular(Identity(3)))
True
>>> ask(Q.upper_triangular(ZeroMatrix(3, 3)))
True
```
**Handler**

Multiply dispatched method: UpperTriangularHandler
Handler for key ‘upper_triangular’.

**References**

[R15]
handler = <dispatched UpperTriangularHandler>

class sympy.assumptions.predicates.matrices.LowerTriangularPredicate(*args, **kwargs)

Lower triangular matrix predicate.

**Explanation**

A matrix $M$ is called lower triangular matrix if $M_{ij} = 0$ for $i > j$.

**Examples**

```python
>>> from sympy import Q, ask, ZeroMatrix, Identity
>>> ask(Q.lower_triangular(Identity(3)))
True
>>> ask(Q.lower_triangular(ZeroMatrix(3, 3)))
True
```

**Handler**

Multiply dispatched method: LowerTriangularHandler
Handler for key ‘lower_triangular’.

**References**

[R16]
handler = <dispatched LowerTriangularHandler>

class sympy.assumptions.predicates.matrices.DiagonalPredicate(*args, **kwargs)

Diagonal matrix predicate.
**Explanation**

`Q.diagonal(x)` is true iff `x` is a diagonal matrix. A diagonal matrix is a matrix in which the entries outside the main diagonal are all zero.

**Examples**

```python
>>> from sympy import Q, ask, MatrixSymbol, ZeroMatrix
>>> X = MatrixSymbol('X', 2, 2)
>>> ask(Q.diagonal(ZeroMatrix(3, 3)))
True
>>> ask(Q.diagonal(X), Q.lower_triangular(X) & ... Q.upper_triangular(X))
True
```

**Handler**

Multiply dispatched method: DiagonalHandler

Handler for key ‘diagonal’.

**References**

[R17]

handler = <dispatched DiagonalHandler>

*class* sympy.assumptions.predicates.matrices.FullRankPredicate(*args, **kwargs)*

Fullrank matrix predicate.

**Explanation**

`Q.fullrank(x)` is true iff `x` is a full rank matrix. A matrix is full rank if all rows and columns of the matrix are linearly independent. A square matrix is full rank iff its determinant is nonzero.

**Examples**

```python
>>> from sympy import Q, ask, MatrixSymbol, ZeroMatrix, Identity
>>> X = MatrixSymbol('X', 2, 2)
>>> ask(Q.fullrank(X.T), Q.fullrank(X))
True
>>> ask(Q.fullrank(ZeroMatrix(3, 3)))
False
>>> ask(Q.fullrank(Identity(3)))
True
```
**Handler**

Multiply dispatched method: FullRankHandler
Handler for key ‘fullrank’.
handler = <dispatched FullRankHandler>

```python
class sympy.assumptions.predicates.matrices.SquarePredicate(*args, **kwargs)
```
Square matrix predicate.

**Explanation**

Q.square(x) is true iff x is a square matrix. A square matrix is a matrix with the same number of rows and columns.

**Examples**

```python
>>> from sympy import Q, ask, MatrixSymbol, ZeroMatrix, Identity
>>> X = MatrixSymbol('X', 2, 2)
>>> Y = MatrixSymbol('X', 2, 3)
>>> ask(Q.square(X))
True
>>> ask(Q.square(Y))
False
>>> ask(Q.square(ZeroMatrix(3, 3)))
True
>>> ask(Q.square(Identity(3)))
True
```

**Handler**

Multiply dispatched method: SquareHandler
Handler for Q.square.

**References**

[R18]

handler = <dispatched SquareHandler>

```python
class sympy.assumptions.predicates.matrices.IntegerElementsPredicate(*args, **kwargs)
```
Integer elements matrix predicate.
Explanation

Q.integer_elements(x) is true iff all the elements of x are integers.

Examples

```python
>>> from sympy import Q, ask, MatrixSymbol
>>> X = MatrixSymbol('X', 4, 4)
>>> ask(Q.integer(X[1, 2]), Q.integer_elements(X))
True
```

Handler

Multiply dispatched method: IntegerElementsHandler
Handler for key 'integer_elements'.
```python
handler = <dispatched IntegerElementsHandler>
```

class sympy.assumptions.predicates.matrices.RealElementsPredicate(*args, **kwargs)

Real elements matrix predicate.

Explanation

Q.real_elements(x) is true iff all the elements of x are real numbers.

Examples

```python
>>> from sympy import Q, ask, MatrixSymbol
>>> X = MatrixSymbol('X', 4, 4)
>>> ask(Q.real(X[1, 2]), Q.real_elements(X))
True
```

Handler

Multiply dispatched method: RealElementsHandler
Handler for key 'real_elements'.
```python
handler = <dispatched RealElementsHandler>
```

class sympy.assumptions.predicates.matrices.ComplexElementsPredicate(*args, **kwargs)

Complex elements matrix predicate.
Explanation

Q.complex_elements(x) is true iff all the elements of x are complex numbers.

Examples

```python
>>> from sympy import Q, ask, MatrixSymbol
>>> X = MatrixSymbol('X', 4, 4)
>>> ask(Q.complex(X[1, 2]), Q.complex_elements(X))
True
>>> ask(Q.complex_elements(X), Q.integer_elements(X))
True
```

Handler

Multiply dispatched method: ComplexElementsHandler
Handler for key ‘complex_elements’.
handler = <dispatched ComplexElementsHandler>

```python
class sympy.assumptions.predicates.matrices.SingularPredicate(*args, **kwargs)
Singular matrix predicate.
A matrix is singular iff the value of its determinant is 0.
```

Examples

```python
>>> from sympy import Q, ask, MatrixSymbol
>>> X = MatrixSymbol('X', 4, 4)
>>> ask(Q.singular(X), Qinvertible(X))
False
>>> ask(Q.singular(X), ~Q.invertible(X))
True
```

Handler

Multiply dispatched method: SingularHandler
Predicate fore key ‘singular’.
References

[R19]
handler = <dispatched SingularHandler>

class sympy.assumptions.predicates.matrices.NormalPredicate(*args, **kwargs)
Normal matrix predicate.
A matrix is normal if it commutes with its conjugate transpose.

Examples

```python
>>> from sympy import Q, ask, MatrixSymbol
>>> X = MatrixSymbol('X', 4, 4)
>>> ask(Q.normal(X), Q.unitary(X))
True
```

Handler

Multiply dispatched method: NormalHandler
Predicate fore key ‘normal’.

References

[R20]
handler = <dispatched NormalHandler>

class sympy.assumptions.predicates.matrices.TriangularPredicate(*args, **kwargs)
Triangular matrix predicate.

Explanation

Q.triangular(X) is true if X is one that is either lower triangular or upper triangular.

Examples

```python
>>> from sympy import Q, ask, MatrixSymbol
>>> X = MatrixSymbol('X', 4, 4)
>>> ask(Q.triangular(X), Q.upper_triangular(X))
True
>>> ask(Q.triangular(X), Q.lower_triangular(X))
True
```
**Handler**

Multiply dispatched method: TriangularHandler
Predicate fore key ‘triangular’.

**References**

[R21]

```
handler = <dispatched TriangularHandler>
```

class sympy.assumptions.predicates.matrices.UnitTriangularPredicate(*args, **kwargs)

Unit triangular matrix predicate.

**Explanation**

A unit triangular matrix is a triangular matrix with 1s on the diagonal.

**Examples**

```
>>> from sympy import Q, ask, MatrixSymbol
>>> X = MatrixSymbol('X', 4, 4)
>>> ask(Q.triangular(X), Q.unit_triangular(X))
True
```

**Handler**

Multiply dispatched method: UnitTriangularHandler
Predicate fore key ‘unit_triangular’.
```
handler = <dispatched UnitTriangularHandler>
```

**Number Theory**

class sympy.assumptions.predicates.ntheory.EvenPredicate(*args, **kwargs)

Even number predicate.
**Explanation**

ask(Q.even(x)) is true iff x belongs to the set of even integers.

**Examples**

```python
>>> from sympy import Q, ask, pi
>>> ask(Q.even(0))
True
>>> ask(Q.even(2))
True
>>> ask(Q.even(3))
False
>>> ask(Q.even(pi))
False
```

**Handler**

Multiply dispatched method: EvenHandler

Handler for key ‘even’.

`handler = <dispatched EvenHandler>`

```python
class sympy.assumptions.predicates.ntheory.OddPredicate(*args, **kwargs)
```

Odd number predicate.

**Explanation**

ask(Q.odd(x)) is true iff x belongs to the set of odd numbers.

**Examples**

```python
>>> from sympy import Q, ask, pi
>>> ask(Q.odd(0))
False
>>> ask(Q.odd(2))
False
>>> ask(Q.odd(3))
True
>>> ask(Q.odd(pi))
False
```
SymPy Documentation, Release 1.12.1

**Handler**

Multiply dispatched method: OddHandler

Handler for key ‘odd’. Test that an expression represents an odd number.

```
handler = <dispatched OddHandler>
```

```python
class sympy.assumptions.predicates.ntheory.PrimePredicate(*args, **kwargs)
Prime number predicate.
```

**Explanation**

`ask(Q.prime(x))` is true iff `x` is a natural number greater than 1 that has no positive divisors other than 1 and the number itself.

**Examples**

```python
>>> from sympy import Q, ask
>>> ask(Q.prime(0))
False
>>> ask(Q.prime(1))
False
>>> ask(Q.prime(2))
True
>>> ask(Q.prime(20))
False
>>> ask(Q.prime(-3))
False
```

**Handler**

Multiply dispatched method: PrimeHandler

Handler for key ‘prime’. Test that an expression represents a prime number. When the expression is an exact number, the result (when True) is subject to the limitations of `isprime()` which is used to return the result.

```
handler = <dispatched PrimeHandler>
```

```python
class sympy.assumptions.predicates.ntheory.CompositePredicate(*args, **kwargs)
Composite number predicate.
```
Explanation

ask(Q.composite(x)) is true iff x is a positive integer and has at least one positive divisor other than 1 and the number itself.

Examples

```python
>>> from sympy import Q, ask
>>> ask(Q.composite(0))
False
>>> ask(Q.composite(1))
False
>>> ask(Q.composite(2))
False
>>> ask(Q.composite(20))
True
```

Handler

Multiply dispatched method: CompositeHandler

Handler for key ‘composite’.

```
handler = <dispatched CompositeHandler>
```

Order

```python
class sympy.assumptions.predicates.order_positivePredicate(*args, **kwargs)
```

Positive real number predicate.

Explanation

Q.positive(x) is true iff x is real and x > 0, that is if x is in the interval (0, ∞). In particular, infinity is not positive.

A few important facts about positive numbers:

- **Note that Q.nonpositive and ~Q.positive are not the same** thing. ~Q.positive(x) simply means that x is not positive, whereas Q.nonpositive(x) means that x is real and not positive, i.e., Q.nonpositive(x) is logically equivalent to Q.negative(x)|Q.zero(x)’. So for example, ~Q.positive(I) is true, whereas Q.nonpositive(I) is false.

- **See the documentation of Q.real for more information about** related facts.
Examples

```python
>>> from sympy import Q, ask, symbols, I
>>> x = symbols('x')
>>> ask(Q.positive(x), Q.real(x) & ~Q.negative(x) & ~Q.zero(x))
True
>>> ask(Q.positive(1))
True
>>> ask(Q.nonpositive(I))
False
>>> ask(~Q.positive(I))
True
```

Handler

Multiply dispatched method: PositiveHandler

Handler for key ‘positive’. Test that an expression is strictly greater than zero.

```python
handler = <dispatched PositiveHandler>
```

class sympy.assumptions.predicates.order.NegativePredicate(*args, **kwargs)

Negative number predicate.

Explanation

Q.negative(x) is true iff x is a real number and x < 0, that is, it is in the interval (−∞, 0). Note in particular that negative infinity is not negative.

A few important facts about negative numbers:

- **Note that Q.nonnegative and ~Q.negative are not the same** thing. ~Q.negative(x) simply means that x is not negative, whereas Q.nonnegative(x) means that x is real and not negative, i.e., Q.nonnegative(x) is logically equivalent to Q.zero(x) | Q.positive(x). So for example, ~Q.negative(I) is true, whereas Q.nonnegative(I) is false.

- **See the documentation of Q.real for more information about related facts.**

Examples

```python
>>> from sympy import Q, ask, symbols, I
>>> x = symbols('x')
>>> ask(Q.negative(x), Q.real(x) & ~Q.positive(x) & ~Q.zero(x))
True
>>> ask(Q.negative(-1))
True
>>> ask(Q.nonnegative(I))
False
>>> ask(~Q.negative(I))
True
```
**Handler**

Multiply dispatched method: NegativeHandler

Handler for \(Q.negative\). Test that an expression is strictly less than zero.

```python
def handler = <dispatched NegativeHandler>
```

```python
class sympy.assumptions.predicates.order.ZeroPredicate(*args, **kwargs)
```

Zero number predicate.

**Explanation**

ask\((Q.zero(x))\) is true iff the value of \(x\) is zero.

**Examples**

```python
>>> from sympy import ask, Q, oo, symbols
>>> x, y = symbols('x, y')
>>> ask(Q.zero(0))
True
>>> ask(Q.zero(1/oo))
True
>>> print(ask(Q.zero(0*oo)))
None
>>> ask(Q.zero(1))
False
>>> ask(Q.zero(x*y), Q.zero(x) | Q.zero(y))
True
```

**Handler**

Multiply dispatched method: ZeroHandler

Handler for key ‘zero’.

```python
def handler = <dispatched ZeroHandler>
```

```python
class sympy.assumptions.predicates.order.NonZeroPredicate(*args, **kwargs)
```

Nonzero real number predicate.

**Explanation**

ask\((Q.nonzero(x))\) is true iff \(x\) is real and \(x\) is not zero. Note in particular that \(Q.nonzero(x)\) is false if \(x\) is not real. Use \(~Q.zero(x)\) if you want the negation of being zero without any real assumptions.

A few important facts about nonzero numbers:

- \(Q.nonzero\) is logically equivalent to \(Q.positive | Q.negative\).
- **See the documentation of \(Q.real\) for more information about related facts.**
Examples

```python
>>> from sympy import Q, ask, symbols, I, oo
>>> x = symbols('x')
>>> print(ask(Q.nonzero(x), ~Q.zero(x)))
None
>>> ask(Q.nonzero(x), Q.positive(x))
True
>>> ask(Q.nonzero(x), Q.zero(x))
False
>>> ask(Q.nonzero(0))
False
>>> ask(Q.nonzero(I))
False
>>> ask(~Q.zero(I))
True
>>> ask(Q.nonzero(oo))
False
```

Handler

Multiply dispatched method: NonZeroHandler

Handler for key ‘zero’. Test that an expression is not identically zero.

```python
handler = <dispatched NonZeroHandler>
```

class sympy.assumptions.predicates.order.NonPositivePredicate(*args, **kwargs)

Nonpositive real number predicate.

Explanation

ask(Q.nonpositive(x)) is true iff x belongs to the set of negative numbers including zero.

- **Note that Q.nonpositive and ~Q.positive are not the same** thing. ~Q.positive(x) simply means that x is not positive, whereas Q.nonpositive(x) means that x is real and not positive, i.e., Q.nonpositive(x) is logically equivalent to Q.negative(x) | Q.zero(x). So for example, ~Q.positive(I) is true, whereas Q.nonpositive(I) is false.

Examples

```python
>>> from sympy import Q, ask, I
```

```python
>>> ask(Q.nonpositive(-1))
True
>>> ask(Q.nonpositive(0))
True
>>> ask(Q.nonpositive(1))
```

(continues on next page)
False
>>> ask(Q.nonpositive(I))
False
>>> ask(Q.nonpositive(-I))
False

**Handler**

Multiply dispatched method: NonPositiveHandler

Handler for key ‘nonpositive’.

```
handler = <dispatched NonPositiveHandler>
```

```
class sympy.assumptions.predicates.order.NonNegativePredicate(*args, **kwargs)
```

Nonnegative real number predicate.

**Explanation**

`ask(Q.nonnegative(x))` is true iff x belongs to the set of positive numbers including zero.

- **Note that Q.nonnegative and ~Q.negative are not the same** thing.  
  `~Q.negative(x)` simply means that x is not negative, whereas Q.nonnegative(x) means that x is real and not negative, i.e., Q.nonnegative(x) is logically equivalent to Q.zero(x) | Q.positive(x).  So for example, ~Q.negative(I) is true, whereas Q.nonnegative(I) is false.

**Examples**

```python
>>> from sympy import Q, ask, I
>>> ask(Q.nonnegative(1))
True
>>> ask(Q.nonnegative(0))
True
>>> ask(Q.nonnegative(-1))
False
>>> ask(Q.nonnegative(I))
False
>>> ask(Q.nonnegative(-I))
False
```
**Handler**

Multiply dispatched method: NonNegativeHandler
Handler for Q.nonnegative.

```
handler = <dispatched NonNegativeHandler>
```

**Sets**

```
class sympy.assumptions.predicates.sets.IntegerPredicate(*args, **kwargs)
Integer predicate.
```

**Explanation**

Q.integer(x) is true iff x belongs to the set of integer numbers.

**Examples**

```
>>> from sympy import Q, ask, S
>>> ask(Q.integer(5))
True
>>> ask(Q.integer(S(1)/2))
False
```

**Handler**

Multiply dispatched method: IntegerHandler
Handler for Q.integer.
Test that an expression belongs to the field of integer numbers.

**References**

[R22]
```
handler = <dispatched IntegerHandler>
```

```
class sympy.assumptions.predicates.sets.RationalPredicate(*args, **kwargs)
Rational number predicate.
```
**Explanation**

Q.rational(x) is true iff x belongs to the set of rational numbers.

**Examples**

```python
>>> from sympy import ask, Q, pi, S
>>> ask(Q.rational(0))
True
>>> ask(Q.rational(S(1)/2))
True
>>> ask(Q.rational(pi))
False
```

**Handler**

Multiply dispatched method: RationalHandler

Handler for Q.rational.

Test that an expression belongs to the field of rational numbers.

**References**

[R23]

handler = <dispatched RationalHandler>

class sympy.assumptions.predicates.sets.IrrationalPredicate(*args, **kwargs)

Irrational number predicate.

**Explanation**

Q.irrational(x) is true iff x is any real number that cannot be expressed as a ratio of integers.

**Examples**

```python
>>> from sympy import ask, Q, pi, S, I
>>> ask(Q.irrational(0))
False
>>> ask(Q.irrational(S(1)/2))
False
>>> ask(Q.irrational(pi))
True
>>> ask(Q.irrational(I))
False
```
**Handler**

Multiply dispatched method: IrrationalHandler

Handler for `Q.irrational`.

Test that an expression is irrational numbers.

**References**

[R24]

```
handler = <dispatched IrrationalHandler>
```

class sympy.assumptions.predicates.sets.RealPredicate(*args, **kwargs)

Real number predicate.

**Explanation**

`Q.real(x)` is true iff `x` is a real number, i.e., it is in the interval \((-\infty, \infty)\). Note that, in particular the infinities are not real. Use `Q.extended_real` if you want to consider those as well.

A few important facts about reals:

- **Every real number is positive, negative, or zero.** Furthermore, because these sets are pairwise disjoint, each real number is exactly one of those three.

- Every real number is also complex.

- Every real number is finite.

- Every real number is either rational or irrational.

- Every real number is either algebraic or transcendental.

- **The facts `Q.negative`, `Q.zero`, `Q.positive`,**
  `Q.nonnegative`, `Q.nonpositive`, `Q.nonzero`, `Q.integer`, `Q.rational`, and `Q. irrational` all imply `Q.real`, as do all facts that imply those facts.

- **The facts `Q.algebraic`, and `Q.transcendental` do not imply**
  `Q.real`; they imply `Q.complex`. An algebraic or transcendental number may or may not be real.

- **The “non” facts (i.e., `Q.nonnegative`, `Q.nonzero`,**
  `Q.nonpositive` and `Q.noninteger`) are not equivalent to not the fact, but rather, not the fact and `Q.real`. For example, `Q.nonnegative` means \(~Q.negative \& \ Q.real\). So for example, `I` is not nonnegative, nonzero, or nonpositive.
Explanations

5.8. Topics
**Handler**

Multiply dispatched method: ExtendedRealHandler
Handler for `Q.extended_real`.
Test that an expression belongs to the field of extended real numbers, that is real numbers union {Infinity, -Infinity}.

```python
handler = <dispatched ExtendedRealHandler>
```

**Explanation**

`ask(Q.hermitian(x))` is true iff `x` belongs to the set of Hermitian operators.

**Handler**

Multiply dispatched method: HermitianHandler
Handler for `Q.hermitian`.
Test that an expression belongs to the field of Hermitian operators.

**References**

[R26]

```python
handler = <dispatched HermitianHandler>
```

**ComplexPredicate**

```python
class sympy.assumptions.predicates.sets.ComplexPredicate(*args, **kwargs)
Complex number predicate.
```

**Explanation**

`Q.complex(x)` is true iff `x` belongs to the set of complex numbers. Note that every complex number is finite.

**Examples**

```python
>>> from sympy import Q, Symbol, ask, I, oo
>>> x = Symbol('x')
>>> ask(Q.complex(0))
True
>>> ask(Q.complex(2 + 3*I))
True
>>> ask(Q.complex(oo))
False
```
**Handler**

Multiply dispatched method: ComplexHandler
Handler for Q.complex.
Test that an expression belongs to the field of complex numbers.

**References**

[R27]

```python
handler = <dispatched ComplexHandler>
```

```python
class sympy.assumptions.predicates.sets.ImaginaryPredicate(*args, **kwargs)
```

Imaginary number predicate.

**Explanation**

Q.imaginary(x) is true iff x can be written as a real number multiplied by the imaginary unit I. Please note that 0 is not considered to be an imaginary number.

**Examples**

```python
>>> from sympy import Q, ask, I
>>> ask(Q.imaginary(3*I))
True
>>> ask(Q.imaginary(2 + 3*I))
False
>>> ask(Q.imaginary(0))
False
```

**Handler**

Multiply dispatched method: ImaginaryHandler
Handler for Q.imaginary.
Test that an expression belongs to the field of imaginary numbers, that is, numbers in the form x*I, where x is real.
References

[R28]
handler = <dispatched ImaginaryHandler>

class sympy.assumptions.predicates.sets.AntihermitianPredicate(*args, **kwargs)
Antihermitian predicate.

Explanation

Q.antihermitian(x) is true iff x belongs to the field of antihermitian operators, i.e.,
operators in the form x*I, where x is Hermitian.

Handler

Multiply dispatched method: AntiHermitianHandler
Handler for Q.antihermitian.
Test that an expression belongs to the field of anti-Hermitian
operators, that is, operators in the form x*I, where x is Hermitian.

References

[R29]
handler = <dispatched AntiHermitianHandler>

class sympy.assumptions.predicates.sets.AlgebraicPredicate(*args, **kwargs)
Algebraic number predicate.

Explanation

Q.algebraic(x) is true iff x belongs to the set of algebraic numbers. x is algebraic if
there is some polynomial in p(x)\in \mathbb\{Q\}[x] such that p(x) = 0.

Examples

```python
>>> from sympy import ask, Q, sqrt, I, pi
>>> ask(Q.algebraic(sqrt(2)))
True
>>> ask(Q.algebraic(I))
True
>>> ask(Q.algebraic(pi))
False
```
**Handler**

Multiply dispatched method: AskAlgebraicpredicateHandler
Handler for key AskAlgebraicpredicateHandler

**References**

[R30]

```python
AlgebraicHandler = <dispatched AlgebraicHandler>
handler = <dispatched AskAlgebraicpredicateHandler>
```

**class** sympy.assumptions.predicates.sets.TranscendentalPredicate(*args, **kwargs)**

Transcendental number predicate.

**Explanation**

Q.transcendental(x) is true iff x belongs to the set of transcendental numbers. A transcendental number is a real or complex number that is not algebraic.

**Handler**

Multiply dispatched method: Transcendental
Handler for Q.transcendental key.

```python
handler = <dispatched Transcendental>
```

**Performance improvements**

On queries that involve symbolic coefficients, logical inference is used. Work on improving satisfiable function (sympy.logic.inference.satisfiable) should result in notable speed improvements.

Logic inference used in one ask could be used to speed up further queries, and current system does not take advantage of this. For example, a truth maintenance system ([https://en.wikipedia.org/wiki/Truth_maintenance_system](https://en.wikipedia.org/wiki/Truth_maintenance_system)) could be implemented.

**Misc**

You can find more examples in the form of tests in the directory sympy/assumptions/tests/
Calculus

Calculus-related methods. This module implements a method to find Euler-Lagrange Equations for given Lagrangian.

```python
sympy.calculus.euler.euler_equations(L, funcs=(), vars=())
```

Find the Euler-Lagrange equations [R31] for a given Lagrangian.

**Parameters**

- `L` : Expr
  The Lagrangian that should be a function of the functions listed in the second argument and their derivatives.
  For example, in the case of two functions \( f(x, y), g(x, y) \) and two independent variables \( x, y \) the Lagrangian has the form:

  \[
  L \left( f(x, y), g(x, y), \frac{\partial f(x, y)}{\partial x}, \frac{\partial f(x, y)}{\partial y}, \frac{\partial g(x, y)}{\partial x}, \frac{\partial g(x, y)}{\partial y}, x, y \right)
  \]

  In many cases it is not necessary to provide anything, except the Lagrangian, it will be auto-detected (and an error raised if this cannot be done).

- `funcs` : Function or an iterable of Functions
  The functions that the Lagrangian depends on. The Euler equations are differential equations for each of these functions.

- `vars` : Symbol or an iterable of Symbols
  The Symbols that are the independent variables of the functions.

**Returns**

- `eqns` : list of Eq
  The list of differential equations, one for each function.

**Examples**

```python
>>> from sympy import euler_equations, Symbol, Function
>>> x = Function('x')
>>> t = Symbol('t')
>>> L = (x(t).diff(t))**2/2 - x(t)**2/2
>>> euler_equations(L, x(t), t)
[Eq(-x(t) - Derivative(x(t), (t, 2)), 0)]
>>> u = Function('u')
>>> x = Symbol('x')
>>> L = (u(t, x).diff(t))**2/2 - (u(t, x).diff(x))**2/2
>>> euler_equations(L, u(t, x), [t, x])
[Eq(-Derivative(u(t, x), (t, 2)) + Derivative(u(t, x), (x, 2)), 0)]
```

Singularity

This module implements algorithms for finding singularities for a function and identifying types of functions.

The differential calculus methods in this module include methods to identify the following function types in the given Interval: - Increasing - Strictly Increasing - Decreasing - Strictly Decreasing - Monotonic

```
sympy.calculus.singularities.is_decreasing(expression, interval=Reals, symbol=None)
```

Return whether the function is decreasing in the given interval.

**Parameters**

- **expression**: Expr
  The target function which is being checked.

- **interval**: Set, optional
  The range of values in which we are testing (defaults to set of all real numbers).

- **symbol**: Symbol, optional
  The symbol present in expression which gets varied over the given range.

**Returns**

- **Boolean**
  True if expression is decreasing (either strictly decreasing or constant) in the given interval, False otherwise.

**Examples**

```python
>>> from sympy import is_decreasing
>>> from sympy.abc import x, y
>>> from sympy import S, Interval, oo
>>> is_decreasing(1/(x**2 - 3*x), Interval.open(S(3)/2, 3))
True
>>> is_decreasing(1/(x**2 - 3*x), Interval.open(1.5, 3))
True
>>> is_decreasing(1/(x**2 - 3*x), Interval.Lopen(3, oo))
True
>>> is_decreasing(1/(x**2 - 3*x), Interval.Ropen(-oo, S(3)/2))
False
>>> is_decreasing(1/(x**2 - 3*x), Interval.Ropen(-oo, 1.5))
False
>>> is_decreasing(-x**2, Interval(-oo, 0))
False
```

(continues on next page)
is_decreasing(-x**2 + y, Interval(-oo, 0), x)
False

sympy.calculus.singularities.is_increasing(expression, interval=Reals, symbol=None)

Return whether the function is increasing in the given interval.

Parameters

expression : Expr
    The target function which is being checked.

interval : Set, optional
    The range of values in which we are testing (defaults to set of all real numbers).

symbol : Symbol, optional
    The symbol present in expression which gets varied over the given range.

Returns

Boolean
    True if expression is increasing (either strictly increasing or constant) in the given interval, False otherwise.

Examples

>>> from sympy import is_increasing
>>> from sympy.abc import x, y
>>> from sympy import S, Interval, oo
>>> is_increasing(x**3 - 3*x**2 + 4*x, S.Reals)
True
>>> is_increasing(-x**2, Interval(-oo, 0))
True
>>> is_increasing(-x**2, Interval(0, oo))
False
>>> is_increasing(4*x**3 - 6*x**2 - 72*x + 30, Interval(-2, 3))
False
>>> is_increasing(x**2 + y, Interval(1, 2), x)
True

sympy.calculus.singularities.is_monotonic(expression, interval=Reals, symbol=None)

Return whether the function is monotonic in the given interval.

Parameters

expression : Expr
    The target function which is being checked.

interval : Set, optional
    The range of values in which we are testing (defaults to set of all real numbers).
symbol : Symbol, optional

The symbol present in expression which gets varied over the given range.

Returns

Boolean

True if expression is monotonic in the given interval, False otherwise.

Raises

NotImplementedError

Monotonicity check has not been implemented for the queried function.

Examples

```python
>>> from sympy import is_monotonic
>>> from sympy.abc import x, y
>>> from sympy import S, Interval, oo
>>> is_monotonic(1/(x**2 - 3*x), Interval.open(S(3)/2, 3))
True
>>> is_monotonic(1/(x**2 - 3*x), Interval.open(1.5, 3))
True
>>> is_monotonic(1/(x**2 - 3*x), Interval.Lopen(3, oo))
True
>>> is_monotonic(x**3 - 3*x**2 + 4*x, S.Reals)
True
>>> is_monotonic(-x**2, S.Reals)
False
>>> is_monotonic(x**2 + y + 1, Interval(1, 2), x)
True
```

sympy.calculus.singularities.is_strictly_decreasing(expression, interval=S.Reals, symbol=None)

Return whether the function is strictly decreasing in the given interval.

Parameters

expression : Expr

The target function which is being checked.

interval : Set, optional

The range of values in which we are testing (defaults to set of all real numbers).

symbol : Symbol, optional

The symbol present in expression which gets varied over the given range.

Returns

Boolean

True if expression is strictly decreasing in the given interval, False otherwise.
Examples

```python
>>> from sympy import is_strictly_decreasing
>>> from sympy import x, y
>>> from sympy import S, Interval, oo

is_strictly_decreasing(1/(x**2 - 3*x), Interval.Lopen(3, oo))
True

is_strictly_decreasing(1/(x**2 - 3*x), Interval.Ropen(-oo, S(3)/2))
False

is_strictly_decreasing(1/(x**2 - 3*x), Interval.Ropen(-oo, 1.5))
False

is_strictly_decreasing(-x**2, Interval(-oo, 0))
False

is_strictly_decreasing(-x**2 + y, Interval(-oo, 0), x)
False
```

```python
sympy.calculus.singularities.is_strictly_increasing(expression, interval=Reals, symbol=None)
```

Return whether the function is strictly increasing in the given interval.

Parameters

- **expression**: Expr
  
The target function which is being checked.

- **interval**: Set, optional
  
The range of values in which we are testing (defaults to set of all real numbers).

- **symbol**: Symbol, optional
  
The symbol present in expression which gets varied over the given range.

Returns

Boolean

True if expression is strictly increasing in the given interval, False otherwise.

Examples

```python
>>> from sympy import is_strictly_increasing
>>> from sympy import x, y
>>> from sympy import Interval, oo

is_strictly_increasing(4*x**3 - 6*x**2 - 72*x + 30, Interval.Ropen(-oo, -2))
True

is_strictly_increasing(4*x**3 - 6*x**2 - 72*x + 30, Interval.Lopen(3, oo))
True

is_strictly_increasing(4*x**3 - 6*x**2 - 72*x + 30, Interval.open(-2, 3))
False
```

(continues on next page)
sympy.calculus.singularities.
monotonicity_helper(expression, predicate, interval=Reals, symbol=None)

Helper function for functions checking function monotonicity.

**Parameters**

- **expression**: Expr
  - The target function which is being checked

- **predicate**: function
  - The property being tested for. The function takes in an integer and returns a boolean. The integer input is the derivative and the boolean result should be true if the property is being held, and false otherwise.

- **interval**: Set, optional
  - The range of values in which we are testing, defaults to all reals.

- **symbol**: Symbol, optional
  - The symbol present in expression which gets varied over the given range.

**It returns a boolean indicating whether the interval in which the function’s derivative satisfies given predicate is a superset of the given interval.**

**Returns**

- **Boolean**
  - True if predicate is true for all the derivatives when symbol is varied in range, False otherwise.

sympy.calculus.singularities.
singularities(expression, symbol, domain=None)

Find singularities of a given function.

**Parameters**

- **expression**: Expr
  - The target function in which singularities need to be found.

- **symbol**: Symbol
  - The symbol over the values of which the singularity in expression in being searched for.

**Returns**

- **Set**
  - A set of values for symbol for which expression has a singularity. An EmptySet is returned if expression has no singularities for any given value of Symbol.

**Raises**

- **NotImplementedError**
Methods for determining the singularities of this function have not been developed.

**Notes**

This function does not find non-isolated singularities nor does it find branch points of the expression.

**Currently supported functions are:**

- univariate continuous (real or complex) functions

**Examples**

```python
>>> from sympy import singularities, Symbol, log
>>> x = Symbol('x', real=True)
>>> y = Symbol('y', real=False)
>>> singularities(x**2 + x + 1, x)
EmptySet
>>> singularities(1/(x + 1), x)
{-1}
>>> singularities(1/(y**2 + 1), y)
{-I, I}
>>> singularities(1/(y**3 + 1), y)
{-1, 1/2 - sqrt(3)*I/2, 1/2 + sqrt(3)*I/2}
>>> singularities(log(x), x)
{0}
```

**References**

[R32]

**Finite difference weights**

This module implements an algorithm for efficient generation of finite difference weights for ordinary differentials of functions for derivatives from 0 (interpolation) up to arbitrary order.

The core algorithm is provided in the finite difference weight generating function (`finite_diff_weights`), and two convenience functions are provided for:

- **estimating a derivative (or interpolate) directly from a series of points** is also provided (apply_finite_diff).

- **differentiating by using finite difference approximations** (differentiate_finite).

```python
sympy.calculus.finite_diff.apply_finite_diff(order, x_list, y_list, x0=0)
```

Calculates the finite difference approximation of the derivative of requested order at x0 from points provided in x_list and y_list.

**Parameters**

- order: int
order of derivative to approximate. 0 corresponds to interpolation.

**x_list:** sequence
Sequence of (unique) values for the independent variable.

**y_list:** sequence
The function value at corresponding values for the independent variable in x_list.

**x0:** Number or Symbol
At what value of the independent variable the derivative should be evaluated. Defaults to 0.

Returns
sympy.core.add.Add or sympy.core.numbers.Number
The finite difference expression approximating the requested derivative order at x0.

### Examples

```python
>>> from sympy import apply_finite_diff
>>> cube = lambda arg: (1.0*arg)**3
>>> xlist = range(-3,3+1)
>>> apply_finite_diff(2, xlist, map(cube, xlist), 2) - 12
-3.55271367880050e-15
```

we see that the example above only contain rounding errors. apply_finite_diff can also be used on more abstract objects:

```python
>>> from sympy import IndexedBase, Idx
>>> x, y = map(IndexedBase, 'xy')
>>> i = Idx('i')
>>> x_list, y_list = zip(*[(x[i+j], y[i+j]) for j in range(-1,2)])
>>> apply_finite_diff(1, x_list, y_list, x[i])
((x[i + 1] - x[i])/(-x[i - 1] + x[i]) - 1)*y[i]/(x[i + 1] - x[i]) -
(x[i + 1] - x[i])*y[i - 1]/((-x[i - 1] + x[i])) +
(-x[i - 1] + x[i])*y[i + 1]/((x[i + 1] - x[i - 1])*(x[i + 1] - x[i]))
```

### Notes

Order = 0 corresponds to interpolation. Only supply so many points you think makes sense to around x0 when extracting the derivative (the function need to be well behaved within that region). Also beware of Runge’s phenomenon.

See also:
```
sympy.calculus.finite_diff.finite_diff_weights (page 296)
```
References

Fortran 90 implementation with Python interface for numerics: finitediff
sympy.calculus.finite_diff.differentiate_finite(expr, *symbols, points=1, x0=None, wrt=None, evaluate=False)

Differentiate expr and replace Derivatives with finite differences.

Parameters

expr : expression
  *symbols : differentiate with respect to symbols
  points: sequence, coefficient or undefined function, optional
    see Derivative.as_finite_difference
  x0: number or Symbol, optional
    see Derivative.as_finite_difference
  wrt: Symbol, optional
    see Derivative.as_finite_difference

Examples

```python
>>> from sympy import sin, Function, differentiate_finite
>>> from sympy.abc import x, y, h
>>> f, g = Function('f'), Function('g')
>>> differentiate_finite(f(x)*g(x), x, points=[x-h, x+h])
-f(-h + x)*g(-h + x)/(2*h) + f(h + x)*g(h + x)/(2*h)
```
differentiate_finite works on any expression, including the expressions with embedded derivatives:

```python
>>> differentiate_finite(f(x) + sin(x), x, 2)
-2*f(x) + f(x - 1) + f(x + 1) - 2*sin(x) + sin(x - 1) + sin(x + 1)
```
```python
>>> differentiate_finite(f(x)*g(x).diff(x), x)
(-g(x) + g(x + 1))*f(x + 1/2) - (g(x) - g(x - 1))*f(x - 1/2)
```
To make finite difference with non-constant discretization step use undefined functions:

```python
>>> dx = Function('dx')
>>> differentiate_finite(f(x)*g(x).diff(x), points=dx(x))
-(g(x - dx(x)/2 - dx(x - dx(x)/2)/2)/dx(x - dx(x)/2) + g(x - dx(x)/2 + dx(x - dx(x)/2)/2)/dx(x - dx(x)/2))*f(x - dx(x)/2)/dx(x) +
(-g(x + dx(x)/2 - dx(x + dx(x)/2)/2)/dx(x + dx(x)/2) + g(x + dx(x)/2 + dx(x + dx(x)/2)/2)/dx(x + dx(x)/2))*f(x + dx(x)/2)/dx(x)
```
sympy.calculus.finite_diff.finite_diff_weights(order, x_list, x0=1)

Calculates the finite difference weights for an arbitrarily spaced one-dimensional grid (x_list) for derivatives at x0 of order 0, 1, ..., up to order using a recursive formula. Order of accuracy is at least len(x_list) - order, if x_list is defined correctly.

Parameters

order: int
Up to what derivative order weights should be calculated. 0 corresponds to interpolation.

x_list: sequence
Sequence of (unique) values for the independent variable. It is useful (but not necessary) to order x_list from nearest to furthest from x0; see examples below.

x0: Number or Symbol
Root or value of the independent variable for which the finite difference weights should be generated. Default is S.One.

Returns

list
A list of sublists, each corresponding to coefficients for increasing derivative order, and each containing lists of coefficients for increasing subsets of x_list.

Examples

>>> from sympy import finite_diff_weights, S
>>> res = finite_diff_weights(1, [-S(1)/2, S(1)/2, S(3)/2, S(5)/2], 0)
>>> res
[[[1, 0, 0, 0],
  [1/2, 1/2, 0, 0],
  [3/8, 3/4, -1/8, 0],
  [5/16, 15/16, -5/16, 1/16]],
 [[0, 0, 0, 0],
  [-1, 1, 0, 0],
  [-1, 1, 0, 0],
  [-23/24, 7/8, 1/8, -1/24]]]
>>> res[0][-1] # FD weights for 0th derivative, using full x_list
[5/16, 15/16, -5/16, 1/16]
>>> res[1][-1] # FD weights for 1st derivative
[-23/24, 7/8, 1/8, -1/24]
>>> res[1][-2] # FD weights for 1st derivative, using x_list[:1]
[-1, 1, 0, 0]
>>> res[1][-1][0] # FD weight for 1st deriv. for x_list[0]
-23/24
>>> res[1][-1][1] # FD weight for 1st deriv. for x_list[1], etc.
7/8

Each sublist contains the most accurate formula at the end. Note, that in the above example res[1][1] is the same as res[1][2]. Since res[1][2] has an order of accuracy of len(x_list[:3]) - order = 3 - 1 = 2, the same is true for res[1][1]!
Let us compare this to a differently defined `x_list`. Pay attention to `foo[i][k]` corresponding to the gridpoint defined by `x_list[k]`.

```python
>>> foo = finite_diff_weights(1, [-S(2), -S(1), S(0), S(1), S(2)], 0)[1]
>>> foo
[[0, 0, 0, 0, 0],
 [-1, 1, 0, 0, 0],
 [1/2, -2, 3/2, 0, 0],
 [1/6, -1, 1/2, 1/3, 0],
 [1/12, -2/3, 0, 2/3, -1/12]]
>>> foo[1] # not the same and of lower accuracy as res[1]!
[-1, 1, 0, 0, 0]
>>> foo[2] # classic double backward step approximation
[1/2, -2, 3/2, 0, 0]
[1/12, -2/3, 0, 2/3, -1/12]
```

Note that, unless you plan on using approximations based on subsets of `x_list`, the order of gridpoints does not matter.

The capability to generate weights at arbitrary points can be used e.g. to minimize Runge's phenomenon by using Chebyshev nodes:

```python
>>> from sympy import cos, symbols, pi, simplify
>>> N, (h, x) = 4, symbols('h x')
>>> x_list = [x+h*cos(i*pi/(N)) for i in range(N,-1,-1)] # chebyshev nodes
>>> print(x_list)
[-h + x, -sqrt(2)*h/2 + x, x, sqrt(2)*h/2 + x, h + x]
>>> mycoeffs = finite_diff_weights(1, x_list, 0)[1][4]
>>> simplify(c) for c in mycoeffs]
[(h**3/2 + h**2*x - 3*h*x**2 - 4*x**3)/h**4,
 (-sqrt(2)*h**3 - 4*h**2*x + 3*sqrt(2)*h*x**2 + 8*x**3)/h**4,
 (6*h**2*x - 8*x**3)/h**4,
 (sqrt(2)*h**3 - 4*h**2*x + 3*sqrt(2)*h*x**2 + 8*x**3)/h**4,
 (-h**3/2 + h**2*x + 3*h*x**2 - 4*x**3)/h**4]
```
Notes

If weights for a finite difference approximation of 3rd order derivative is wanted, weights
for 0th, 1st and 2nd order are calculated “for free”, so are formulae using subsets of
x_list. This is something one can take advantage of to save computational cost. Be
aware that one should define x_list from nearest to furthest from x0. If not, subsets of
x_list will yield poorer approximations, which might not grand an order of accuracy of
len(x_list) - order.

References

[R33]
sympy.calculus.util.continuous_domain(f, symbol, domain)
Returns the intervals in the given domain for which the function is continuous. This
method is limited by the ability to determine the various singularities and discontinuities
of the given function.

Parameters

f : Expr (page 999)
The concerned function.
symbol : Symbol (page 1028)
The variable for which the intervals are to be determined.
domain : Interval (page 1239)
The domain over which the continuity of the symbol has to be
checked.

Returns

Interval (page 1239)
Union of all intervals where the function is continuous.

Raises

NotImplementedError
If the method to determine continuity of such a function has not yet
been developed.

Examples

```python
>>> from sympy import Interval, Symbol, S, tan, log, pi, sqrt
>>> from sympy.calculus.util import continuous_domain
>>> x = Symbol('x')
>>> continuous_domain(1/x, x, S.Reals)
Union(Interval.open(-oo, 0), Interval.open(0, oo))
>>> continuous_domain(tan(x), x, Interval(0, pi))
Union(Interval.Ropen(0, pi/2), Interval.Lopen(pi/2, pi))
>>> continuous_domain(sqrt(x - 2), x, Interval(-5, 5))
```
(continues on next page)
sympy.calculus.util.function_range \( f, \) \( symbol, \) \( domain \)

Finds the range of a function in a given domain. This method is limited by the ability to determine the singularities and determine limits.

**Parameters**
- \( f : \) \textit{Expr} (page 999)
  - The concerned function.
- \( symbol : \) \textit{Symbol} (page 1028)
  - The variable for which the range of function is to be determined.
- \( domain : \) \textit{Interval} (page 1239)
  - The domain under which the range of the function has to be found.

**Returns**
- \( Interval \) (page 1239)
  - Union of all ranges for all intervals under domain where function is continuous.

**Raises**
- \textit{NotImplementedError}
  - If any of the intervals, in the given domain, for which function is continuous are not finite or real, OR if the critical points of the function on the domain cannot be found.

**Examples**

```python
>>> from sympy import Interval, Symbol, S, exp, log, pi, sqrt, sin, tan
>>> from sympy.calculus.util import function_range
>>> x = Symbol('x')
>>> function_range(sin(x), x, Interval(0, 2*pi))
Interval(-1, 1)
>>> function_range(tan(x), x, Interval(-pi/2, pi/2))
Interval(-oo, oo)
>>> function_range(1/x, x, S.Reals)
Union(Interval.open(-oo, 0), Interval.open(0, oo))
>>> function_range(exp(x), x, S.Reals)
Interval.open(0, oo)
>>> function_range(log(x), x, S.Reals)
Interval(-oo, oo)
>>> function_range(sqrt(x), x, Interval(-5, 9))
Interval(0, 3)
```

sympy.calculus.util.is_convex \( f, *syms, domain=\textit{Reals} \)

Determines the convexity of the function passed in the argument.
Parameters

- **f**: `Expr` (page 999)
  - The concerned function.
- **syms**: Tuple of `Symbol` (page 1028)
  - The variables with respect to which the convexity is to be determined.
- **domain**: `Interval` (page 1239), optional
  - The domain over which the convexity of the function has to be checked. If unspecified, `S.Reals` will be the default domain.

Returns

- **bool**
  - The method returns `True` if the function is convex otherwise it returns `False`.

Raises

- **NotImplementedError**
  - The check for the convexity of multivariate functions is not implemented yet.

Notes

To determine concavity of a function pass \(-f\) as the concerned function. To determine logarithmic convexity of a function pass \(\log(f)\) as concerned function. To determine logarithmic concavity of a function pass \(-\log(f)\) as concerned function.

Currently, convexity check of multivariate functions is not handled.

Examples

```python
>>> from sympy import is_convex, symbols, exp, oo, Interval
>>> x = symbols('x')
>>> is_convex(exp(x), x)
True
>>> is_convex(x**3, x, domain = Interval(-1, oo))
False
>>> is_convex(1/x**2, x, domain=Interval.open(0, oo))
True
```

References

[R34], [R35], [R36], [R37], [R38]

**sympy.calculus.util.lcim(numbers)**

Returns the least common integral multiple of a list of numbers.

The numbers can be rational or irrational or a mixture of both. *None* is returned for incommensurable numbers.
Parameters
numbers : list
    Numbers (rational and/or irrational) for which lcm is to be found.

Returns
number
    lcm if it exists, otherwise None for incommensurable numbers.

Examples

```python
>>> from sympy.calculus.util import lcm
>>> from sympy import S, pi
>>> lcm([S(1)/2, S(3)/4, S(5)/6])
15/2
>>> lcm([2*pi, 3*pi, pi, pi/2])
6*pi
>>> lcm([S(1), 2*pi])
```

SymPy.calculus.util.maximum(f, symbol, domain=Reals)
Returns the maximum value of a function in the given domain.

Parameters
f : Expr (page 999)
    The concerned function.
symbol : Symbol (page 1028)
    The variable for maximum value needs to be determined.
domain : Interval (page 1239)
    The domain over which the maximum have to be checked. If unspecified, then the global maximum is returned.

Returns
number
    Maximum value of the function in given domain.

Examples

```python
>>> from sympy import Interval, Symbol, S, sin, cos, pi, maximum
>>> x = Symbol('x')

>>> f = -x**2 + 2*x + 5
>>> maximum(f, x, S.Reals)
6

>>> maximum(sin(x), x, Interval(-pi, pi/4))
sqrt(2)/2
```
sympy.calculus.util.minimum(f, symbol, domain=Reals)
Returns the minimum value of a function in the given domain.

Parameters
f : Expr
   The concerned function.
symbol : Symbol
   The variable for minimum value needs to be determined.
domain : Interval
   The domain over which the minimum have to be checked. If unspecified, then the global minimum is returned.

Returns
number
   Minimum value of the function in the given domain.

Examples
>>> from sympy import Interval, Symbol, S, sin, cos, minimum
>>> x = Symbol('x')

>>> f = x**2 + 2*x + 5
>>> minimum(f, x, S.Reals)
4

>>> minimum(sin(x), x, Interval(2, 3))
sin(3)

>>> minimum(sin(x)*cos(x), x)
-1/2

sympy.calculus.util.not_empty_in(finset_intersection, *syms)
Finds the domain of the functions in finset_intersection in which the finite_set is not-empty.

Parameters
finset_intersection : Intersection of FiniteSet
   The unevaluated intersection of FiniteSet containing real-valued functions with Union of Sets
syms : Tuple of symbols
   Symbol for which domain is to be found

Raises
NotImplementedError
The algorithms to find the non-emptiness of the given \( \text{FiniteSet} \) are not yet implemented.

**ValueError**

The input is not valid.

**RuntimeError**

It is a bug, please report it to the github issue tracker (https://github.com/sympy/sympy/issues).

**Examples**

```python
>>> from sympy import FiniteSet, Interval, not_empty_in, oo
>>> from sympy.abc import x
>>> not_empty_in(FiniteSet(x/2).intersect(Interval(0, 1)), x)
Interval(0, 2)
>>> not_empty_in(FiniteSet(x, x**2).intersect(Interval(1, 2)), x)
Union(Interval(1, 2), Interval(-sqrt(2), -1))
>>> not_empty_in(FiniteSet(x**2/(x + 2)).intersect(Interval(1, oo)), x)
Union(Interval.Lopen(-2, -1), Interval(2, oo))
```

**sympy.calculus.util.peri**

The concerned function.

**symbol** : \( Symbol \) (page 1028)

The variable for which the period is to be determined.

**check** : bool, optional

The flag to verify whether the value being returned is a period or not.

**Returns**

<table>
<thead>
<tr>
<th>period</th>
</tr>
</thead>
</table>
| The period of the function is returned. None is returned when the function is aperiodic or has a complex period. The value of 0 is returned as the period of a constant function.

**Raises**

**NotImplementedError**

The value of the period computed cannot be verified.
Notes

Currently, we do not support functions with a complex period. The period of functions having complex periodic values such as \( \exp \), \( \sinh \) is evaluated to None.

The value returned might not be the “fundamental” period of the given function i.e. it may not be the smallest periodic value of the function.

The verification of the period through the check flag is not reliable due to internal simplification of the given expression. Hence, it is set to False by default.

Examples

```python
>>> from sympy import periodicity, Symbol, sin, cos, tan, exp
>>> x = Symbol('x')
>>> f = sin(x) + sin(2*x) + sin(3*x)
>>> periodicity(f, x)
2*pi
>>> periodicity(sin(x)**cos(x), x)
pi
>>> periodicity(exp(tan(2*x) - 1), x)
pi/2
>>> periodicity(sin(4*x)**cos(2*x), x)
pi
>>> periodicity(exp(x), x)
```

`sympy.calculus.util.stationary_points(f, symbol, domain=Reals)`

Returns the stationary points of a function (where derivative of the function is 0) in the given domain.

Parameters

- **f**: `Expr` (page 999)
  - The concerned function.

- **symbol**: `Symbol` (page 1028)
  - The variable for which the stationary points are to be determined.

- **domain**: `Interval` (page 1239)
  - The domain over which the stationary points have to be checked. If unspecified, `S.Reals` will be the default domain.

Returns

Set

A set of stationary points for the function. If there are no stationary point, an `EmptySet` (page 1245) is returned.
Examples

```python
>>> from sympy import Interval, Symbol, S, sin, pi, pprint, stationary_points
>>> x = Symbol('x')
```

```python
>>> stationary_points(1/x, x, S.Reals)
EmptySet
```

```python
>>> pprint(stationary_points(sin(x), x), use_unicode=False)
\{2*n*pi + -- | n in Integers\} U \{2*n*pi + ---- | n in Integers\}
  2
```

```python
>>> stationary_points(sin(x), x, Interval(0, 4*pi))
\{pi/2, 3*pi/2, 5*pi/2, 7*pi/2\}
```

Combinatorics

Contents

Partitions

```python
class sympy.combinatorics.partitions.Particle(*partition)
```
This class represents an abstract partition.

A partition is a set of disjoint sets whose union equals a given set.

See also:

* `sympy.utilities.iterables.partitions` (page 2159), `sympy.utilities.iterables.multiset_partitions` (page 2154)

**property RGS**

Returns the “restricted growth string” of the partition.

Explanation

The RGS is returned as a list of indices, L, where L[i] indicates the block in which element i appears. For example, in a partition of 3 elements (a, b, c) into 2 blocks ([c], [a, b]) the RGS is [1, 1, 0]: “a” is in block 1, “b” is in block 1 and “c” is in block 0.
Examples

```python
>>> from sympy.combinatorics import Partition
>>> a = Partition([1, 2], [3], [4, 5])
>>> a.members
(1, 2, 3, 4, 5)
>>> a.RGS
(0, 0, 1, 2, 2)
>>> a + 1
Partition({3}, {4}, {5}, {1, 2})
>>> _.RGS
(0, 0, 1, 2, 3)
```

classmethod `from_rgs`(rgs, elements)

Creates a set partition from a restricted growth string.

Explanation

The indices given in rgs are assumed to be the index of the element as given in elements as provided (the elements are not sorted by this routine). Block numbering starts from 0. If any block was not referenced in rgs an error will be raised.

Examples

```python
>>> from sympy.combinatorics import Partition
>>> Partition.from_rgs([0, 1, 2, 0, 1], list('abcde'))
Partition({c}, {a, d}, {b, e})
>>> Partition.from_rgs([0, 1, 2, 0, 1], list('cbead'))
Partition({e}, {a, c}, {b, d})
>>> a = Partition([1, 4], [2], [3, 5])
>>> Partition.from_rgs(a.RGS, a.members)
Partition({2}, {1, 4}, {3, 5})
```

property `partition`

Return partition as a sorted list of lists.

Examples

```python
>>> from sympy.combinatorics import Partition
>>> Partition([1], [2, 3]).partition
[[[1], [2, 3]]]
```

property `rank`

Gets the rank of a partition.
Examples

```python
>>> from sympy.combinatorics import Partition
>>> a = Partition([1, 2], [3], [4, 5])
>>> a.rank
13
```

**sort_key**(order=None)

Return a canonical key that can be used for sorting.

Ordering is based on the size and sorted elements of the partition and ties are broken with the rank.

Examples

```python
>>> from sympy import default_sort_key
>>> from sympy.combinatorics import Partition
>>> from sympy.abc import x
>>> a = Partition([1, 2])
>>> b = Partition([3, 4])
>>> c = Partition([1, x])
>>> d = Partition(list(range(4)))
>>> l = [d, b, a + 1, a, c]
>>> l.sort(key=default_sort_key); l
[Partition({1, 2}), Partition({1}, {2}), Partition({1, x}), Partition({0, 1, 2, 3})]
```

class sympy.combinatorics.partitions.IntegerPartition(partition, integer=None)

This class represents an integer partition.

Explanation

In number theory and combinatorics, a partition of a positive integer, \( n \), also called an integer partition, is a way of writing \( n \) as a list of positive integers that sum to \( n \). Two partitions that differ only in the order of summands are considered to be the same partition; if order matters then the partitions are referred to as compositions. For example, \( 4 \) has five partitions: [4], [3, 1], [2, 2], [2, 1, 1], and [1, 1, 1, 1]; the compositions [1, 2, 1] and [1, 1, 2] are the same as partition [2, 1, 1].

See also:

- `sympy.utilities.iterables.partitions` (page 2159), `sympy.utilities.iterables.multiset_partitions` (page 2154)
References

[R55]

\texttt{as\_dict()}

Return the partition as a dictionary whose keys are the partition integers and the values are the multiplicity of that integer.

\textbf{Examples}

\begin{verbatim}
>>> from sympy.combinatorics.partitions import IntegerPartition
>>> IntegerPartition([1]*3 + [2] + [3]*4).as_dict()
{1: 3, 2: 1, 3: 4}
\end{verbatim}

\texttt{as\_ferrers(char='\#')}

Prints the ferrer diagram of a partition.

\textbf{Examples}

\begin{verbatim}
>>> from sympy.combinatorics.partitions import IntegerPartition
>>> print(IntegerPartition([1, 1, 5]).as_ferrers())
#####
#
#
\end{verbatim}

\texttt{property conjugate}

Computes the conjugate partition of itself.

\textbf{Examples}

\begin{verbatim}
>>> from sympy.combinatorics.partitions import IntegerPartition
>>> a = IntegerPartition([6, 3, 3, 2, 1])
>>> a.conjugate
[5, 4, 3, 1, 1, 1]
\end{verbatim}

\texttt{next\_lex()}

Return the next partition of the integer, \( n \), in lexical order, wrapping around to \([n]\) if the partition is \([1, \ldots, 1]\).

\textbf{Examples}

\begin{verbatim}
>>> from sympy.combinatorics.partitions import IntegerPartition
>>> p = IntegerPartition([3, 1])
>>> print(p.next_lex())
[4]
>>> p.partition < p.next_lex().partition
True
\end{verbatim}
**prev_lex()**

Return the previous partition of the integer, \(n\), in lexical order, wrapping around to [1, ..., 1] if the partition is \([n]\).

**Examples**

```python
>>> from sympy.combinatorics.partitions import IntegerPartition
>>> p = IntegerPartition([4])
>>> print(p.prev_lex())
[3, 1]
>>> p.partition > p.prev_lex().partition
True
```

**sympy.combinatorics.partitions.random_integer_partition\((n, seed=None)\)**

Generates a random integer partition summing to \(n\) as a list of reverse-sorted integers.

**Examples**

```python
>>> from sympy.combinatorics.partitions import random_integer_partition
```

For the following, a seed is given so a known value can be shown; in practice, the seed would not be given.

```python
>>> random_integer_partition(100, seed=[1, 1, 12, 1, 2, 1, 85, 1])
[85, 12, 2, 1]
>>> random_integer_partition(10, seed=[1, 2, 3, 1, 5, 1])
[5, 3, 1, 1]
>>> random_integer_partition(1)
[1]
```

**sympy.combinatorics.partitions.RGS_generalized\((m)\)**

Computes the \(m + 1\) generalized unrestricted growth strings and returns them as rows in matrix.

**Examples**

```python
>>> from sympy.combinatorics.partitions import RGS_generalized
>>> RGS_generalized(6)
Matrix([  
[1, 1, 1, 1, 1, 1],  
[1, 2, 3, 4, 5, 6],  
[2, 5, 10, 17, 26, 0],  
[5, 15, 37, 77, 0, 0],  
[15, 52, 151, 0, 0, 0],  
[52, 203, 0, 0, 0, 0],  
[203, 0, 0, 0, 0, 0])
```

**sympy.combinatorics.partitions.RGS_enum\((m)\)**

RGS_enum computes the total number of restricted growth strings possible for a super-set of size \(m\).
Examples

```python
>>> from sympy.combinatorics.partitions import RGS_enum
>>> from sympy.combinatorics import Partition
>>> RGS_enum(4)
15
>>> RGS_enum(5)
52
>>> RGS_enum(6)
203
```

We can check that the enumeration is correct by actually generating the partitions. Here, the 15 partitions of 4 items are generated:

```python
>>> a = Partition(list(range(4)))
>>> s = set()
>>> for i in range(20):
...     s.add(a)
...     a += 1
...
>>> assert len(s) == 15
```

sympy.combinatorics.partitions.RGS_unrank(rank, m)

Gives the unranked restricted growth string for a given superset size.

Examples

```python
>>> from sympy.combinatorics.partitions import RGS_unrank
>>> RGS_unrank(14, 4)
[0, 1, 2, 3]
>>> RGS_unrank(0, 4)
[0, 0, 0, 0]
```

sympy.combinatorics.partitions.RGS_rank(rgs)

Computes the rank of a restricted growth string.

Examples

```python
>>> from sympy.combinatorics.partitions import RGS_rank, RGS_unrank
>>> RGS_rank([0, 1, 2, 1, 3])
42
>>> RGS_rank(RGS_unrank(4, 7))
4
```
Permutations

class sympy.combinatorics.permutations.Permutation(*args, size=None, **kwargs)

A permutation, alternatively known as an ‘arrangement number’ or ‘ordering’ is an arrangement of the elements of an ordered list into a one-to-one mapping with itself. The permutation of a given arrangement is given by indicating the positions of the elements after re-arrangement [R74]. For example, if one started with elements [x, y, a, b] (in that order) and they were reordered as [x, y, b, a] then the permutation would be [0, 1, 3, 2]. Notice that (in SymPy) the first element is always referred to as 0 and the permutation uses the indices of the elements in the original ordering, not the elements (a, b, ...) themselves.

```python
>>> from sympy.combinatorics import Permutation
>>> from sympy import init_printing
>>> init_printing(perm_cyclic=False, pretty_print=False)
```

Permutations Notation

Permutations are commonly represented in disjoint cycle or array forms.

Array Notation And 2-line Form

In the 2-line form, the elements and their final positions are shown as a matrix with 2 rows:

```
[0 1 2 ... n-1] [p(0) p(1) p(2) ... p(n-1)]
```

Since the first line is always range(n), where n is the size of p, it is sufficient to represent the permutation by the second line, referred to as the “array form” of the permutation. This is entered in brackets as the argument to the Permutation class:

```python
>>> p = Permutation([0, 2, 1]); p
Permutation([0, 2, 1])
```

Given i in range(p.size), the permutation maps i to i^p

```python
>>> [i^p for i in range(p.size)]
[0, 2, 1]
```

The composite of two permutations p*q means first apply p, then q, so i^(p*q) = (i^p)^q which is i^p^q according to Python precedence rules:

```python
>>> q = Permutation([2, 1, 0])
>>> [i^p^q for i in range(3)]
[2, 0, 1]
>>> [i^(p*q) for i in range(3)]
[2, 0, 1]
```

One can use also the notation p(i) = i^p, but then the composition rule is (p*q)(i) = q(p(i)), not p(q(i)):  

```python
```
Disjoint Cycle Notation

In disjoint cycle notation, only the elements that have shifted are indicated.

For example, [1, 3, 2, 0] can be represented as (0, 1, 3)(2). This can be understood from the 2 line format of the given permutation. In the 2-line form, [0 1 2 3][1 3 2 0]

The element in the 0th position is 1, so 0 -> 1. The element in the 1st position is three, so 1 -> 3. And the element in the third position is again 0, so 3 -> 0. Thus, 0 -> 1 -> 3 -> 0, and 2 -> 2. Thus, this can be represented as 2 cycles: (0, 1, 3)(2). In common notation, singular cycles are not explicitly written as they can be inferred implicitly.

Only the relative ordering of elements in a cycle matter:

```python
>>> Permutation(1,2,3) == Permutation(2,3,1) == Permutation(3,1,2)
True
```

The disjoint cycle notation is convenient when representing permutations that have several cycles in them:

```python
>>> Permutation(1, 2)(3, 5) == Permutation([[1, 2], [3, 5]])
True
```

It also provides some economy in entry when computing products of permutations that are written in disjoint cycle notation:

```python
>>> Permutation(1, 2)(1, 3)(2, 3)
Permutation([0, 3, 2, 1])
>>> _ == Permutation([[1, 2]])*Permutation([[1, 3]])*Permutation([[2, 3]])
True
```

Caution: when the cycles have common elements between them then the order in which the permutations are applied matters. This module applies the permutations from left to right.

```python
>>> Permutation(1, 2)(2, 3) == Permutation([[1, 2], (2, 3)])
True
>>> Permutation(1, 2)(2, 3).list()
[0, 3, 1, 2]
```

In the above case, (1,2) is computed before (2,3). As 0 -> 0, 0 -> 0, element in position 0 is 0. As 1 -> 2, 2 -> 3, element in position 1 is 3. As 2 -> 1, 1 -> 1, element in position 2 is 1. As 3 -> 3, 3 -> 2, element in position 3 is 2.

If the first and second elements had been swapped first, followed by the swapping of the second and third, the result would have been [0, 2, 3, 1]. If, you
want to apply the cycles in the conventional right to left order, call the function
with arguments in reverse order as demonstrated below:

```python
>>> Permutation([(1, 2), (2, 3)][::-1]).list()
[0, 2, 3, 1]
```

Entering a singleton in a permutation is a way to indicate the size of the permutation. The `size` keyword can also be used.

**Array-form entry:**

```python
>>> Permutation([[1, 2], [9]])
Permutation([0, 2, 1], size=10)

>>> Permutation([[1, 2]], size=10)
Permutation([0, 2, 1], size=10)
```

**Cyclic-form entry:**

```python
>>> Permutation(1, 2, size=10)
Permutation([0, 2, 1], size=10)

>>> Permutation(9)(1, 2)
Permutation([0, 2, 1], size=10)
```

Caution: no singleton containing an element larger than the largest in any previous
 cycle can be entered. This is an important difference in how `Permutation` and `Cycle` handle the `__call__` syntax. A singleton argument at the start of a `Permutation` performs instantiation of the `Permutation` and is permitted:

```python
>>> Permutation(5)
Permutation([], size=6)
```

A singleton entered after instantiation is a call to the permutation – a function call – and if the argument is out of range it will trigger an error. For this reason, it is better to start the cycle with the singleton:

The following fails because there is no element 3:

```python
>>> Permutation(1, 2)(3)
Traceback (most recent call last):
...
IndexError: list index out of range
```

This is ok: only the call to an out of range singleton is prohibited; otherwise the permutation autosizes:

```python
>>> Permutation(3)(1, 2)
Permutation([0, 2, 1, 3])

>>> Permutation(1, 2)(3, 4) == Permutation(3, 4)(1, 2)
True
```
Equality Testing

The array forms must be the same in order for permutations to be equal:

```python
>>> Permutation([1, 0, 2, 3]) == Permutation([1, 0])
False
```

Identity Permutation

The identity permutation is a permutation in which no element is out of place. It can be entered in a variety of ways. All the following create an identity permutation of size 4:

```python
>>> I = Permutation([0, 1, 2, 3])
>>> all(p == I for p in [...
... Permutation(3),
... Permutation(range(4)),
... Permutation([], size=4),
... Permutation(size=4)])
True
```

Watch out for entering the range `inside` a set of brackets (which is cycle notation):

```python
>>> I == Permutation([range(4)])
False
```

Permutation Printing

There are a few things to note about how Permutations are printed.

Deprecated since version 1.6: Configuring Permutation printing by setting `Permutation.print_cyclic` is deprecated. Users should use the `perm_cyclic` flag to the printers, as described below.

1) If you prefer one form (array or cycle) over another, you can set `init_printing` with the `perm_cyclic` flag.

```python
>>> from sympy import init_printing
>>> p = Permutation(1, 2)(4, 5)(3, 4)
```

```python
>>> p
Permutation([0, 2, 1, 4, 5, 3])
```

```python
>>> init_printing(perm_cyclic=True, pretty_print=False)
```

```python
>>> p
(1 2)(3 4 5)
```

2) Regardless of the setting, a list of elements in the array for cyclic form can be obtained and either of those can be copied and supplied as the argument to `Permutation`:

```python
>>> p.array_form
[0, 2, 1, 4, 5, 3]
```

```python
>>> p.cyclic_form
[[1, 2], [3, 4, 5]]
```

(continues on next page)
>>> Permutation(_) == p
True

3) Printing is economical in that as little as possible is printed while retaining all information about the size of the permutation:

```python
>>> init_printing(perm_cyclic=False, pretty_print=False)
>>> Permutation([1, 0, 2, 3])
Permutation([1, 0, 2, 3])
```

```python
>>> Permutation([1, 0, 2, 3], size=20)
Permutation([1, 0], size=20)
```

```python
>>> Permutation([1, 0, 2, 4, 3, 5, 6], size=20)
Permutation([1, 0, 2, 4, 3], size=20)
```

```python
>>> p = Permutation([1, 0, 2, 3])
>>> init_printing(perm_cyclic=True, pretty_print=False)
>>> p
(0 1)
>>> init_printing(perm_cyclic=False, pretty_print=False)
```

The 2 was not printed but it is still there as can be seen with the array_form and size methods:

```python
>>> p.array_form
[1, 0, 2, 3]
```

```python
>>> p.size
4
```

**Short Introduction To Other Methods**

The permutation can act as a bijective function, telling what element is located at a given position

```python
>>> q = Permutation([5, 2, 3, 4, 1, 0])
>>> q.array_form[1] # the hard way
2
>>> q(1) # the easy way
2
>>> {i: q(i) for i in range(q.size)} # showing the bijection
{0: 5, 1: 2, 2: 3, 3: 4, 4: 1, 5: 0}
```

The full cyclic form (including singletons) can be obtained:

```python
>>> p.full_cyclic_form
[[0, 1], [2], [3]]
```

Any permutation can be factored into transpositions of pairs of elements:

```python
>>> Permutation([[1, 2], [3, 4, 5]]).transpositions()
[(1, 2), (3, 5), (3, 4)]
>>> Permutation.rmul(*[Permutation([ti], size=6) for ti in _]).cyclic_`
The number of permutations on a set of n elements is given by n! and is called the cardinality.

```python
>>> p.size
4
>>> p.cardinality
24
```

A given permutation has a rank among all the possible permutations of the same elements, but what that rank is depends on how the permutations are enumerated. (There are a number of different methods of doing so.) The lexicographic rank is given by the rank method and this rank is used to increment a permutation with addition/subtraction:

```python
>>> p.rank()
6
>>> p + 1
Permutation([1, 0, 3, 2])
>>> p.next_lex()
Permutation([1, 0, 3, 2])
>>> _.rank()
7
>>> p.unrank_lex(p.size, rank=7)
Permutation([1, 0, 3, 2])
```

The product of two permutations p and q is defined as their composition as functions, \((p \circ q)(i) = q(p(i))\) [R78].

```python
>>> p = Permutation([1, 0, 2, 3])
>>> q = Permutation([2, 3, 1, 0])
>>> list(q*p)
[2, 3, 0, 1]
>>> list(p*q)
[3, 2, 1, 0]
>>> [q(p(i)) for i in range(p.size)]
[3, 2, 1, 0]
```

The permutation can be ‘applied’ to any list-like object, not only Permutations:

```python
>>> p(["zero", "one", "four", "two"])
["one", "zero", "four", "two"]
>>> p(['zo42'])
['o', 'z', '4', '2']
```

If you have a list of arbitrary elements, the corresponding permutation can be found with the from_sequence method:

```python
>>> Permutation.from_sequence('SymPy')
Permutation([1, 3, 2, 0, 4])
```
Checking If A Permutation Is Contained In A Group

Generally if you have a group of permutations $G$ on $n$ symbols, and you’re checking if a permutation on less than $n$ symbols is part of that group, the check will fail.

Here is an example for $n=5$ and we check if the cycle $(1,2,3)$ is in $G$:

```python
>>> from sympy import init_printing
>>> init_printing(perms_cyclic=True, pretty_print=False)
>>> from sympy.combinatorics import Cycle, Permutation
>>> from sympy.combinatorics.perm_groups import PermutationGroup
>>> G = PermutationGroup(Cycle(2,3)(4,5), Cycle(1,2,3,4,5))
>>> p1 = Permutation(Cycle(2,5,3))
>>> p2 = Permutation(Cycle(1,2,3))
>>> a1 = Permutation(Cycle(1,2,3).list(6))
>>> a2 = Permutation(Cycle(1,2,3)(5))
>>> a3 = Permutation(Cycle(1,2,3), size=6)
>>> for p in [p1,p2,a1,a2,a3]: p, G.contains(p)
((2 5 3), True)
((1 2 3), False)
((5)(1 2 3), True)
((5)(1 2 3), True)
((5)(1 2 3), True)
```

The check for $p_2$ above will fail.

Checking if $p_1$ is in $G$ works because SymPy knows $G$ is a group on 5 symbols, and $p_1$ is also on 5 symbols (its largest element is 5).

For $a_1$, the `.list(6)` call will extend the permutation to 5 symbols, so the test will work as well. In the case of $a_2$ the permutation is being extended to 5 symbols by using a singleton, and in the case of $a_3$ it’s extended through the constructor argument `size=6`.

There is another way to do this, which is to tell the `contains` method that the number of symbols the group is on does not need to match perfectly the number of symbols for the permutation:

```python
>>> G.contains(p2, strict=False)
True
```

This can be via the `strict` argument to the `contains` method, and SymPy will try to extend the permutation on its own and then perform the containment check.

See also:

*Cycle (page 339)*
apply(i)

Apply the permutation to an expression.

**Parameters**

i : Expr

It should be an integer between 0 and \( n - 1 \) where \( n \) is the size of the permutation.

If it is a symbol or a symbolic expression that can have integer values, an AppliedPermutation object will be returned which can represent an unevaluated function.

**Notes**

Any permutation can be defined as a bijective function \( \sigma : \{0, 1, \ldots, n-1\} \rightarrow \{0, 1, \ldots, n-1\} \) where \( n \) denotes the size of the permutation.

The definition may even be extended for any set with distinctive elements, such that the permutation can even be applied for real numbers or such, however, it is not implemented for now for computational reasons and the integrity with the group theory module.

This function is similar to the \_call\_ magic, however, \_call\_ magic already has some other applications like permuting an array or attaching new cycles, which would not always be mathematically consistent.

This also guarantees that the return type is a SymPy integer, which guarantees the safety to use assumptions.

**property array_form**

Returns a copy of the attribute \_array_form\_

Examples == ======

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([[2, 0], [3, 1]])
>>> p.array_form
[2, 3, 0, 1]
>>> Permutation([[2, 0, 3, 1]]).array_form
[3, 2, 0, 1]
>>> Permutation([[2, 0, 3, 1]]).array_form
[2, 0, 3, 1]
>>> Permutation([[1, 2], [4, 5]]).array_form
[0, 2, 1, 3, 5, 4]
```

**ascents()**

Returns the positions of ascents in a permutation, ie, the location where \( p[i] < p[i+1] \)
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([4, 0, 1, 3, 2])
>>> p.ascents()
[1, 2]
```

See also:
- `descents` (page 322), `inversions` (page 327), `min` (page 331), `max` (page 330)

`atoms()`
Returns all the elements of a permutation

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> Permutation([0, 1, 2, 3, 4, 5]).atoms()
{0, 1, 2, 3, 4, 5}
>>> Permutation([[0, 1], [2, 3], [4, 5]]).atoms()
{0, 1, 2, 3, 4, 5}
```

property `cardinality`
Returns the number of all possible permutations.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([0, 1, 2, 3])
>>> p.cardinality
24
```

See also:
- `length` (page 330), `order` (page 332), `rank` (page 334), `size` (page 337)

`commutator`(x)
Return the commutator of self and x: ~x*~self*x*self
If f and g are part of a group, G, then the commutator of f and g is the group identity iff f and g commute, i.e. fg == gf.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> from sympy import init_printing
>>> init_printing(perm_cyclic=False, pretty_print=False)
>>> p = Permutation([0, 2, 3, 1])
>>> x = Permutation([2, 0, 3, 1])
>>> c = p.commutor(x); c
```

(continues on next page)
References

[R80]  

\texttt{commutes\_with}(\texttt{other})

Checks if the elements are commuting.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> a = Permutation([1, 4, 3, 0, 2, 5])
>>> b = Permutation([0, 1, 2, 3, 4, 5])
>>> a.commutes_with(b)
True
>>> b = Permutation([2, 3, 5, 4, 1, 0])
>>> a.commutes_with(b)
False
```

property \texttt{cycle\_structure}

Return the cycle structure of the permutation as a dictionary indicating the multiplicity of each cycle length.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> Permutation(3).cycle_structure
{1: 4}
>>> Permutation([0, 4, 3])(1, 2)(5, 6).cycle_structure
{2: 2, 3: 1}
```

property \texttt{cycles}

Returns the number of cycles contained in the permutation (including singletons).

5.8. Topics
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> Permutation([0, 1, 2]).cycles
3
>>> Permutation([0, 1, 2]).full_cyclic_form
[[0], [1], [2]]
>>> Permutation([0, 1, 2]).cycles
2
```

See also:

* sympy.functions.combinatorial.numbers.stirling (page 501)

property cyclic_form

This is used to convert to the cyclic notation from the canonical notation. Singletons are omitted.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([0, 3, 1, 2])
>>> p.cyclic_form
[[1, 3, 2]]
>>> Permutation([1, 0, 2, 4, 3, 5]).cyclic_form
[[0, 1], [3, 4]]
```

See also:

* array_form (page 319), full_cyclic_form (page 323)

descents()

Returns the positions of descents in a permutation, ie, the location where p[i] > p[i+1]

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([4, 0, 1, 3, 2])
>>> p.descents()
[0, 3]
```

See also:

* ascents (page 319), inversions (page 327), min (page 331), max (page 330)

classmethod from_inversion_vector(inversion)

Calculates the permutation from the inversion vector.
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> from sympy import init_printing
>>> init_printing(perm_cyclic=False, pretty_print=False)
>>> Permutation.from_inversion_vector([3, 2, 1, 0, 0])
Permutation([3, 2, 1, 0, 4, 5])

classmethod from_sequence(i, key=None)

Return the permutation needed to obtain i from the sorted elements of i. If custom sorting is desired, a key can be given.

Examples

```python
>>> from sympy.combinatorics import Permutation

```python
>>> Permutation.from_sequence('SymPy')
(4)(0 1 3)
>>> _((sorted("SymPy"))
['S', 'y', 'm', 'P', 'y']
>>> Permutation.from_sequence('SymPy', key=lambda x: x.lower())
(4)(0 2)(1 3)

property full_cyclic_form

Return permutation in cyclic form including singletons.

Examples

```python
>>> from sympy.combinatorics import Permutation

```python
>>> Permutation([0, 2, 1]).full_cyclic_form
[[0], [1, 2]]

get_adjacency_distance(other)

Computes the adjacency distance between two permutations.

Explanation

This metric counts the number of times a pair i,j of jobs is adjacent in both p and p'. If n_adj is this quantity then the adjacency distance is n - n_adj - 1 [1]

**Examples**

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([0, 3, 1, 2, 4])
>>> q = Permutation.josephus(4, 5, 2)
>>> p.get_adjacency_distance(q)
3
>>> r = Permutation([0, 2, 1, 4, 3])
>>> p.get_adjacency_distance(r)
4
```

See also:

*get_precedence_matrix* (page 325), *get_precedence_distance* (page 325),
*get_adjacency_matrix* (page 324)

**get_adjacency_matrix()**

Computes the adjacency matrix of a permutation.

**Explanation**

If job $i$ is adjacent to job $j$ in a permutation $p$ then we set $m[i, j] = 1$ where $m$ is the adjacency matrix of $p$.

**Examples**

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation.josephus(3, 6, 1)
>>> p.get_adjacency_matrix()
Matrix([[0, 0, 0, 0, 0, 0],
[0, 0, 0, 0, 1, 0],
[0, 0, 0, 0, 0, 1],
[0, 1, 0, 0, 0, 0],
[1, 0, 0, 0, 0, 0],
[0, 0, 0, 1, 0, 0]])
>>> q = Permutation([0, 1, 2, 3])
>>> q.get_adjacency_matrix()
Matrix([[0, 1, 0, 0],
[0, 0, 1, 0],
[0, 0, 0, 1],
[0, 0, 0, 0]])
```

See also:

*get_precedence_matrix* (page 325), *get_precedence_distance* (page 325),
*get_adjacency_distance* (page 323)

**get_positional_distance**(other)

Computes the positional distance between two permutations.
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([0, 3, 1, 2, 4])
>>> q = Permutation.josephus(4, 5, 2)
>>> r = Permutation([3, 1, 4, 0, 2])
>>> p.get_positional_distance(q)
12
>>> p.get_positional_distance(r)
12
```

See also:

* get_precedence_distance (page 325), get_adjacency_distance (page 323)

**get_precedence_distance**(other)

Computes the precedence distance between two permutations.

Explanation

Suppose p and p' represent n jobs. The precedence metric counts the number of times a job j is preceded by job i in both p and p'. This metric is commutative.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([2, 0, 4, 3, 1])
>>> q = Permutation([3, 1, 2, 4, 0])
>>> p.get_precedence_distance(q)
7
>>> q.get_precedence_distance(p)
7
```

See also:

* get_precedence_matrix (page 325), get_adjacency_matrix (page 324), get_adjacency_distance (page 323)

**get_precedence_matrix**()

Gets the precedence matrix. This is used for computing the distance between two permutations.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> from sympy import init_printing
>>> init_printing(perm_cyclic=False, pretty_print=False)
>>> p = Permutation.josephus(3, 6, 1)
>>> p
Permutation([2, 5, 3, 1, 4, 0])
```

(continues on next page)
See also:

- `get_precedence_distance` (page 325), `get_adjacency_matrix` (page 324),
- `get_adjacency_distance` (page 323)

### index()

Returns the index of a permutation.

The index of a permutation is the sum of all subscripts \( j \) such that \( p[j] \) is greater than \( p[j+1] \).

#### Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([3, 0, 2, 1, 4])
>>> p.index()
2
```

### inversion_vector()

Return the inversion vector of the permutation.

The inversion vector consists of elements whose value indicates the number of elements in the permutation that are lesser than it and lie on its right hand side.

The inversion vector is the same as the Lehmer encoding of a permutation.

#### Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([4, 8, 0, 7, 1, 5, 3, 6, 2])
>>> p.inversion_vector()
[4, 7, 0, 5, 0, 2, 1, 1]
>>> p = Permutation([3, 2, 1, 0])
>>> p.inversion_vector()
[3, 2, 1]
```

The inversion vector increases lexicographically with the rank of the permutation, the \( i \)th element cycling through \( 0..i \).
p = p.next_lex()

(2) [0, 0] 0
(1 2) [0, 1] 1
(2)(0 1) [1, 0] 2
(0 1 2) [1, 1] 3
(0 2 1) [2, 0] 4
(0 2) [2, 1] 5

See also:

from_inversion_vector (page 322)

inversions()
Computes the number of inversions of a permutation.

Explanation
An inversion is where i > j but p[i] < p[j].
For small length of p, it iterates over all i and j values and calculates the number of inversions. For large length of p, it uses a variation of merge sort to calculate the number of inversions.

Examples

>>> from sympy.combinatorics import Permutation
>>> p = Permutation([0, 1, 2, 3, 4, 5])
>>> p.inversions()
0
>>> Permutation([3, 2, 1, 0]).inversions()
6

See also:

descents (page 322), ascents (page 319), min (page 331), max (page 330)

References

[R81]

property is_Empty
Checks to see if the permutation is a set with zero elements
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> Permutation([]).is_Empty
True
>>> Permutation([0]).is_Empty
False
```

See also:

* is_Singleton (page 328)

property is_Identity

Returns True if the Permutation is an identity permutation.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([])
>>> p.is_Identity
True
>>> p = Permutation([0, 1, 2])
>>> p.is_Identity
True
>>> p = Permutation([0, 2, 1])
>>> p.is_Identity
False
```

See also:

* order (page 332)

property is_Singleton

Checks to see if the permutation contains only one number and is thus the only possible permutation of this set of numbers

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> Permutation([0]).is_Singleton
True
>>> Permutation([0, 1]).is_Singleton
False
```

See also:

* is_Empty (page 327)

property is_even

Checks if a permutation is even.
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([0, 1, 2, 3])
>>> p.is_even
True
>>> p = Permutation([3, 2, 1, 0])
>>> p.is_even
True
```

See also:

* `is_odd` (page 329)

**property is_odd**

Checks if a permutation is odd.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([0, 1, 2, 3])
>>> p.is_odd
False
>>> p = Permutation([3, 2, 0, 1])
>>> p.is_odd
True
```

See also:

* `is_even` (page 328)

**classmethod josephus** *(m, n, s=1)*

Return as a permutation the shuffling of range(n) using the Josephus scheme in which every m-th item is selected until all have been chosen. The returned permutation has elements listed by the order in which they were selected.

The parameter `s` stops the selection process when there are `s` items remaining and these are selected by continuing the selection, counting by 1 rather than by `m`.

Consider selecting every 3rd item from 6 until only 2 remain:

<table>
<thead>
<tr>
<th>choices</th>
<th>chosen</th>
</tr>
</thead>
<tbody>
<tr>
<td>012345</td>
<td>0145</td>
</tr>
<tr>
<td>01 345</td>
<td>2</td>
</tr>
<tr>
<td>01 34</td>
<td>25</td>
</tr>
<tr>
<td>01  4</td>
<td>253</td>
</tr>
<tr>
<td>0   4</td>
<td>2531</td>
</tr>
<tr>
<td>0</td>
<td>25314</td>
</tr>
<tr>
<td></td>
<td>253140</td>
</tr>
</tbody>
</table>
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> Permutation.josephus(3, 6, 2).array_form
[2, 5, 3, 1, 4, 0]
```

References

[R82], [R83], [R84]

```
length()
```

Returns the number of integers moved by a permutation.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> Permutation([0, 3, 2, 1]).length()
2
>>> Permutation([[0, 1], [2, 3]]).length()
4
```

```
list(size=None)
```

Return the permutation as an explicit list, possibly trimming unmoved elements if size is less than the maximum element in the permutation; if this is desired, setting size=-1 will guarantee such trimming.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation(2, 3)(4, 5)
>>> p.list()
[0, 1, 3, 2, 5, 4]
>>> p.list(10)
[0, 1, 3, 2, 5, 4, 6, 7, 8, 9]
```

Passing a length too small will trim trailing, unchanged elements in the permutation:

```python
>>> Permutation(2, 4)(1, 2, 4).list(-1)
[0, 2, 1]
>>> Permutation(3).list(-1)
[]
```

```
max()
```

The maximum element moved by the permutation.
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([1, 0, 2, 3, 4])
>>> p.max()
1
```

See also:
min (page 331), descents (page 322), ascents (page 319), inversions (page 327)

min()
The minimum element moved by the permutation.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([0, 1, 4, 3, 2])
>>> p.min()
2
```

See also:
max (page 330), descents (page 322), ascents (page 319), inversions (page 327)

mul_inv (other)
other*~self, self and other have _array_form

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([2, 3, 1, 0])
>>> p = Permutation([2, 3, 1, 0]); p.rank()
17
>>> p = p.next_lex(); p.rank()
18
```

See also:
rank (page 334), unrank_lex (page 338)

next_nonlex()
Returns the next permutation in nonlex order [3]. If self is the last permutation in this order it returns None.
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> from sympy import init_printing
>>> init_printing(perm_cyclic=False, pretty_print=False)
>>> p = Permutation([2, 0, 3, 1]); p.rank_nonlex()
5
>>> p = p.next_nonlex(); p
Permutation([3, 0, 1, 2])
>>> p.rank_nonlex()
6
```

See also:

`rank_nonlex` (page 334), `unrank_nonlex` (page 339)

`next_trotterjohnson()`

Returns the next permutation in Trotter-Johnson order. If self is the last permutation it returns None. See [4] section 2.4. If it is desired to generate all such permutations, they can be generated in order more quickly with the `generate_bell` function.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> from sympy import init_printing
>>> init_printing(perm_cyclic=False, pretty_print=False)
>>> p = Permutation([3, 0, 2, 1])
>>> p.rank_trotterjohnson()
4
>>> p = p.next_trotterjohnson(); p
Permutation([0, 3, 2, 1])
>>> p.rank_trotterjohnson()
5
```

See also:

`rank_trotterjohnson` (page 334), `unrank_trotterjohnson` (page 339), `sympy.utilities.iterables.generate_bell` (page 2144)

`order()`

Computes the order of a permutation.

When the permutation is raised to the power of its order it equals the identity permutation.
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> from sympy import init_printing
>>> init_printing(perm_cyclic=False, pretty_print=False)
>>> p = Permutation([3, 1, 5, 2, 4, 0])
>>> p.order()
4
>>> (p**(p.order()))
Permutation([], size=6)
```

See also:

`identity` (page 364), `cardinality` (page 320), `length` (page 330), `rank` (page 334), `size` (page 337)

`parity()`

Computes the parity of a permutation.

Explanation

The parity of a permutation reflects the parity of the number of inversions in the permutation, i.e., the number of pairs of \( x \) and \( y \) such that \( x > y \) but \( p[x] < p[y] \).

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([0, 1, 2, 3])
>>> p.parity()
0
>>> p = Permutation([3, 2, 0, 1])
>>> p.parity()
1
```

See also:

`_af_parity` (page 341)

`classmethod random(n)`

Generates a random permutation of length \( n \).

Uses the underlying Python pseudo-random number generator.
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> Permutation.random(2) in (Permutation([1, 0]), Permutation([0, 1]))
True
```

`rank()`

Returns the lexicographic rank of the permutation.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([0, 1, 2, 3])
>>> p.rank()
0
>>> p = Permutation([3, 2, 1, 0])
>>> p.rank()
23
```

See also:

[next_lex](page 331), [unrank_lex](page 338), [cardinality](page 320), [length](page 330), [order](page 332), [size](page 337)

`rank_nonlex(inv_perm=None)`

This is a linear time ranking algorithm that does not enforce lexicographic order [3].

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([0, 1, 2, 3])
>>> p.rank_nonlex()
23
```

See also:

[next_nonlex](page 331), [unrank_nonlex](page 339)

`rank_trotterjohnson()`

Returns the Trotter Johnson rank, which we get from the minimal change algorithm. See [4] section 2.4.
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([0, 1, 2, 3])
>>> p.rank_trotterjohnson()
0
>>> p = Permutation([0, 2, 1, 3])
>>> p.rank_trotterjohnson()
7
```

See also:

*unrank_trotterjohnson* (page 339), *next_trotterjohnson* (page 332)

### resize(n)

Resize the permutation to the new size \( n \).

**Parameters**

\( n \) : int  

The new size of the permutation.

**Raises**

*ValueError*  

If the permutation cannot be resized to the given size. This may only happen when resized to a smaller size than the original.

Examples

```python
>>> from sympy.combinatorics import Permutation

Increasing the size of a permutation:

```python
>>> p = Permutation([0, 1, 2])
>>> p = p.resize(5)
>>> p
(4)(0 1 2)
```

Decreasing the size of the permutation:

```python
>>> p = p.resize(4)
>>> p
(3)(0 1 2)
```

If resizing to the specific size breaks the cycles:

```python
>>> p.resize(2)
Traceback (most recent call last):
...
ValueError: The permutation cannot be resized to 2 because the cycle (0, 1, 2) may break.
```
static rmul(*args)
    Return product of Permutations [a, b, c, ...] as the Permutation whose ith value is
    a(b(c(i))).
    a, b, c, ... can be Permutation objects or tuples.

Examples

>>> from sympy.combinatorics import Permutation

>>> a, b = [1, 0, 2], [0, 2, 1]
>>> a = Permutation(a); b = Permutation(b)
>>> list(Permutation.rmul(a, b))
[1, 2, 0]
>>> [a(b(i)) for i in range(3)]
[1, 2, 0]

This handles the operands in reverse order compared to the * operator:

>>> a = Permutation(a); b = Permutation(b)
>>> list(a*b)
[2, 0, 1]
>>> [b(a(i)) for i in range(3)]
[2, 0, 1]

Notes

All items in the sequence will be parsed by Permutation as necessary as long as the
first item is a Permutation:

>>> Permutation.rmul(a, [0, 2, 1]) == Permutation.rmul(a, b)
True

The reverse order of arguments will raise a TypeError.

classmethod rmul_with_af(*args)
    same as rmul, but the elements of args are Permutation objects which have _array_form

runs()
    Returns the runs of a permutation.
    An ascending sequence in a permutation is called a run [5].
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([2, 5, 7, 3, 6, 0, 1, 4, 8])
>>> p.runs()
[[2, 5, 7], [3, 6], [0, 1, 4, 8]]
>>> q = Permutation([1, 3, 2, 0])
>>> q.runs()
[[1, 3], [2], [0]]
```

**signature()**

Gives the signature of the permutation needed to place the elements of the permutation in canonical order.

The signature is calculated as \((-1)^{\text{number of inversions}}\)

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([0, 1, 2])
>>> p.inversions()
0
>>> p.signature()
1
>>> q = Permutation([0, 2, 1])
>>> q.inversions()
1
>>> q.signature()
-1
```

See also: `inversions` (page 327)

**property size**

Returns the number of elements in the permutation.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> Permutation([[3, 2], [0, 1]]).size
4
```

See also: `cardinality` (page 320), `length` (page 330), `order` (page 332), `rank` (page 334)

**support()**

Return the elements in permutation, P, for which P[i] != i.
Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([[3, 2], [0, 1], [4]])
>>> p.array_form
[1, 0, 3, 2, 4]
>>> p.support()
[0, 1, 2, 3]
```

transpositions()

Return the permutation decomposed into a list of transpositions.

Explanation

It is always possible to express a permutation as the product of transpositions, see [1]

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> p = Permutation([[1, 2, 3], [0, 4, 5, 6, 7]])
>>> t = p.transpositions()
>>> print(''.join(str(c) for c in t))
(0, 7)(0, 6)(0, 5)(0, 4)(1, 3)(1, 2)
>>> Permutation.rmul(*[Permutation([ti], size=p.size) for ti in t])
True
```

References

[R85]

classmethod unrank_lex(size, rank)

Lexicographic permutation unranking.

Examples

```python
>>> from sympy.combinatorics import Permutation
>>> from sympy import init_printing
>>> init_printing(perm_cyclic=False, pretty_print=False)
>>> a = Permutation.unrank_lex(5, 10)
>>> a.rank()
10
>>> a
Permutation([0, 2, 4, 1, 3])
```
### See also:

*rank* (page 334), *next_lex* (page 331)

**classmethod unrank_nonlex**\(n, r\)

This is a linear time unranking algorithm that does not respect lexicographic order [3].

#### Examples

```python
>>> from sympy.combinatorics import Permutation
>>> from sympy import init_printing
>>> init_printing(perm_cyclic=False, pretty_print=False)
>>> Permutation.unrank_nonlex(4, 5)
Permutation([2, 0, 3, 1])
>>> Permutation.unrank_nonlex(4, -1)
Permutation([0, 1, 2, 3])
```

**See also:**

*next_nonlex* (page 331), *rank_nonlex* (page 334)

**classmethod unrank_trotterjohnson**\(size, rank\)

#### Examples

```python
>>> from sympy.combinatorics import Permutation
>>> from sympy import init_printing
>>> init_printing(perm_cyclic=False, pretty_print=False)
>>> Permutation.unrank_trotterjohnson(5, 10)
Permutation([0, 3, 1, 2, 4])
```

**See also:**

*rank_trotterjohnson* (page 334), *next_trotterjohnson* (page 332)

### class sympy.combinatorics.permutations.Cycle(*args)

Wrapper around dict which provides the functionality of a disjoint cycle.

#### Explanation

A cycle shows the rule to use to move subsets of elements to obtain a permutation. The Cycle class is more flexible than Permutation in that 1) all elements need not be present in order to investigate how multiple cycles act in sequence and 2) it can contain singletons:

```python
>>> from sympy.combinatorics.permutations import Perm, Cycle
```

A Cycle will automatically parse a cycle given as a tuple on the rhs:

```python
>>> Cycle(1, 2)(2, 3)
(1 3 2)
```
The identity cycle, Cycle(), can be used to start a product:

```python
>>> Cycle()(1, 2)(2, 3)
(1 3 2)
```

The array form of a Cycle can be obtained by calling the list method (or passing it to the list function) and all elements from 0 will be shown:

```python
>>> a = Cycle(1, 2)
>>> a.list()
[0, 2, 1]
>>> list(a)
[0, 2, 1]
```

If a larger (or smaller) range is desired use the list method and provide the desired size – but the Cycle cannot be truncated to a size smaller than the largest element that is out of place:

```python
>>> b = Cycle(2, 4)(1, 2)(3, 1, 4)(1, 3)
>>> b.list()
[0, 2, 1, 3, 4]
>>> b.list(b.size + 1)
[0, 2, 1, 3, 4, 5]
>>> b.list(-1)
[0, 2, 1]
```

Singletons are not shown when printing with one exception: the largest element is always shown – as a singleton if necessary:

```python
>>> Cycle(1, 4, 10)(4, 5)
(1 5 4 10)
>>> Cycle(1, 2)(4)(5)(10)
(1 2)(10)
```

The array form can be used to instantiate a Permutation so other properties of the permutation can be investigated:

```python
>>> Perm(Cycle(1, 2)(3, 4).list()).transpositions()
[(1, 2), (3, 4)]
```

### Notes

The underlying structure of the Cycle is a dictionary and although the _iter_ method has been redefined to give the array form of the cycle, the underlying dictionary items are still available with the such methods as items():

```python
>>> list(Cycle(1, 2).items())
[(1, 2), (2, 1)]
```

**See also:**

*Permutation* (page 312)
list(size=None)

Return the cycles as an explicit list starting from 0 up to the greater of the largest value in the cycles and size.

Truncation of trailing unmoved items will occur when size is less than the maximum element in the cycle; if this is desired, setting size=-1 will guarantee such trimming.

Examples

```
>>> from sympy.combinatorics import Cycle
>>> p = Cycle(2, 3)(4, 5)
>>> p.list()
[0, 1, 3, 2, 5, 4]
>>> p.list(10)
[0, 1, 3, 2, 5, 4, 6, 7, 8, 9]
```

Passing a length too small will trim trailing, unchanged elements in the permutation:

```
>>> Cycle(2, 4)(1, 2, 4).list(-1)
[0, 2, 1]
```

sympy.combinatorics.permutations._af_parity(pi)

Computes the parity of a permutation in array form.

Explanation

The parity of a permutation reflects the parity of the number of inversions in the permutation, i.e., the number of pairs of x and y such that x > y but p[x] < p[y].

Examples

```
>>> from sympy.combinatorics.permutations import _af_parity
>>> _af_parity([0, 1, 2, 3])
0
>>> _af_parity([3, 2, 0, 1])
1
```

See also:

Permutation (page 312)
Generators

generators.symmetric()
Generates the symmetric group of order n, Sn.

Examples

```python
>>> from sympy.combinatorics.generators import symmetric
>>> list(symmetric(3))
[(2), (1 2), (2)(0 1), (0 1 2), (0 2 1), (0 2)]
```

generators.cyclic()
Generates the cyclic group of order n, Cn.

Examples

```python
>>> from sympy.combinatorics.generators import cyclic
>>> list(cyclic(5))
[(4), (0 1 2 3 4), (0 2 4 1 3), (0 3 1 4 2), (0 4 3 2 1)]
```

See also:
dihedral (page 342)

generators.alternating()
Generates the alternating group of order n, An.

Examples

```python
>>> from sympy.combinatorics.generators import alternating
>>> list(alternating(3))
[(2), (0 1 2), (0 2 1)]
```

generators.dihedral()
Generates the dihedral group of order 2n, Dn.

The result is given as a subgroup of Sn, except for the special cases n=1 (the group S2) and n=2 (the Klein 4-group) where that’s not possible and embeddings in S2 and S4 respectively are given.
Examples

```python
from sympy.combinatorics.generators import dihedral
list(dihedral(3))
[[(2), (0 2), (0 1 2), (1 2), (0 2 1), (2)(0 1)]
```

See also:
cyclic (page 342)

Permutation Groups

```python
class sympy.combinatorics.perm_groups.PermutationGroup(*args, dups=True, **kwargs)
```

The class defining a Permutation group.

Explanation

PermutationGroup([p1, p2, ..., pn]) returns the permutation group generated by
the list of permutations. This group can be supplied to Polyhedron if one desires to
decorate the elements to which the indices of the permutation refer.

Examples

```python
from sympy.combinatorics import Permutation, PermutationGroup
from sympy.combinatorics import Polyhedron
```

The permutations corresponding to motion of the front, right and bottom face of a 2 x 2
Rubik’s cube are defined:

```python
F = Permutation((2, 19, 21, 8)(3, 17, 20, 10)(4, 6, 7, 5)
R = Permutation((1, 5, 21, 14)(3, 7, 23, 12)(8, 10, 11, 9)
D = Permutation((6, 18, 14, 10)(7, 19, 15, 11)(20, 22, 23, 21)
```

These are passed as permutations to PermutationGroup:

```python
G = PermutationGroup(F, R, D)
G.order()
3674160
```

The group can be supplied to a Polyhedron in order to track the objects being moved.
An example involving the 2 x 2 Rubik’s cube is given there, but here is a simple demon-
stration:

```python
a = Permutation((2, 1))
b = Permutation((1, 0))
G = PermutationGroup(a, b)
P = Polyhedron(list('ABC'), pgroup=G)
P.corners
(A, B, C)
```
(continues on next page)
```python
>>> P.rotate(0)  # apply permutation 0
>>> P.corners
(A, C, B)
>>> P.reset()
>>> P.corners
(A, B, C)
```

Or one can make a permutation as a product of selected permutations and apply them to an iterable directly:

```python
>>> P10 = G.make_perm([0, 1])
>>> P10('ABC')
['C', 'A', 'B']
```

See also:

- `sympy.combinatorics.polyhedron.Polyhedron` (page 387), `sympy.combinatorics.permutations.Permutation` (page 312)

References

[R56], [R57], [R58], [R59], [R60], [R61], [R62], [R63], [R64], 10, 11, 12, 13, 14

__contains__(i)

Return True if i is contained in PermutationGroup.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> p = Permutation(1, 2, 3)
>>> Permutation(3) in PermutationGroup(p)
True
```

__mul__(other)

Return the direct product of two permutation groups as a permutation group.

---

10 https://en.wikipedia.org/wiki/Centralizer_and_normalizer
11 https://groupprops.subwiki.org/wiki/Derived_subgroup
12 https://en.wikipedia.org/wiki/Nilpotent_group
13 https://www.math.colostate.edu/~hulpke/CCT/cgtnotes.pdf
Explanation

This implementation realizes the direct product by shifting the index set for the
generators of the second group: so if we have $G$ acting on $n_1$ points and $H$ acting on
$n_2$ points, $G \times H$ acts on $n_1 + n_2$ points.

Examples

```python
>>> from sympy.combinatorics.named_groups import CyclicGroup
>>> G = CyclicGroup(5)
>>> H = G*G
>>> H
PermutationGroup([[(9)(0 1 2 3 4),
                  (5 6 7 8 9)]])
>>> H.order()
25
```

```
static __new__(cls, *args, dups=True, **kwargs)
    The default constructor. Accepts Cycle and Permutation forms. Removes duplicates
    unless dups keyword is False.

__weakref__
    list of weak references to the object (if defined)

_coset_representative(g, H)
    Return the representative of $Hg$ from the transversal that would be computed by
    self.coset_transversal(H).

classmethod _distinct_primes_lemma(primes)
    Subroutine to test if there is only one cyclic group for the order.

property _elements
    Returns all the elements of the permutation group as a list

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> p = PermutationGroup(Permutation(1, 3), Permutation(1, 2))
>>> p._elements
[(3), (3)(1 2), (1 3), (2 3), (1 2 3), (1 3 2)]
```

```
_eval_is_alt_sym_monte_carlo(eps=0.05, perms=None)
    A test using monte-carlo algorithm.

    Parameters
    eps : float, optional
        The criterion for the incorrect False return.
    perms : list[Permutation], optional
```
If explicitly given, it tests over the given candidates for testing.
If None, it randomly computes \( N_{\text{eps}} \) and chooses \( N_{\text{eps}} \) sample of the permutation from the group.

See also:

_\text{check\_cycles\_alt\_sym} (page 417)

_\text{eval\_is\_alt\_sym\_naive}(\text{only\_sym}=\text{False}, \text{only\_alt}=\text{False})
A naive test using the group order.

_\text{p\_elements\_group}(p)
For an abelian p-group, return the subgroup consisting of all elements of order p
(and the identity)

_\text{random\_pr\_init}(r, n, _\text{random\_prec\_n}=\text{None})
Initialize random generators for the product replacement algorithm.

**Explanation**

The implementation uses a modification of the original product replacement algo-
rithm due to Leedham-Green, as described in [1], pp. 69-71; also, see [2], pp. 27-29
for a detailed theoretical analysis of the original product replacement algorithm,
and [4].

The product replacement algorithm is used for producing random, uniformly dis-
tributed elements of a group \( G \) with a set of generators \( S \). For the initialization
_\text{random\_pr\_init}, a list \( R \) of \( \max\{r, |S|\} \) group generators is created as the attribute
\text{G._\text{random\_gens}}, repeating elements of \( S \) if necessary, and the identity element of
\( G \) is appended to \( R \) - we shall refer to this last element as the accumulator. Then
the function \text{random\_pr()} is called \( n \) times, randomizing the list \( R \) while preserv-
ing the generation of \( G \) by \( R \). The function \text{random\_pr()} itself takes two random
elements \( g, h \) among all elements of \( R \) but the accumulator and replaces \( g \)
with a randomly chosen element from \( \{gh, g(h), hg, (h)g\} \). Then the accumulator is mul-
tiplied by whatever \( g \) was replaced by. The new value of the accumulator is then
returned by \text{random\_pr()}.

The elements returned will eventually (for \( n \) large enough) become uniformly dis-
tributed across \( G \) ([5]). For practical purposes however, the values \( n = 50, \ r = 11 \)
are suggested in [1].

**Notes**

THIS FUNCTION HAS SIDE EFFECTS: it changes the attribute \text{self._random\_gens}

See also:

\text{random\_pr} (page 379)

_\text{sylow\_alt\_sym}(p)
Return a p-Sylow subgroup of a symmetric or an alternating group.
Explanation

The algorithm for this is hinted at in [1], Chapter 4, Exercise 4.

For Sym(n) with n = p^i, the idea is as follows. Partition the interval [0..n-1] into p equal parts, each of length p^(i-1): [0..p^(i-1)-1], [p^(i-1)..2*p^(i-1)-1]...(p-1)*p^(i-1)..p^i-1. Find a p-Sylow subgroup of Sym(p^(i-1)) (treated as a subgroup of self) acting on each of the parts. Call the subgroups P_1, P_2...P_p. The generators for the subgroups P_2...P_p can be obtained from those of P_1 by applying a “shifting” permutation to them, that is, a permutation mapping [0..p^(i-1)-1] to the second part (the other parts are obtained by using the shift multiple times). The union of this permutation and the generators of P_1 is a p-Sylow subgroup of self.

For n not equal to a power of p, partition [0..n-1] in accordance with how n would be written in base p. E.g. for p=2 and n=11, 11 = 2^3 + 2^2 + 1 so the partition is [[0..7], [8..9], {10}]. To generate a p-Sylow subgroup, take the union of the generators for each of the parts. For the above example, {{0 1}, (0 2)(1 3), (0 4), (1 5)(2 7)} from the first part, {{8 9}} from the second part and nothing from the third. This gives 4 generators in total, and the subgroup they generate is p-Sylow.

Alternating groups are treated the same except when p=2. In this case, (0 1)(s s+1) should be added for an appropriate s (the start of a part) for each part in the partitions.

See also:

sylow_subgroup (page 386), is_alt_sym (page 365)

_union_find_merge(first, second, ranks, parents, not_rep)
Merges two classes in a union-find data structure.

Explanation

Used in the implementation of Atkinson’s algorithm as suggested in [1], pp. 83-87. The class merging process uses union by rank as an optimization. ([7])

Notes

THIS FUNCTION HAS SIDE EFFECTS: the list of class representatives, parents, the list of class sizes, ranks, and the list of elements that are not representatives, not_rep, are changed due to class merging.

See also:

minimal_block (page 374), _union_find_rep (page 348)
SymPy Documentation, Release 1.12.1

References

[R65], [R71]

_union_find_rep(num, parents)
Find representative of a class in a union-find data structure.

Explanation

Used in the implementation of Atkinson’s algorithm as suggested in [1], pp. 83-87. After the representative of the class to which num belongs is found, path compression is performed as an optimization ([7]).

Notes

THIS FUNCTION HAS SIDE EFFECTS: the list of class representatives, parents, is altered due to path compression.

minimal_block (page 374), _union_find_merge (page 347)

References

[R67], [R73]

_verify(K, phi, z, alpha)
Return a list of relators rels in generators gens`_h` that are mapped to `\`H. generators by phi so that given a finite presentation <gens_k | rels_k> of K on a subset of gens_h <gens_h | rels_k + rels> is a finite presentation of H.

Explanation

H should be generated by the union of K.generators and z (a single generator), and H.stabilizer(alpha) == K; phi is a canonical injection from a free group into a permutation group containing H.

The algorithm is described in [1], Chapter 6.

Examples

```python
>>> from sympy.combinatorics import free_group, Permutation,
   PermutationGroup
>>> from sympy.combinatorics.homomorphisms import homomorphism
>>> from sympy.combinatorics.fp_groups import FpGroup
```
>>> H = PermutationGroup(Permutation(0, 2), Permutation (1, 5))
>>> K = PermutationGroup(Permutation(5)(0, 2))
>>> F = free_group("x_0 x_1")[0]
>>> gens = F.generators
>>> phi = homomorphism(F, H, F.generators, H.generators)
>>> rels_k = [gens[0]**2] # relators for presentation of K
>>> z = Permutation(1, 5)
>>> check, rels_h = H._verify(K, phi, z, 1)
>>> check
True
>>> rels = rels_k + rels_h
>>> G = FpGroup(F, rels) # presentation of H
>>> G.order() == H.order()
True

See also:

strong_presentation (page 384), presentation (page 379), stabilizer (page 383)

abelian_invariants()

Returns the abelian invariants for the given group. Let G be a nontrivial finite abelian group. Then G is isomorphic to the direct product of finitely many nontrivial cyclic groups of prime-power order.

Explanation

The prime-powers that occur as the orders of the factors are uniquely determined by G. More precisely, the primes that occur in the orders of the factors in any such decomposition of G are exactly the primes that divide |G| and for any such prime p, if the orders of the factors that are p-groups in one such decomposition of G are \( p^{t_1} \geq p^{t_2} \geq \ldots p^{t_r} \), then the orders of the factors that are p-groups in any such decomposition of G are \( p^{t_1} \geq p^{t_2} \geq \ldots p^{t_r} \).

The uniquely determined integers \( p^{t_1} \geq p^{t_2} \geq \ldots p^{t_r} \), taken for all primes that divide |G| are called the invariants of the nontrivial group G as suggested in ([14], p. 542).
Notes

We adopt the convention that the invariants of a trivial group are `[]`.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation([0, 2, 1])
>>> b = Permutation([1, 0, 2])
>>> G = PermutationGroup([a, b])
>>> G.abelian_invariants()
[2]
>>> from sympy.combinatorics import CyclicGroup
>>> G = CyclicGroup(7)
>>> G.abelian_invariants()
[7]
```

**property base**

Return a base from the Schreier-Sims algorithm.

Explanation

For a permutation group \( G \), a base is a sequence of points \( B = (b_1, b_2, \ldots, b_k) \) such that no element of \( G \) apart from the identity fixes all the points in \( B \). The concepts of a base and strong generating set and their applications are discussed in depth in [1], pp. 87-89 and [2], pp. 55-57.

An alternative way to think of \( B \) is that it gives the indices of the stabilizer cosets that contain more than the identity permutation.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> G = PermutationGroup([Permutation([0, 1, 3])(2, 4)])
>>> G.base
[0, 2]
```

See also:

- `strong_gens` (page 383), `basic_transversals` (page 353), `basic_orbits` (page 352), `basic_stabilizers` (page 352)
- `baseswap(base, strong_gens, pos, randomized=False, transversals=None, basic_orbits=None, strong_gens_distr=None)`

Swap two consecutive base points in base and strong generating set.

**Parameters**

- `base, strong_gens`
  - The base and strong generating set.
- `pos`

```python```
The position at which swapping is performed.

**randomized**
A switch between randomized and deterministic version.

**transversals**
The transversals for the basic orbits, if known.

**basic_orbits**
The basic orbits, if known.

**strong_gens_distr**
The strong generators distributed by basic stabilizers, if known.

**Returns**
(base, strong_gens)

`base` is the new base, and `strong_gens` is a generating set relative to it.

**Explanation**
If a base for a group $G$ is given by $(b_1, b_2, ..., b_k)$, this function returns a base $(b_1, b_2, ..., b_{i+1}, b_i, ..., b_k)$, where $i$ is given by `pos`, and a strong generating set relative to that base. The original base and strong generating set are not modified. The randomized version (default) is of Las Vegas type.

**Examples**

```python
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> from sympy.combinatorics.testutil import _verify_bsgs
>>> from sympy.combinatorics.perm_groups import PermutationGroup
>>> S = SymmetricGroup(4)
>>> S.schreier_sims()
>>> S.base
[0, 1, 2]
>>> base, gens = S.baseswap(S.base, S.strong_gens, 1, randomized=False)
>>> base, gens
([0, 2, 1],
[(0 1 2 3), (3)(0 1), (1 3 2),
(2 3), (1 3)])
```

check that base, gens is a BSGS

```python
>>> S1 = PermutationGroup(gens)
>>> _verify_bsgs(S1, base, gens)
True
```
Notes

The deterministic version of the algorithm is discussed in [1], pp. 102-103; the randomized version is discussed in [1], p.103, and [2], p.98. It is of Las Vegas type. Notice that [1] contains a mistake in the pseudocode and discussion of BASESWAP: on line 3 of the pseudocode, $|\beta_{i+1}^{(T)}|$ should be replaced by $|\beta_{i}^{(T)}|$, and the same for the discussion of the algorithm.

See also:

*schreier_sims*(page 380)

property basic_orbits

Return the basic orbits relative to a base and strong generating set.

Explanation

If $(b_1, b_2, \ldots, b_k)$ is a base for a group $G$, and $G^{(i)} = G_{b_1, b_2, \ldots, b_{i-1}}$ is the i-th basic stabilizer (so that $G^{(1)} = G$), the i-th basic orbit relative to this base is the orbit of $b_i$ under $G^{(i)}$. See [1], pp. 87-89 for more information.

Examples

```python
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> S = SymmetricGroup(4)
>>> S.basic_orbits
[[0, 1, 2, 3], [1, 2, 3], [2, 3]]
```

See also:

*base*(page 350), *strong_gens*(page 383), *basic_transversals*(page 353), *basic_stabilizers*(page 352)

property basic_stabilizers

Return a chain of stabilizers relative to a base and strong generating set.

Explanation

The i-th basic stabilizer $G^{(i)}$ relative to a base $(b_1, b_2, \ldots, b_k)$ is $G_{b_1, b_2, \ldots, b_{i-1}}$. For more information, see [1], pp. 87-89.

Examples

```python
>>> from sympy.combinatorics.named_groups import AlternatingGroup
>>> A = AlternatingGroup(4)
>>> A.schreier_sims()
>>> A.base
[0, 1]
>>> for g in A.basic_stabilizers:
...    print(g)
```

(continues on next page)
See also:

- base (page 350), strong gens (page 383), basic orbits (page 352),
  basic_transversals (page 353)

**property basic_transversals**
Return basic transversals relative to a base and strong generating set.

**Explanation**

The basic transversals are transversals of the basic orbits. They are provided as a list of dictionaries, each dictionary having keys - the elements of one of the basic orbits, and values - the corresponding transversal elements. See [1], pp. 87-89 for more information.

**Examples**

```python
>>> from sympy.combinatorics.named_groups import AlternatingGroup
>>> A = AlternatingGroup(4)
>>> A.basic_transversals
[{0: (3), 1: (3)(0 1 2), 2: (3)(0 2 1), 3: (0 3 1)}, {1: (3), 2: (1 2 → 3), 3: (1 3 2)}]
```

See also:

- strong gens (page 383), base (page 350), basic orbits (page 352),
  basic_stabilizers (page 352)

**center()**

Return the center of a permutation group.

**Explanation**

The center for a group $G$ is defined as $Z(G) = \{z \in G | \forall g \in G, zg = gz\}$, the set of elements of $G$ that commute with all elements of $G$. It is equal to the centralizer of $G$ inside $G$, and is naturally a subgroup of $G$ ([9]).
Examples

```python
>>> from sympy.combinatorics.named_groups import DihedralGroup
>>> D = DihedralGroup(4)
>>> G = D.center()
>>> G.order()
2
```

Notes

This is a naive implementation that is a straightforward application of `.centralizer()`

See also:

`centralizer` (page 354)

`centralizer`(*other*)

Return the centralizer of a group/set/element.

Parameters

*other*

a permutation group/list of permutations/single permutation

Explanation

The centralizer of a set of permutations \( S \) inside a group \( G \) is the set of elements of \( G \) that commute with all elements of \( S \):

\[
C_G(S) = \{ g \in G \mid gs = sg \ \forall s \in S \} \quad ([10])
\]

Usually, \( S \) is a subset of \( G \), but if \( G \) is a proper subgroup of the full symmetric group, we allow for \( S \) to have elements outside \( G \).

It is naturally a subgroup of \( G \); the centralizer of a permutation group is equal to the centralizer of any set of generators for that group, since any element commuting with the generators commutes with any product of the generators.

Examples

```python
>>> from sympy.combinatorics.named_groups import (SymmetricGroup,
... CyclicGroup)
>>> S = SymmetricGroup(6)
>>> C = CyclicGroup(6)
>>> H = S.centralizer(C)
>>> H.is_subgroup(C)
True
```
Notes

The implementation is an application of .subgroup_search() with tests using a spe-
cific base for the group G.

See also:

subgroup_search (page 384)

commutator\((G, H)\)

Return the commutator of two subgroups.

Explanation

For a permutation group \(K\) and subgroups \(G, H\), the commutator of \(G\) and \(H\) is defined
as the group generated by all the commutators \([g, h] = hgh^{-1}g^{-1}\) for \(g\) in \(G\) and \(h\) in \(H\).
It is naturally a subgroup of \(K\) ([1], p.27).

Examples

```python
>>> from sympy.combinatorics.named_groups import (SymmetricGroup,
... AlternatingGroup)
>>> S = SymmetricGroup(5)
>>> A = AlternatingGroup(5)
>>> G = S.commutator(S, A)
>>> G.is_subgroup(A)
True
```

Notes

The commutator of two subgroups \(H, G\) is equal to the normal closure of the com-
mutators of all the generators, i.e. \(hgh^{-1}g^{-1}\) for \(h\) a generator of \(H\) and \(g\) a generator
of \(G\) ([1], p.28)

See also:

derived_subgroup (page 361)

composition_series()

Return the composition series for a group as a list of permutation groups.

Explanation

The composition series for a group \(G\) is defined as a subnormal series \(G = H_0 >
H_1 > H_2 \ldots\) A composition series is a subnormal series such that each factor group
\(H(i+1)/H(i)\) is simple. A subnormal series is a composition series only if it is of
maximum length.

The algorithm works as follows: Starting with the derived series the idea is to fill the
gap between \(G = \text{der}[i]\) and \(H = \text{der}[i+1]\) for each \(i\) independently. Since, all subgroups
of the abelian group \(G/H\) are normal so, first step is to take the generators \(g\) of \(G\)
and add them to generators of \(H\) one by one.
The factor groups formed are not simple in general. Each group is obtained from the previous one by adding one generator $g$, if the previous group is denoted by $H$ then the next group $K$ is generated by $g$ and $H$. The factor group $K/H$ is cyclic and it’s order is $K.order()//G.order()$. The series is then extended between $K$ and $H$ by groups generated by powers of $g$ and $H$. The series formed is then prepended to the already existing series.

**Examples**

```python
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> from sympy.combinatorics.named_groups import CyclicGroup
>>> S = SymmetricGroup(12)
>>> G = S.sylow_subgroup(2)
>>> C = G.composition_series()
>>> [H.order() for H in C]
[1024, 512, 256, 128, 64, 32, 16, 8, 4, 2, 1]
>>> G = S.sylow_subgroup(3)
>>> C = G.composition_series()
>>> [H.order() for H in C]
[243, 81, 27, 9, 3, 1]
>>> G = CyclicGroup(12)
>>> C = G.composition_series()
>>> [H.order() for H in C]
[12, 6, 3, 1]
```

**conjugacy_class**(x)

Return the conjugacy class of an element in the group.

**Explanation**

The conjugacy class of an element $g$ in a group $G$ is the set of elements $x$ in $G$ that are conjugate with $g$, i.e. for which

$$g = x a x^{-1}$$

for some $a$ in $G$.

Note that conjugacy is an equivalence relation, and therefore that conjugacy classes are partitions of $G$. For a list of all the conjugacy classes of the group, use the `conjugacy_classes()` method.

In a permutation group, each conjugacy class corresponds to a particular `cyclestructure`. For example, in `S_3`, the conjugacy classes are:

- the identity class, `{()}
- all transpositions, `{(1 2), (1 3), (2 3)}`
- all 3-cycles, `{(1 2 3), (1 3 2)}`
Examples

```python
>>> from sympy.combinatorics import Permutation, SymmetricGroup
>>> S3 = SymmetricGroup(3)
>>> S3.conjugacy_class(Permutation(0, 1, 2))
{(0 1 2), (0 2 1)}
```

Notes

This procedure computes the conjugacy class directly by finding the orbit of the element under conjugation in \( G \). This algorithm is only feasible for permutation groups of relatively small order, but is like the orbit() function itself in that respect.

**conjugacy_classes()**

Return the conjugacy classes of the group.

Explanation

As described in the documentation for the .conjugacy_class() function, conjugacy is an equivalence relation on a group \( G \) which partitions the set of elements. This method returns a list of all these conjugacy classes of \( G \).

Examples

```python
>>> from sympy.combinatorics import SymmetricGroup
>>> SymmetricGroup(3).conjugacy_classes()
[{{(2)}}, {{(0 1 2), (0 2 1)}}, {{(0 2), (1 2), (2)(0 1)}}]
```

**contains\( (g, \text{strict}=True) \)**

Test if permutation \( g \) belong to self, \( G \).

Explanation

If \( g \) is an element of \( G \) it can be written as a product of factors drawn from the cosets of \( G \)’s stabilizers. To see if \( g \) is one of the actual generators defining the group use \( G\text{.has}(g) \).

If \( \text{strict} \) is not \( True \), \( g \) will be resized, if necessary, to match the size of permutations in self.
Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup

>>> a = Permutation(1, 2)
>>> b = Permutation(2, 3, 1)
>>> G = PermutationGroup(a, b, degree=5)
>>> G.contains(G[0])  # trivial check
True
>>> elem = Permutation([[2, 3]], size=5)
>>> G.contains(elem)
True
>>> G.contains(Permutation(4)(0, 1, 2, 3))
False
```

If `strict` is False, a permutation will be resized, if necessary:

```python
>>> H = PermutationGroup(Permutation(5))
>>> H.contains(Permutation(3))
False
>>> H.contains(Permutation(3), strict=False)
True
```

To test if a given permutation is present in the group:

```python
>>> elem in G.generators
False
>>> G.has(elem)
False
```

See also:

- `coset_factor` (page 358), `sympy.core.basic.Basic.has` (page 985), `__contains__` (page 344)

```
coset_factor(g, factor_index=False)
```

Return `G`'s (self's) coset factorization of `g`

**Explanation**

If `g` is an element of `G` then it can be written as the product of permutations drawn from the Schreier-Sims coset decomposition,

The permutations returned in `f` are those for which the product gives `g`: $g = f[n]*..f[1]*f[0]$ where $n = \text{len}(B)$ and $B = G\.base$. `f[i]` is one of the permutations in `self._basic_orbits[i]`.

If `factor_index`==True, returns a tuple `[b[0],..,b[n]]`, where `b[i]` belongs to `self._basic_orbits[i]`
Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation(0, 1, 3, 7, 6, 4)(2, 5)
>>> b = Permutation(0, 1, 3, 2)(4, 5, 7, 6)
>>> G = PermutationGroup([a, b])
```

Define g:

```python
>>> g = Permutation(7)(1, 2, 4)(3, 6, 5)
```

Confirm that it is an element of G:

```python
>>> G.contains(g)
True
```

Thus, it can be written as a product of factors (up to 3) drawn from u. See below that a factor from u1 and u2 and the Identity permutation have been used:

```python
>>> f = G.coset_factor(g)
>>> f[2]*f[1]*f[0] == g
True
>>> f1 = G.coset_factor(g, True); f1
[0, 4, 4]
>>> tr = G.basic_transversals
>>> f[0] == tr[0][f1[0]]
True
```

If g is not an element of G then [] is returned:

```python
>>> c = Permutation(5, 6, 7)
>>> G.coset_factor(c)
[]
```

See also:

- `sympy.combinatorics.util._strip` (page 421)
- `coset_rank(g)`
  rank using Schreier-Sims representation.

Explanation

The coset rank of g is the ordering number in which it appears in the lexicographic listing according to the coset decomposition.

The ordering is the same as in G.generate(method='coset'). If g does not belong to the group it returns None.
Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation(0, 1, 3, 7, 6, 4)(2, 5)
>>> b = Permutation(0, 1, 3, 2)(4, 5, 7, 6)
>>> G = PermutationGroup([a, b])
>>> c = Permutation(7)(2, 4)(3, 5)
>>> G.coset_rank(c)
16
>>> G.coset_unrank(16)
(7)(2 4)(3 5)
```

See also:

- `coset_factor` (page 358)
- `coset_table` ($H$)
  - Return the standardised (right) coset table of self in $H$ as a list of lists.
- `coset_transversal` ($H$)
  - Return a transversal of the right cosets of self by its subgroup $H$ using the second method described in [1], Subsection 4.6.7
- `coset_unrank` ($rank$, $af=False$)
  - Unrank using Schreier-Sims representation
  - `coset_unrank` is the inverse operation of `coset_rank` if $0 \leq rank < order$; otherwise it returns `None`.

property `degree`

Returns the size of the permutations in the group.

Explanation

The number of permutations comprising the group is given by `len(group)`; the number of permutations that can be generated by the group is given by `group.order()`.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation([1, 0, 2])
>>> G = PermutationGroup([a])
>>> G.degree
3
>>> len(G)
1
>>> G.order()
2
>>> list(G.generate())
[(2), (2)(0 1)]
```

See also:

- `order` (page 378)
derived_series()
Return the derived series for the group.

Returns
A list of permutation groups containing the members of the derived series in the order $G = G_0, G_1, G_2, ...$.

Explanation
The derived series for a group $G$ is defined as $G = G_0 > G_1 > G_2 > ...$ where $G_i = [G_{i-1}, G_{i-1}]$, i.e. $G_i$ is the derived subgroup of $G_{i-1}$, for $i \in \mathbb{N}$. When we have $G_k = G_{k-1}$ for some $k \in \mathbb{N}$, the series terminates.

Examples

```python
>>> from sympy.combinatorics.named_groups import (SymmetricGroup, ...
   AlternatingGroup, DihedralGroup)
>>> A = AlternatingGroup(5)
>>> len(A.derived_series())
1
>>> S = SymmetricGroup(4)
>>> len(S.derived_series())
4
>>> S.derived_series()[1].is_subgroup(AlternatingGroup(4))
True
>>> S.derived_series()[2].is_subgroup(DihedralGroup(2))
True
```

See also:
derived_subgroup (page 361)

derived_subgroup()
Compute the derived subgroup.

Explanation
The derived subgroup, or commutator subgroup is the subgroup generated by all commutators $[g, h] = hgh^{-1}g^{-1}$ for $g, h \in G$; it is equal to the normal closure of the set of commutators of the generators ([1], p.28, [11]).
Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation([1, 0, 2, 4, 3])
>>> b = Permutation([0, 1, 3, 2, 4])
>>> G = PermutationGroup([a, b])
>>> C = G.derived_subgroup()
>>> list(C.generate(af=True))
[[0, 1, 2, 3, 4], [0, 1, 3, 4, 2], [0, 1, 4, 2, 3]]
```

See also:

`derived_series` (page 361)

property `elements`

Returns all the elements of the permutation group as a set

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> p = PermutationGroup(Permutation(1, 3), Permutation(1, 2))
>>> p.elements
{(1 2 3), (1 3 2), (1 3), (2 3), (3), (3)(1 2)}
```

equals(other)

Return True if PermutationGroup generated by elements in the group are same i.e they represent the same PermutationGroup.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> p = Permutation(0, 1, 2, 3, 4, 5)
>>> G = PermutationGroup([p, p**2])
>>> H = PermutationGroup([p**2, p])
>>> G.generators == H.generators
False
>>> G.equals(H)
True
```

generate(method='coset', af=False)

Return iterator to generate the elements of the group.
**Explanation**

Iteration is done with one of these methods:

- `method='coset'` using the Schreier-Sims coset representation
- `method='dimino'` using the Dimino method

If `af = True` it yields the array form of the permutations

**Examples**

```python
>>> from sympy.combinatorics import PermutationGroup
>>> from sympy.combinatorics.polyhedron import tetrahedron

The permutation group given in the tetrahedron object is also true groups:

```python
>>> G = tetrahedron.pgroup
>>> G.is_group
True
```

Also the group generated by the permutations in the tetrahedron pgroup – even the first two – is a proper group:

```python
>>> H = PermutationGroup(G[0], G[1])
>>> J = PermutationGroup(list(H.generate())); J
PermutationGroup([[(0 1)(2 3),
(1 2 3),
(1 3 2),
(0 3 1),
(0 2 3),
(0 3)(1 2),
(0 1 3),
(3)(0 2 1),
(0 3 2),
(3)(0 1 2),
(0 2)(1 3)]])
>>> J.is_group
True
```

**generate_dimino**(af=False)

Yield group elements using Dimino’s algorithm.

If `af == True` it yields the array form of the permutations.
Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation([0, 2, 1, 3])
>>> b = Permutation([0, 2, 3, 1])
>>> g = PermutationGroup([a, b])
>>> list(g.generate_dimino(af=True))
[[0, 1, 2, 3], [0, 2, 1, 3], [0, 2, 3, 1],
 [0, 1, 3, 2], [0, 3, 2, 1], [0, 3, 1, 2]]
```

References

[R69]

generate_schreier_sims(af=False)

Yield group elements using the Schreier-Sims representation in coset_rank order
If af=True it yields the array form of the permutations

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation([0, 2, 1, 3])
>>> b = Permutation([0, 2, 3, 1])
>>> g = PermutationGroup([a, b])
>>> list(g.generate_schreier_sims(af=True))
[[0, 1, 2, 3], [0, 2, 1, 3], [0, 2, 3, 1],
 [0, 1, 3, 2], [0, 3, 2, 1], [0, 3, 1, 2]]
```

generator_product(g, original=False)

Return a list of strong generators \([s_1, \ldots, s_n]\) s.t \(g = s_n \times \cdots \times s_1\). If original=True, make the list contain only the original group generators

property generators

Returns the generators of the group.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation([0, 2, 1, 3])
>>> b = Permutation([0, 2, 3, 1])
>>> G = PermutationGroup([a, b])
>>> G.generators
[(1 2), (2)(0 1)]
```

property identity

Return the identity element of the permutation group.

index(H)

Returns the index of a permutation group.
**Examples**

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation(1,2,3)
>>> b = Permutation(3)
>>> G = PermutationGroup([a])
>>> H = PermutationGroup([b])
>>> G.index(H)
3
```

**property is_abelian**

Test if the group is Abelian.

**Examples**

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation([0, 2, 1])
>>> b = Permutation([1, 0, 2])
>>> G = PermutationGroup([a, b])
>>> G.is_abelian
False
>>> a = Permutation([0, 2, 1])
>>> G = PermutationGroup([a])
>>> G.is_abelian
True
```

**is_alt_sym** (*eps=0.05, _random_prec=None*)

Monte Carlo test for the symmetric/alternating group for degrees >= 8.

**Explanation**

More specifically, it is one-sided Monte Carlo with the answer True (i.e., G is symmetric/alternating) guaranteed to be correct, and the answer False being incorrect with probability eps.

For degree < 8, the order of the group is checked so the test is deterministic.

**Notes**

The algorithm itself uses some nontrivial results from group theory and number theory: 1) If a transitive group $G$ of degree $n$ contains an element with a cycle of length $n/2 < p < n-2$ for $p$ a prime, $G$ is the symmetric or alternating group ([1], pp. 81-82) 2) The proportion of elements in the symmetric/alternating group having the property described in 1) is approximately $\log(2)/\log(n)$ ([1], p.82; [2], pp. 226-227). The helper function `_check_cycles_alt_sym` is used to go over the cycles in a permutation and look for ones satisfying 1).
Examples

```python
>>> from sympy.combinatorics.named_groups import DihedralGroup
>>> D = DihedralGroup(10)
>>> D.is_alt_sym()
False
```

See also:

`_check_cycles_alt_sym` (page 417)

**property is_alternating**

Return True if the group is alternating.

Examples

```python
>>> from sympy.combinatorics import AlternatingGroup
>>> g = AlternatingGroup(5)
>>> g.is_alternating
True
```

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> g = PermutationGroup(...
...    Permutation(0, 1, 2, 3, 4),
...    Permutation(2, 3, 4))
>>> g.is_alternating
True
```

Notes

This uses a naive test involving the computation of the full group order. If you need more quicker taxonomy for large groups, you can use `PermutationGroup.is_alt_sym` (page 365). However, `PermutationGroup.is_alt_sym` (page 365) may not be accurate and is not able to distinguish between an alternating group and a symmetric group.

See also:

`is_alt_sym` (page 365)

**property is_cyclic**

Return True if the group is Cyclic.
Examples

```python
>>> from sympy.combinatorics.named_groups import AbelianGroup
>>> G = AbelianGroup(3, 4)
>>> G.is_cyclic
True
>>> G = AbelianGroup(4, 4)
>>> G.is_cyclic
False
```

Notes

If the order of a group $n$ can be factored into the distinct primes $p_1, p_2, \ldots, p_s$ and if

$$
\forall i, j \in \{1, 2, \ldots, s\} : p_i \not\equiv 1 \pmod{p_j}
$$

holds true, there is only one group of the order $n$ which is a cyclic group [R70]. This is a generalization of the lemma that the group of order 15, 35, \ldots are cyclic.

And also, these additional lemmas can be used to test if a group is cyclic if the order of the group is already found.

- If the group is abelian and the order of the group is square-free, the group is cyclic.
- If the order of the group is less than 6 and is not 4, the group is cyclic.
- If the order of the group is prime, the group is cyclic.

References

[R70]

**property is_dihedral**

Return True if the group is dihedral.

Examples

```python
>>> from sympy.combinatorics.perm_groups import PermutationGroup
>>> from sympy.combinatorics.permutations import Permutation
>>> from sympy.combinatorics.named_groups import SymmetricGroup,
CyclicGroup
>>> G = PermutationGroup(Permutation(1, 6)(2, 5)(3, 4), Permutation(0,
1, 2, 3, 4, 5, 6))
>>> G.is_dihedral
True
>>> G = SymmetricGroup(3)
>>> G.is_dihedral
True
>>> G = CyclicGroup(6)
>>> G.is_dihedral
False
```
is_elementary($p$)

Return True if the group is elementary abelian. An elementary abelian group is a finite abelian group, where every nontrivial element has order $p$, where $p$ is a prime.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation([0, 2, 1])
>>> G = PermutationGroup([a])
>>> G.is_elementary(2)
True
>>> a = Permutation([0, 2, 1, 3])
>>> b = Permutation([3, 1, 2, 0])
>>> G = PermutationGroup([a, b])
>>> G.is_elementary(2)
True
>>> G.is_elementary(3)
False
```

property is_nilpotent

Test if the group is nilpotent.

Explanation

A group $G$ is nilpotent if it has a central series of finite length. Alternatively, $G$ is nilpotent if its lower central series terminates with the trivial group. Every nilpotent group is also solvable ([1], p.29, [12]).

Examples

```python
>>> from sympy.combinatorics.named_groups import SymmetricGroup, CyclicGroup
>>> C = CyclicGroup(6)
>>> C.is_nilpotent
True
>>> S = SymmetricGroup(5)
>>> S.is_nilpotent
False
```

See also:

- `lower_central_series` (page 373), `is_solvable` (page 370)

is_normal($gr$, strict=True)

Test if $G=self$ is a normal subgroup of $gr$. 
Explanation

G is normal in G if for each g2 in G, g1 in G, g = g1*g2*g1**-1 belongs to G. It is sufficient to check this for each g1 in G.generators and g2 in G.generators.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation([1, 2, 0])
>>> b = Permutation([1, 0, 2])
>>> G = PermutationGroup([a, b])
>>> G1 = PermutationGroup([a, Permutation([2, 0, 1])])
>>> G1.is_normal(G)
True
```

**property is_perfect**

Return True if the group is perfect. A group is perfect if it equals to its derived subgroup.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation((1,2,3)(4,5))
>>> b = Permutation((1,2,3,4,5))
>>> G = PermutationGroup([a, b])
>>> G.is_perfect
False
```

**property is_polycyclic**

Return True if a group is polycyclic. A group is polycyclic if it has a subnormal series with cyclic factors. For finite groups, this is the same as if the group is solvable.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation((0, 2, 1, 3])
>>> b = Permutation((2, 0, 1, 3])
>>> G = PermutationGroup([a, b])
>>> G.is_polycyclic
True
```

**isPrimitive(randomized=True)**

Test if a group is primitive.
Explanation

A permutation group \(G\) acting on a set \(S\) is called primitive if \(S\) contains no nontrivial block under the action of \(G\) (a block is nontrivial if its cardinality is more than 1).

Notes

The algorithm is described in [1], p.83, and uses the function minimal_block to search for blocks of the form \(\{0,k\}\) for \(k\) ranging over representatives for the orbits of \(G_0\), the stabilizer of 0. This algorithm has complexity \(O(n^2)\) where \(n\) is the degree of the group, and will perform badly if \(G_0\) is small.

There are two implementations offered: one finds \(G_0\) deterministically using the function stabilizer, and the other (default) produces random elements of \(G_0\) using random_stab, hoping that they generate a subgroup of \(G_0\) with not too many more orbits than \(G_0\) (this is suggested in [1], p.83). Behavior is changed by the randomized flag.

Examples

```python
>>> from sympy.combinatorics.named_groups import DihedralGroup
>>> D = DihedralGroup(10)
>>> D.is Primitive()
False
```

See also:

minimal_block (page 374), random_stab (page 380)

property is_solvable

Test if the group is solvable.

\(G\) is solvable if its derived series terminates with the trivial group ([1], p.29).

Examples

```python
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> S = SymmetricGroup(3)
>>> S.is_solvable
True
```

See also:

is_nilpotent (page 368), derived_series (page 361)

is_subgroup \((G, \text{strict}=\text{True})\)

Return True if all elements of self belong to \(G\).

If \text{strict} is False then if self’s degree is smaller than \(G\)’s, the elements will be resized to have the same degree.
Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> from sympy.combinatorics import SymmetricGroup, CyclicGroup
```

Testing is strict by default: the degree of each group must be the same:

```python
>>> p = Permutation(0, 1, 2, 3, 4, 5)
>>> G1 = PermutationGroup([Permutation(0, 1, 2), Permutation(0, 1)])
>>> G2 = PermutationGroup([Permutation(0, 2), Permutation(0, 1, 2)])
>>> G3 = PermutationGroup([p, p**2])
>>> assert G1.order() == G2.order() == G3.order() == 6
>>> G1.is_subgroup(G2)
True
>>> G1.is_subgroup(G3)
False
>>> G3.is_subgroup(PermutationGroup(G3[1]))
False
>>> G3.is_subgroup(PermutationGroup(G3[0]))
True
```

To ignore the size, set strict to False:

```python
>>> S3 = SymmetricGroup(3)
>>> S5 = SymmetricGroup(5)
>>> S3.is_subgroup(S5, strict=False)
True
>>> C7 = CyclicGroup(7)
>>> G = S5*C7
>>> S5.is_subgroup(G, False)
True
>>> C7.is_subgroup(G, 0)
False
```

**property is_symmetric**

Return True if the group is symmetric.

Examples

```python
>>> from sympy.combinatorics import SymmetricGroup
>>> g = SymmetricGroup(5)
>>> g.is_symmetric
True
```

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> g = PermutationGroup(  
...     Permutation(0, 1, 2, 3, 4),  
...     Permutation(2, 3))
>>> g.is_symmetric
True
```
Notes

This uses a naive test involving the computation of the full group order. If you need more quicker taxonomy for large groups, you can use `PermutationGroup.is_alt_sym()` (page 365). However, `PermutationGroup.is_alt_sym()` (page 365) may not be accurate and is not able to distinguish between an alternating group and a symmetric group.

See also:

`is_alt_sym` (page 365)

`is_transitive(strict=True)`

Test if the group is transitive.

Explanation

A group is transitive if it has a single orbit.

If `strict` is `False` the group is transitive if it has a single orbit of length different from 1.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation([0, 2, 1, 3])
>>> b = Permutation([2, 0, 1, 3])
>>> G1 = PermutationGroup([a, b])
>>> G1.is_transitive()
False
>>> G1.is_transitive(strict=False)
True
>>> c = Permutation([2, 3, 0, 1])
>>> G2 = PermutationGroup([a, c])
>>> G2.is_transitive()
True
>>> d = Permutation([1, 0, 2, 3])
>>> e = Permutation([0, 1, 3, 2])
>>> G3 = PermutationGroup([d, e])
>>> G3.is_transitive() or G3.is_transitive(strict=False)
False
```

property `is_trivial`

Test if the group is the trivial group.

This is true if the group contains only the identity permutation.
Examples

>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> G = PermutationGroup([Permutation([0, 1, 2])])
>>> G.is_trivial
True

lower_central_series()
Return the lower central series for the group.

The lower central series for a group \( G \) is the series \( G = G_0 > G_1 > G_2 > \ldots \) where
\( G_k = [G, G_{k-1}] \), i.e. every term after the first is equal to the commutator of \( G \) and the
previous term in \( G_1 \) ([1], p.29).

Returns
A list of permutation groups in the order \( G = G_0, G_1, G_2, \ldots \)

Examples

>>> from sympy.combinatorics.named_groups import (AlternatingGroup,
... DihedralGroup)
>>> A = AlternatingGroup(4)
>>> len(A.lower_central_series())
2
>>> A.lower_central_series()[1].is_subgroup(DihedralGroup(2))
True

See also:
commutator (page 355), derived_series (page 361)

make_perm(\( n, seed=None \))
Multiply \( n \) randomly selected permutations from pgroup together, starting with the
identity permutation. If \( n \) is a list of integers, those integers will be used to select
the permutations and they will be applied in L to R order: make_perm((A, B, C)) will
give CBA(I) where I is the identity permutation.

seed is used to set the seed for the random selection of permutations from pgroup. If
this is a list of integers, the corresponding permutations from pgroup will be selected
in the order give. This is mainly used for testing purposes.

Examples

>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a, b = [Permutation([1, 0, 3, 2]), Permutation([1, 3, 0, 2])]
>>> G = PermutationGroup([a, b])
>>> G.make_perm(1, [0])
(0 1)(2 3)
>>> G.make_perm(3, [0, 1, 0])
(0 2 3 1)
>>> G.make_perm([0, 1, 0])
(0 2 3 1)
See also:

`random` (page 379)

**property max_div**

Maximum proper divisor of the degree of a permutation group.

**Explanation**

Obviously, this is the degree divided by its minimal proper divisor (larger than 1, if one exists). As it is guaranteed to be prime, the sieve from `sympy.ntheory` is used. This function is also used as an optimization tool for the functions `minimal_block` and `_union_find_merge`.

**Examples**

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> G = PermutationGroup([Permutation([0, 2, 1, 3])])
>>> G.max_div
2
```

See also:

`minimal_block` (page 374), `_union_find_merge` (page 347)

**minimal_block**(points)

For a transitive group, finds the block system generated by points.

**Explanation**

If a group $G$ acts on a set $S$, a nonempty subset $B$ of $S$ is called a block under the action of $G$ if for all $g$ in $G$ we have $gB = B$ (g fixes B) or $gB$ and $B$ have no common points (g moves B entirely). ([1], p.23; [6]).

The distinct translates $gB$ of a block $B$ for $g$ in $G$ partition the set $S$ and this set of translates is known as a block system. Moreover, we obviously have that all blocks in the partition have the same size, hence the block size divides $|S|$ ([1], p.23). A $G$-congruence is an equivalence relation $\sim$ on the set $S$ such that $a \sim b$ implies $g(a) \sim g(b)$ for all $g$ in $G$. For a transitive group, the equivalence classes of a $G$-congruence and the blocks of a block system are the same thing ([1], p.23).

The algorithm below checks the group for transitivity, and then finds the $G$-congruence generated by the pairs $(p_0, p_1)$, $(p_0, p_2)$, ..., $(p_0, p_{\{k-1\}})$ which is the same as finding the maximal block system (i.e., the one with minimum block size) such that $p_0$, ..., $p_{\{k-1\}}$ are in the same block ([1], p.83).

It is an implementation of Atkinson's algorithm, as suggested in [1], and manipulates an equivalence relation on the set $S$ using a union-find data structure. The running time is just above $O(|points||S|)$. ([1], pp. 83-87; [7]).
Examples

```python
>>> from sympy.combinatorics.named_groups import DihedralGroup
>>> D = DihedralGroup(10)
>>> D.minimal_block([0, 5])
[0, 1, 2, 3, 4, 0, 1, 2, 3, 4]
>>> D.minimal_block([0, 1])
[0, 0, 0, 0, 0, 0, 0, 0, 0, 0]
```

See also:

- `_union_find_rep` (page 348), `_union_find_merge` (page 347), `is_transitive` (page 372), `is_primitive` (page 369)

**minimal_blocks**(randomized=True)

For a transitive group, return the list of all minimal block systems. If a group is intransitive, return `False`.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> from sympy.combinatorics.named_groups import DihedralGroup

>>> DihedralGroup(6).minimal_blocks()
[[0, 1, 0, 1, 0, 1], [0, 1, 2, 0, 1, 2]]

>>> G = PermutationGroup(Permutation([1, 2, 5]))

>>> G.minimal_blocks()
False
```

See also:

- `minimal_block` (page 374), `is_transitive` (page 372), `is_primitive` (page 369)

**normal_closure**(other, k=10)

Return the normal closure of a subgroup/set of permutations.

**Parameters**

- **other**
  
a subgroup/list of permutations/single permutation

- **k**
  
an implementation-specific parameter that determines the number of conjugates that are adjoined to other at once

**Explanation**

If $S$ is a subset of a group $G$, the normal closure of $A$ in $G$ is defined as the intersection of all normal subgroups of $G$ that contain $A$ ([1], p.14). Alternatively, it is the group generated by the conjugates $x^{-1}yx$ for $x$ a generator of $G$ and $y$ a generator of the subgroup $\langle S \rangle$ generated by $S$ (for some chosen generating set for $\langle S \rangle$) ([1], p.73).
Examples

```python
>>> from sympy.combinatorics.named_groups import (SymmetricGroup,
... CyclicGroup, AlternatingGroup)

>>> S = SymmetricGroup(5)
>>> C = CyclicGroup(5)
>>> G = S.normal_closure(C)

>>> G.order()
60
>>> G.is_subgroup(AlternatingGroup(5))
True
```

Notes

The algorithm is described in [1], pp. 73-74; it makes use of the generation of random elements for permutation groups by the product replacement algorithm.

See also:

- commutator (page 355), derived_subgroup (page 361), random_pr (page 379)

orbit(alpha, action='tuples')

Compute the orbit of alpha \( \{g(\alpha) | g \in G\} \) as a set.

Explanation

The time complexity of the algorithm used here is \( O(|\text{Orb}| \times r) \) where \( |\text{Orb}| \) is the size of the orbit and \( r \) is the number of generators of the group. For a more detailed analysis, see [1], p.78, [2], pp. 19-21. Here alpha can be a single point, or a list of points.

If alpha is a single point, the ordinary orbit is computed. if alpha is a list of points, there are three available options:

- 'union' - computes the union of the orbits of the points in the list 'tuples' - computes the orbit of the list interpreted as an ordered tuple under the group action ( i.e., \( g((1,2,3)) = (g(1), g(2), g(3)) \) ) 'sets' - computes the orbit of the list interpreted as a sets

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup

>>> a = Permutation([1, 2, 0, 4, 5, 6, 3])
>>> G = PermutationGroup([a])
>>> G.orbit(0)
{0, 1, 2}
>>> G.orbit([0, 4], 'union')
{0, 1, 2, 3, 4, 5, 6}
```

See also:

- orbit_transversal (page 377)
orbit_rep(alpha, beta, schreier_vector=None)

Return a group element which sends alpha to beta.

Explanation

If beta is not in the orbit of alpha, the function returns False. This implementation makes use of the schreier vector. For a proof of correctness, see [1], p.80

Examples

```python
>>> from sympy.combinatorics.named_groups import AlternatingGroup
>>> G = AlternatingGroup(5)
>>> G.orbit_rep(0, 4)
(0 4 1 2 3)
```

See also:
schreier_vector (page 382)

orbit_transversal(alpha, pairs=False)

Computes a transversal for the orbit of alpha as a set.

Explanation

For a permutation group \( G \), a transversal for the orbit \( \text{Orb} = \{ g(\alpha) | g \in G \} \) is a set \( \{ g_\beta | g_\beta(\alpha) = \beta \} \) for \( \beta \in \text{Orb} \). Note that there may be more than one possible transversal. If pairs is set to True, it returns the list of pairs \((\beta, g_\beta)\). For a proof of correctness, see [1], p.79

Examples

```python
>>> from sympy.combinatorics.named_groups import DihedralGroup
>>> G = DihedralGroup(6)
>>> G.orbit_transversal(0)
[(5), (0 1 2 3 4 5), (0 5)(1 4)(2 3), (0 2 4)(1 3 5), (5)(0 4)(1 3),
 (0 3)(1 4)(2 5)]
```

See also:
orbit (page 376)

orbits(rep=False)

Return the orbits of self, ordered according to lowest element in each orbit.
Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation(1, 5)(2, 3)(4, 0, 6)
>>> b = Permutation(1, 5)(3, 4)(2, 6, 0)
>>> G = PermutationGroup([a, b])
>>> G.orbits()
[\{0, 2, 3, 4, 6\}, \{1, 5\}]
```

order()

Return the order of the group: the number of permutations that can be generated from elements of the group.

The number of permutations comprising the group is given by `len(group)`; the length of each permutation in the group is given by `group.size`.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup

>>> a = Permutation([1, 0, 2])
>>> G = PermutationGroup([a])
>>> G.degree
3
>>> len(G)
1
>>> G.order()
2
>>> list(G.generate())
[(2), (2)(0 1)]
```

See also:

degree (page 360)

pointwise_stabilizer(points, incremental=True)

Return the pointwise stabilizer for a set of points.
Explanation

For a permutation group $G$ and a set of points $\{p_1, p_2, \ldots, p_k\}$, the pointwise stabilizer of $p_1, p_2, \ldots, p_k$ is defined as $G_{p_1, \ldots, p_k} = \{ g \in G | g(p_i) = p_i \forall i \in \{1, 2, \ldots, k\} \}$ ([1],p20). It is a subgroup of $G$.

Examples

```python
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> S = SymmetricGroup(7)
>>> Stab = S.pointwise_stabilizer([2, 3, 5])
>>> Stab.is_subgroup(S.stabilizer(2).stabilizer(3).stabilizer(5))
True
```

Notes

When incremental == True, rather than the obvious implementation using successive calls to .stabilizer(), this uses the incremental Schreier-Sims algorithm to obtain a base with starting segment - the given points.

See also:

stabilizer (page 383), schreier_sims_incremental (page 380)

polycyclic_group()

Return the PolycyclicGroup instance with below parameters:

**Explanation**

- pc_sequence: Polycyclic sequence is formed by collecting all the missing generators between the adjacent groups in the derived series of given permutation group.
- pc_series: Polycyclic series is formed by adding all the missing generators of $\text{der}[i+1]$ in $\text{der}[i]$, where $\text{der}$ represents the derived series.
- relative_order: A list, computed by the ratio of adjacent groups in pc_series.

presentation(\text{eliminate gens= True})

Return an $FpGroup$ presentation of the group.

The algorithm is described in [1], Chapter 6.1.

random(af=False)

Return a random group element

random_pr(gen_count=11, iterations=50, _random_prec=None)

Return a random group element using product replacement.
**Explanation**

For the details of the product replacement algorithm, see `_random_pr_init` in `random_pr` the actual ‘product replacement’ is performed. Notice that if the attribute `_random_gens` is empty, it needs to be initialized by `_random_pr_init`.

**See also:**

- `_random_pr_init` (page 346)
- `random_stab(alpha, schreier_vector=None, _random_prec=None)`
  - Random element from the stabilizer of `alpha`.
  - The schreier vector for `alpha` is an optional argument used for speeding up repeated calls. The algorithm is described in [1], p.81
  - **See also:**
    - `random_pr` (page 379), `orbit_rep` (page 376)

**schreier_sims()**

Schreier-Sims algorithm.

**Explanation**

It computes the generators of the chain of stabilizers $G > G_{b_1} > .. > G_{b_1...b_s} > 1$ in which $G_{b_1...b_i}$ stabilizes $b_1,...,b_i$, and the corresponding $s$ cosets. An element of the group can be written as the product $h_1 * .. * h_s$.

We use the incremental Schreier-Sims algorithm.

**Examples**

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation([0, 2, 1])
>>> b = Permutation([1, 0, 2])
>>> G = PermutationGroup([a, b])
>>> G.schreier_sims()
>>> G.basic_transversals
[{{0: (2)(0 1), 1: (2), 2: (1 2)},
  {0: (2), 2: (0 2)}}]
```

**schreier_sims_incremental(base=base, gens=None, slp_dict=False)**

Extend a sequence of points and generating set to a base and strong generating set.

**Parameters**

- **base**
  - The sequence of points to be extended to a base. Optional parameter with default value `[]`.

- **gens**
  - The generating set to be extended to a strong generating set relative to the base obtained. Optional parameter with default value `self`. generators.
slp_dict

If \( \text{True} \), return a dictionary \( g : \text{gens} \) for each strong generator \( g \) where \( \text{gens} \) is a list of strong generators coming before \( g \) in \( \text{strong_gens} \), such that the product of the elements of \( \text{gens} \) is equal to \( g \).

**Returns**

(\( \text{base} \), \( \text{strong_gens} \))

\( \text{base} \) is the base obtained, and \( \text{strong_gens} \) is the strong generating set relative to it. The original parameters \( \text{base} \), \( \text{gens} \) remain unchanged.

**Examples**

```python
>>> from sympy.combinatorics.named_groups import AlternatingGroup
>>> from sympy.combinatorics.testutil import _verify_bsgs
>>> A = AlternatingGroup(7)
>>> base = [2, 3]
>>> seq = [2, 3]
>>> base, strong_gens = A.schreier_sims_incremental(base=seq)
>>> _verify_bsgs(A, base, strong_gens)
True
>>> base[:2]
[2, 3]
```

**Notes**

This version of the Schreier-Sims algorithm runs in polynomial time. There are certain assumptions in the implementation - if the trivial group is provided, \( \text{base} \) and \( \text{gens} \) are returned immediately, as any sequence of points is a base for the trivial group. If the identity is present in the generators \( \text{gens} \), it is removed as it is a redundant generator. The implementation is described in [1], pp. 90-93.

**See also:**

- \textit{schreier_sims} (page 380), \textit{schreier_sims_random} (page 381)
- \textit{schreier_sims_random}(base=None, gens=None, consec_succ=10, _random_prec=None)

Randomized Schreier-Sims algorithm.

**Parameters**

- \textit{base}
  
The sequence to be extended to a base.

- \textit{gens}
  
The generating set to be extended to a strong generating set.

- \textit{consec_succ}
  
The parameter defining the probability of a wrong answer.

- \textit{_random_prec}
  
An internal parameter used for testing purposes.
Returns
(base, strong gens)

base is the base and strong gens is the strong generating set relative to it.

Explanation

The randomized Schreier-Sims algorithm takes the sequence base and the generating set gens, and extends base to a base and gens to a strong generating set relative to that base with probability of a wrong answer at most \(2^{-\text{consec succ}}\), provided the random generators are sufficiently random.

Examples

```python
>>> from sympy.combinatorics.testutil import _verify_bsgs
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> S = SymmetricGroup(5)
>>> base, strong gens = S.schreier_sims_random(consec_succ=5)
>>> _verify_bsgs(S, base, strong gens)
True
```

Notes

The algorithm is described in detail in [1], pp. 97-98. It extends the orbits orbs and the permutation groups stabs to basic orbits and basic stabilizers for the base and strong generating set produced in the end. The idea of the extension process is to “sift” random group elements through the stabilizer chain and amend the stabilizers/orbits along the way when a sift is not successful. The helper function _strip is used to attempt to decompose a random group element according to the current state of the stabilizer chain and report whether the element was fully decomposed (successful sift) or not (unsuccessful sift). In the latter case, the level at which the sift failed is reported and used to amend stabs, base, gens and orbs accordingly. The halting condition is for consec succ consecutive successful sifts to pass. This makes sure that the current base and gens form a BSGS with probability at least \(1 - 1/\text{consec succ}\).

See also:

schreier_sims (page 380)

schreier_vector(alpha)

Computes the schreier vector for alpha.
Explanation

The Schreier vector efficiently stores information about the orbit of alpha. It can later be used to quickly obtain elements of the group that send alpha to a particular element in the orbit. Notice that the Schreier vector depends on the order in which the group generators are listed. For a definition, see [3]. Since list indices start from zero, we adopt the convention to use “None” instead of 0 to signify that an element does not belong to the orbit. For the algorithm and its correctness, see [2], pp. 78-80.

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation([2, 4, 6, 3, 1, 5, 0])
>>> b = Permutation([0, 1, 3, 5, 4, 6, 2])
>>> G = PermutationGroup([a, b])
>>> G.schreier_vector(0)
[-1, None, 0, 1, None, 1, 0]
```

See also:

- `orbit (page 376)`
- `stabilizer(alpha)`

Return the stabilizer subgroup of alpha.

Explanation

The stabilizer of alpha is the group $G_\alpha = \{g \in G | g(\alpha) = \alpha\}$. For a proof of correctness, see [1], p. 79.

Examples

```python
>>> from sympy.combinatorics.named_groups import DihedralGroup
>>> G = DihedralGroup(6)
>>> G.stabilizer(5)
PermutationGroup([PermutationGroupElement((5)(0 4)(1 3))])
```

See also:

- `orbit (page 376)`

- `property strong_gens`

Return a strong generating set from the Schreier-Sims algorithm.
**Explanation**

A generating set $S = \{g_1, g_2, \ldots, g_t\}$ for a permutation group $G$ is a strong generating set relative to the sequence of points (referred to as a “base”) $(b_1, b_2, \ldots, b_k)$ if, for $1 \leq i \leq k$ we have that the intersection of the pointwise stabilizer $G^{(i+1)} := G_{b_1, b_2, \ldots, b_i}$ with $S$ generates the pointwise stabilizer $G^{(i+1)}$. The concepts of a base and strong generating set and their applications are discussed in depth in [1], pp. 87-89 and [2], pp. 55-57.

**Examples**

```
>>> from sympy.combinatorics.named_groups import DihedralGroup
>>> D = DihedralGroup(4)
>>> D.strong_gens
[(0 1 2 3), (0 3)(1 2), (1 3)]
>>> D.base
[0, 1]
```

See also:

base (page 350), basic_transversals (page 353), basic_orbits (page 352), basic_stabilizers (page 352)

**strong_presentation()**

Return a strong finite presentation of group. The generators of the returned group are in the same order as the strong generators of group.

The algorithm is based on Sims’ Verify algorithm described in [1], Chapter 6.

**Examples**

```
>>> from sympy.combinatorics.named_groups import DihedralGroup
>>> P = DihedralGroup(4)
>>> G = P.strong_presentation()
>>> P.order() == G.order()
True
```

See also:

presentation (page 379), _verify (page 348)

**subgroup(gens)**

Return the subgroup generated by $gens$ which is a list of elements of the group

```
>>> subgroup_search(prop, base=None, strong_gens=None, tests=None,
init_subgroup=None)
```

Find the subgroup of all elements satisfying the property $prop$.

**Parameters**

- **prop**
  
The property to be used. Has to be callable on group elements and always return True or False. It is assumed that all group elements satisfying $prop$ indeed form a subgroup.
base
A base for the supergroup.

strong_gens
A strong generating set for the supergroup.

tests
A list of callables of length equal to the length of base. These are used to rule out group elements by partial base images, so that tests[l](g) returns False if the element g is known not to satisfy prop on where g sends the first l + 1 base points.

init_subgroup
if a subgroup of the sought group is known in advance, it can be passed to the function as this parameter.

Returns
res
The subgroup of all elements satisfying prop. The generating set for this group is guaranteed to be a strong generating set relative to the base base.

Explanation
This is done by a depth-first search with respect to base images that uses several tests to prune the search tree.

Examples

```
>>> from sympy.combinatorics.named_groups import (SymmetricGroup, ...
... AlternatingGroup)
>>> from sympy.combinatorics.testutil import _verify_bsgs
>>> S = SymmetricGroup(7)
>>> prop_even = lambda x: x.is_even
>>> base, strong gens = S.schreier_sims_incremental()
>>> G = S.subgroup_search(prop_even, base=base, strong_gens=strong_ ...
... gens)
>>> G.is_subgroup(AlternatingGroup(7))
True
>>> _verify_bsgs(G, base, G.generators)
True
```
Notes

This function is extremely lengthy and complicated and will require some careful attention. The implementation is described in [1], pp. 114-117, and the comments for the code here follow the lines of the pseudocode in the book for clarity.

The complexity is exponential in general, since the search process by itself visits all members of the supergroup. However, there are a lot of tests which are used to prune the search tree, and users can define their own tests via the tests parameter, so in practice, and for some computations, it’s not terrible.

A crucial part in the procedure is the frequent base change performed (this is line 11 in the pseudocode) in order to obtain a new basic stabilizer. The book mentions that this can be done by using .baseswap(...), however the current implementation uses a more straightforward way to find the next basic stabilizer - calling the function .stabilizer(...) on the previous basic stabilizer.

**sylow_subgroup(p)**

Return a p-Sylow subgroup of the group.

The algorithm is described in [1], Chapter 4, Section 7

**Examples**

```python
>>> from sympy.combinatorics.named_groups import DihedralGroup
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> from sympy.combinatorics.named_groups import AlternatingGroup

>>> D = DihedralGroup(6)
>>> S = D.sylow_subgroup(2)
>>> S.order()
4
>>> G = SymmetricGroup(6)
>>> S = G.sylow_subgroup(5)
>>> S.order()
5

>>> G1 = AlternatingGroup(3)
>>> G2 = AlternatingGroup(5)
>>> G3 = AlternatingGroup(9)

>>> S1 = G1.sylow_subgroup(3)
>>> S2 = G2.sylow_subgroup(3)
>>> S3 = G3.sylow_subgroup(3)

>>> len1 = len(S1.lower_central_series())
>>> len2 = len(S2.lower_central_series())
>>> len3 = len(S3.lower_central_series())

>>> len1 == len2
True
>>> len1 < len3
True
```
property transitivity_degree
  Compute the degree of transitivity of the group.

Explanation

A permutation group \( G \) acting on \( \Omega = \{0, 1, \ldots, n - 1\} \) is \( k \)-fold transitive, if, for any \( k \) points \((a_1, a_2, \ldots, a_k) \in \Omega \) and any \( k \) points \((b_1, b_2, \ldots, b_k) \in \Omega \) there exists \( g \in G \) such that \( g(a_1) = b_1, g(a_2) = b_2, \ldots, g(a_k) = b_k \). The degree of transitivity of \( G \) is the maximum \( k \) such that \( G \) is \( k \)-fold transitive. ([8])

Examples

```python
>>> from sympy.combinatorics import Permutation, PermutationGroup
>>> a = Permutation([1, 2, 0])
>>> b = Permutation([1, 0, 2])
>>> G = PermutationGroup([a, b])
>>> G.transitivity_degree
3
```

See also:

`is_transitive` (page 372), `orbit` (page 376)

Polyhedron

class sympy.combinatorics.polyhedron.Polyhedron(corners, faces=(), pgroup=())

Represents the polyhedral symmetry group (PSG).

Explanation

The PSG is one of the symmetry groups of the Platonic solids. There are three polyhedral groups: the tetrahedral group of order 12, the octahedral group of order 24, and the icosahedral group of order 60.

All doctests have been given in the docstring of the constructor of the object.

References

[R86]

property array_form
  Return the indices of the corners.

  The indices are given relative to the original position of corners.
Examples

```python
>>> from sympy.combinatorics.polyhedron import tetrahedron
>>> tetrahedron = tetrahedron.copy()
>>> tetrahedron.array_form
[0, 1, 2, 3]
```

```python
>>> tetrahedron.rotate(0)
>>> tetrahedron.array_form
[0, 2, 3, 1]
>>> tetrahedron.pgroup[0].array_form
[0, 2, 3, 1]
```

See also:

- `corners` (page 388), `cyclic_form` (page 388)

property corners

Get the corners of the Polyhedron. The method `vertices` is an alias for `corners`.

Examples

```python
>>> from sympy.combinatorics import Polyhedron
>>> from sympy.abc import a, b, c, d
>>> p = Polyhedron(list('abcd'))
>>> p.corners == p.vertices == (a, b, c, d)
True
```

See also:

- `array_form` (page 387), `cyclic_form` (page 388)

property cyclic_form

Return the indices of the corners in cyclic notation. The indices are given relative to the original position of corners.

See also:

- `corners` (page 388), `array_form` (page 387)

property edges

Given the faces of the polyhedra we can get the edges.
Examples

```python
>>> from sympy.combinatorics import Polyhedron
>>> from sympy.abc import a, b, c
>>> corners = (a, b, c)
>>> faces = [[0, 1, 2]]
>>> Polyhedron(corners, faces).edges
{(0, 1), (0, 2), (1, 2)}
```

**property faces**
Get the faces of the Polyhedron.

**property pgroup**
Get the permutations of the Polyhedron.

**reset()**
Return corners to their original positions.

Examples

```python
>>> from sympy.combinatorics.polyhedron import tetrahedron as T
>>> T = T.copy()
>>> T.corners
(0, 1, 2, 3)
>>> T.rotate(0)
>>> T.corners
(0, 2, 3, 1)
>>> T.reset()
>>> T.corners
(0, 1, 2, 3)
```

**rotate(perm)**
Apply a permutation to the polyhedron in place. The permutation may be given as a Permutation instance or an integer indicating which permutation from pgroup of the Polyhedron should be applied.

This is an operation that is analogous to rotation about an axis by a fixed increment.

**Notes**

When a Permutation is applied, no check is done to see if that is a valid permutation for the Polyhedron. For example, a cube could be given a permutation which effectively swaps only 2 vertices. A valid permutation (that rotates the object in a physical way) will be obtained if one only uses permutations from the pgroup of the Polyhedron. On the other hand, allowing arbitrary rotations (applications of permutations) gives a way to follow named elements rather than indices since Polyhedron allows vertices to be named while Permutation works only with indices.
Examples

```python
>>> from sympy.combinatorics import Polyhedron, Permutation
>>> from sympy.combinatorics.polyhedron import cube
>>> cube = cube.copy()
>>> cube.corners
(0, 1, 2, 3, 4, 5, 6, 7)
>>> cube.rotate(0)
>>> cube.corners
(1, 2, 3, 0, 5, 6, 7, 4)
```

A non-physical “rotation” that is not prohibited by this method:

```python
>>> cube.reset()
>>> cube.rotate(Permutation([[1, 2], size=8]))
>>> cube.corners
(0, 2, 1, 3, 4, 5, 6, 7)
```

Polyhedron can be used to follow elements of set that are identified by letters instead of integers:

```python
>>> shadow = h5 = Polyhedron(list('abcde'))
>>> p = Permutation([3, 0, 1, 2, 4])
>>> h5.rotate(p)
>>> h5.corners
(d, a, b, c, e)
>>> _ == shadow.corners
True
>>> copy = h5.copy()
>>> h5.rotate(p)
>>> h5.corners == copy.corners
False
```

**property size**
Get the number of corners of the Polyhedron.

**property vertices**
Get the corners of the Polyhedron.

The method vertices is an alias for corners.

Examples

```python
>>> from sympy.combinatorics import Polyhedron
>>> from sympy.abc import a, b, c, d
>>> p = Polyhedron(list('abcd'))
>>> p.corners == p.vertices == (a, b, c, d)
True
```

See also:

*array_form* (page 387), *cyclic_form* (page 388)
Prufer Sequences

class sympy.combinatorics.prufer.Prufer(*args, **kw_args)

The Prufer correspondence is an algorithm that describes the bijection between labeled
trees and the Prufer code. A Prufer code of a labeled tree is unique up to isomorphism
and has a length of \( n - 2 \).

Prufer sequences were first used by Heinz Prufer to give a proof of Cayley’s formula.

References

[R87]

static edges(*runs)

Return a list of edges and the number of nodes from the given runs that connect
nodes in an integer-labelled tree.

All node numbers will be shifted so that the minimum node is 0. It is not a problem
if edges are repeated in the runs; only unique edges are returned. There is no
assumption made about what the range of the node labels should be, but all nodes
from the smallest through the largest must be present.

Examples

```python
>>> from sympy.combinatorics.prufer import Prufer
>>> Prufer.edges(([1, 2, 3], [2, 4, 5])) # a T
([[0, 1], [1, 2], [1, 3], [3, 4]], 5)
```

Duplicate edges are removed:

```python
>>> Prufer.edges(([0, 1, 2, 3], [1, 4, 5], [1, 4, 6])) # a K
([[0, 1], [1, 2], [1, 4], [2, 3], [4, 5], [4, 6]], 7)
```

next(delta=1)

Generates the Prufer sequence that is delta beyond the current one.

Examples

```python
>>> from sympy.combinatorics.prufer import Prufer
>>> a = Prufer([[0, 1], [0, 2], [0, 3]])
>>> b = a.next(1) # == a.next()
>>> b.tree_repr
[[0, 2], [0, 1], [1, 3]]
>>> b.rank
1
```

See also:

* prufer_rank (page 392), rank (page 393), prev (page 392), size (page 393)

property nodes

Returns the number of nodes in the tree.
Examples

```python
>>> from sympy.combinatorics.prufer import Pruf
>>> Pruf([[0, 3], [1, 3], [2, 3], [3, 4], [4, 5]]).nodes
6
>>> Pruf([1, 0, 0]).nodes
5
```

**prev**(delta=1)
Generates the Pruf sequence that is -delta before the current one.

Examples

```python
>>> from sympy.combinatorics.prufer import Pruf
>>> a = Pruf([[0, 1], [1, 2], [2, 3], [1, 4]])
>>> a.rank
36
>>> b = a.prev()
>>> b
Pruf([1, 2, 0])
>>> b.rank
35
```

See also:

- prufer_rank (page 392), rank (page 393), next (page 391), size (page 393)
- pruf_rank()
Computes the rank of a Pruf sequence.

Examples

```python
>>> from sympy.combinatorics.prufer import Pruf
>>> a = Pruf([[0, 1], [0, 2], [0, 3]])
>>> a.prufer_rank()
0
```

See also:

- rank (page 393), next (page 391), prev (page 392), size (page 393)
- property prufer_repr
Returns Pruf sequence for the Pruf object.

This sequence is found by removing the highest numbered vertex, recording the node it was attached to, and continuing until only two vertices remain. The Pruf sequence is the list of recorded nodes.
Examples

```python
>>> from sympy.combinatorics.prufer import Prufer
>>> Prufer([[0, 3], [1, 3], [2, 3], [3, 4], [4, 5]]).prufer_repr
[3, 3, 3, 4]
>>> Prufer([1, 0, 0]).prufer_repr
[1, 0, 0]
```

See also:
- `to_prufer` (page 393)

property rank

Returns the rank of the Prüfer sequence.

Examples

```python
>>> from sympy.combinatorics.prufer import Prufer
>>> p = Prufer([[0, 3], [1, 3], [2, 3], [3, 4], [4, 5]])
>>> p.rank
778
>>> p.next(1).rank
779
>>> p.prev().rank
777
```

See also:
- `prufer_rank` (page 392), `next` (page 391), `prev` (page 392), `size` (page 393)

property size

Return the number of possible trees of this Prüfer object.

Examples

```python
>>> from sympy.combinatorics.prufer import Prufer
>>> Prufer([0]*4).size == Prufer([6]*4).size == 1296
True
```

See also:
- `prufer_rank` (page 392), `rank` (page 393), `next` (page 391), `prev` (page 392)

static to_prufer(tree, n)

Return the Prüfer sequence for a tree given as a list of edges where n is the number of nodes in the tree.
Examples

>>> from sympy.combinatorics.prufer import Prufer
>>> a = Prufer([[0, 1], [0, 2], [0, 3]])
>>> a.prufer_repr
[0, 0]
>>> Prufer.to_prufer([[0, 1], [0, 2], [0, 3]], 4)
[0, 0]

See also:

`prufer_repr` (page 392)
returns Prufer sequence of a Prufer object.

static `to_tree(prufer)`
Return the tree (as a list of edges) of the given Prufer sequence.

Examples

>>> from sympy.combinatorics.prufer import Prufer
>>> a = Prufer([0, 2], 4)
>>> a.tree_repr
[[0, 1], [0, 2], [2, 3]]
>>> Prufer.to_tree([0, 2])
[[0, 1], [0, 2], [2, 3]]

See also:

`tree_repr` (page 394)
returns tree representation of a Prufer object.

References

[R88]

property `tree_repr`
Returns the tree representation of the Prufer object.

Examples

>>> from sympy.combinatorics.prufer import Prufer
>>> Prufer([[0, 3], [1, 3], [2, 3], [3, 4], [4, 5]]).tree_repr
[[0, 3], [1, 3], [2, 3], [3, 4], [4, 5]]
>>> Prufer([1, 0, 0]).tree_repr
[[1, 2], [0, 1], [0, 3], [0, 4]]

See also:

`to_tree` (page 394)
**classmethod unrank**(*rank*, *n*)

Finds the unranked Prufer sequence.

**Examples**

```python
>>> from sympy.combinatorics.prufer import Prufer
>>> Prufer.unrank(0, 4)
Prufer([0, 0])
```

**Subsets**

**class** sympy.combinatorics.subsets.Subset(*subset, superset*)

Represents a basic subset object.

**Explanation**

We generate subsets using essentially two techniques, binary enumeration and lexicographic enumeration. The Subset class takes two arguments, the first one describes the initial subset to consider and the second describes the superset.

**Examples**

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset(['c', 'd'], ['a', 'b', 'c', 'd'])
>>> a.next_binary().subset
['b']
>>> a.prev_binary().subset
['c']
```

**classmethod bitlist_from_subset**(*subset, superset*)

Gets the bitlist corresponding to a subset.

**Examples**

```python
>>> from sympy.combinatorics import Subset
>>> Subset.bitlist_from_subset(['c', 'd'], ['a', 'b', 'c', 'd'])
'0011'
```

**See also:**

*subset_from_bitlist* (page 400)

**property cardinality**

Returns the number of all possible subsets.
Examples

```python
from sympy.combinatorics import Subset

a = Subset(["c", "d"], ["a", "b", "c", "d"])
a.cardinality

16
```

See also:
- `subset` (page 400), `superset` (page 401), `size` (page 399), `superset_size` (page 401)

`iterate_binary(k)`
This is a helper function. It iterates over the binary subsets by k steps. This variable can be both positive or negative.

Examples

```python
from sympy.combinatorics import Subset

a = Subset(["c", "d"], ["a", "b", "c", "d"])
a.iterate_binary(-2).subset
['d']
a = Subset(["a", "b", "c"], ["a", "b", "c", "d"])
a.iterate_binary(2).subset
[]
```

See also:
- `next_binary` (page 396), `prev_binary` (page 397)

`iterate_graycode(k)`
Helper function used for `prev_gray` and `next_gray`. It performs k step overs to get the respective Gray codes.

Examples

```python
from sympy.combinatorics import Subset

a = Subset([1, 2, 3], [1, 2, 3, 4])
a.iterate_graycode(3).subset
[1, 4]
a.iterate_graycode(-2).subset
[1, 2, 4]
```

See also:
- `next_gray` (page 397), `prev_gray` (page 398)

`next_binary()`
Generates the next binary ordered subset.
Examples

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset(['c', 'd'], ['a', 'b', 'c', 'd'])
>>> a.next_binary().subset
['b']
>>> a = Subset(['a', 'b', 'c', 'd'], ['a', 'b', 'c', 'd'])
>>> a.next_binary().subset
[]
```

See also:

prev_binary (page 397), iterate_binary (page 396)

next_gray()
Generates the next Gray code ordered subset.

Examples

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset([1, 2, 3], [1, 2, 3, 4])
>>> a.next_gray().subset
[1, 3]
```

See also:

iterate_graycode (page 396), prev_gray (page 398)

next_lexicographic()
Generates the next lexicographically ordered subset.

Examples

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset(['c', 'd'], ['a', 'b', 'c', 'd'])
>>> a.next_lexicographic().subset
['d']
>>> a = Subset(['d'], ['a', 'b', 'c', 'd'])
>>> a.next_lexicographic().subset
[]
```

See also:

prev_lexicographic (page 398)

prev_binary()
Generates the previous binary ordered subset.
Examples

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset([], ['a', 'b', 'c', 'd'])
>>> a.prev_binary().subset
['a', 'b', 'c', 'd']
>>> a = Subset(['c', 'd'], ['a', 'b', 'c', 'd'])
>>> a.prev_binary().subset
['c']
```

See also:

`next_binary` (page 396), `iterate_binary` (page 396)

prev_gray()
Generates the previous Gray code ordered subset.

Examples

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset([2, 3, 4], [1, 2, 3, 4, 5])
>>> a.prev_gray().subset
[2, 3, 4, 5]
```

See also:

`iterate_graycode` (page 396), `next_gray` (page 397)

prev_lexicographic()
Generates the previous lexicographically ordered subset.

Examples

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset([], ['a', 'b', 'c', 'd'])
>>> a.prev_lexicographic().subset
['d']
>>> a = Subset(['c','d'], ['a', 'b', 'c', 'd'])
>>> a.prev_lexicographic().subset
['c']
```

See also:

`next_lexicographic` (page 397)

property rank_binary
Computes the binary ordered rank.
Examples

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset([], ['a', 'b', 'c', 'd'])
>>> a.rank_binary
0
>>> a = Subset(['c', 'd'], ['a', 'b', 'c', 'd'])
>>> a.rank_binary
3
```

See also:
* `iterate_binary` (page 396), `unrank_binary` (page 401)

**property rank_gray**
Computes the Gray code ranking of the subset.

Examples

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset(['c', 'd'], ['a', 'b', 'c', 'd'])
>>> a.rank_gray
2
>>> a = Subset([2, 4, 5], [1, 2, 3, 4, 5, 6])
>>> a.rank_gray
27
```

See also:
* `iterate_graycode` (page 396), `unrank_gray` (page 402)

**property rank_lexicographic**
Computes the lexicographic ranking of the subset.

Examples

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset(['c', 'd'], ['a', 'b', 'c', 'd'])
>>> a.rank_lexicographic
14
>>> a = Subset([2, 4, 5], [1, 2, 3, 4, 5, 6])
>>> a.rank_lexicographic
43
```

**property size**
Gets the size of the subset.
Examples

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset(['c', 'd'], ['a', 'b', 'c', 'd'])
>>> a.size
2
```

See also:

- `subset` (page 400), `superset` (page 401), `superset_size` (page 401), `cardinality` (page 395)

**property subset**

Gets the subset represented by the current instance.

Examples

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset(['c', 'd'], ['a', 'b', 'c', 'd'])
>>> a.subset
['c', 'd']
```

See also:

- `superset` (page 401), `size` (page 399), `superset_size` (page 401), `cardinality` (page 395)

**classmethod subset_from_bitlist**(*super_set*, *bitlist*)

Gets the subset defined by the bitlist.

Examples

```python
>>> from sympy.combinatorics import Subset
>>> Subset.subset_from_bitlist(['a', 'b', 'c', 'd'], '0011').subset
['c', 'd']
```

See also:

- `bitlist_from_subset` (page 395)

**classmethod subset_indices**(*subset*, *superset*)

Return indices of subset in superset in a list; the list is empty if all elements of subset are not in superset.
Examples

```python
>>> from sympy.combinatorics import Subset
>>> superset = [1, 3, 2, 5, 4]
>>> Subset.subset_indices([3, 2, 1], superset)
[1, 2, 0]
>>> Subset.subset_indices([1, 6], superset)
[]
>>> Subset.subset_indices([], superset)
[]
```

**property superset**

 Gets the superset of the subset.

**Examples**

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset(['c', 'd'], ['a', 'b', 'c', 'd'])
>>> a.superset
['a', 'b', 'c', 'd']
```

See also:

subset (page 400), size (page 399), superset_size (page 401), cardinality (page 395)

**property superset_size**

 Returns the size of the superset.

**Examples**

```python
>>> from sympy.combinatorics import Subset
>>> a = Subset(['c', 'd'], ['a', 'b', 'c', 'd'])
>>> a.superset_size
4
```

See also:

subset (page 400), superset (page 401), size (page 399), cardinality (page 395)

**classmethod unrank_binary(rank, superset)**

 Gets the binary ordered subset of the specified rank.
Examples

```python
>>> from sympy.combinatorics import Subset
>>> Subset.unrank_binary(4, ['a', 'b', 'c', 'd']).subset
['b']
```

See also:

iterate_binary (page 396), rank_binary (page 398)

classmethod unrank_gray(rank, superset)

Gets the Gray code ordered subset of the specified rank.

Examples

```python
>>> from sympy.combinatorics import Subset
>>> Subset.unrank_gray(4, ['a', 'b', 'c']).subset
['a', 'b']
>>> Subset.unrank_gray(0, ['a', 'b', 'c']).subset
[]
```

See also:

iterate_graycode (page 396), rank_gray (page 399)

subsets.ksubsets(k)

Finds the subsets of size k in lexicographic order.

This uses the itertools generator.

Examples

```python
>>> from sympy.combinatorics.subsets import ksubsets
>>> list(ksubsets([1, 2, 3], 2))
[(1, 2), (1, 3), (2, 3)]
>>> list(ksubsets([1, 2, 3, 4, 5], 2))
[(1, 2), (1, 3), (1, 4), (1, 5), (2, 3), (2, 4), (2, 5), (3, 4), (3, 5), (4, 5)]
```

See also:

Subset (page 395)
Gray Code

class sympy.combinatorics.graycode.GrayCode(n, *args, **kw_args)

A Gray code is essentially a Hamiltonian walk on a n-dimensional cube with edge length of one. The vertices of the cube are represented by vectors whose values are binary. The Hamilton walk visits each vertex exactly once. The Gray code for a 3d cube is ['000', '100', '110', '010', '011', '111', '101', '001'].

A Gray code solves the problem of sequentially generating all possible subsets of n objects in such a way that each subset is obtained from the previous one by either deleting or adding a single object. In the above example, 1 indicates that the object is present, and 0 indicates that its absent.

Gray codes have applications in statistics as well when we want to compute various statistics related to subsets in an efficient manner.

Examples

```python
>>> from sympy.combinatorics import GrayCode
>>> a = GrayCode(3)
>>> list(a.generate_gray())
['000', '001', '011', '010', '110', '111', '101', '100']
>>> a = GrayCode(4)
>>> list(a.generate_gray())
['0000', '0001', '0011', '0010', '0110', '0111', '0101', '0100',
 '1100', '1101', '1111', '1110', '1010', '1011', '1001', '1000']
```

References

[R44], [R45]

property current

Returns the currently referenced Gray code as a bit string.

Examples

```python
>>> from sympy.combinatorics import GrayCode
>>> GrayCode(3, start='100').current
'100'
```

generate_gray(**hints)

Generates the sequence of bit vectors of a Gray Code.
Examples

```python
>>> from sympy.combinatorics import GrayCode
>>> a = GrayCode(3)
>>> list(a.generate_gray())
['000', '001', '011', '010', '110', '111', '101', '100']
>>> list(a.generate_gray(start='011'))
['011', '010', '110', '111', '101', '100']
>>> list(a.generate_gray(rank=4))
['110', '111', '101', '100']
```

See also:

`skip` (page 405)

References

[R46]

property n

Returns the dimension of the Gray code.

Examples

```python
>>> from sympy.combinatorics import GrayCode
>>> a = GrayCode(5)
>>> a.n
5
```

next(delta=1)

Returns the Gray code a distance delta (default = 1) from the current value in canonical order.

Examples

```python
>>> from sympy.combinatorics import GrayCode
>>> a = GrayCode(3, start='110')
>>> a.next().current
'111'
>>> a.next(-1).current
'010'
```

property rank

Ranks the Gray code.

A ranking algorithm determines the position (or rank) of a combinatorial object among all the objects w.r.t. a given order. For example, the 4 bit binary reflected Gray code (BRGC) '0101' has a rank of 6 as it appears in the 6th position in the canonical ordering of the family of 4 bit Gray codes.
Examples

```python
>>> from sympy.combinatorics import GrayCode
>>> a = GrayCode(3)
>>> list(a.generate_gray())
['000', '001', '011', '010', '110', '111', '101', '100']
>>> GrayCode(3, start='100').rank
7
>>> GrayCode(3, rank=7).current
'100'
```

See also:

`unrank` (page 406)

References

[R47]

property selections

Returns the number of bit vectors in the Gray code.

Examples

```python
>>> from sympy.combinatorics import GrayCode
>>> a = GrayCode(3)
>>> a.selections
8
```

skip()

Skips the bit generation.

Examples

```python
>>> from sympy.combinatorics import GrayCode
>>> a = GrayCode(3)
>>> for i in a.generate_gray():
...    if i == '010':
...        a.skip()
...        print(i)
...        000
    001
    011
    111
    101
    100
```
See also:

`generate_gray` (page 403)

**classmethod unrank**(\(n, rank\))

Unranks an \(n\)-bit sized Gray code of rank \(k\). This method exists so that a derivative GrayCode class can define its own code of a given rank.

The string here is generated in reverse order to allow for tail-call optimization.

**Examples**

```python
>>> from sympy.combinatorics import GrayCode
>>> GrayCode(5, rank=3).current
'00010'
>>> GrayCode.unrank(5, 3)
'00010'
```

See also:

`rank` (page 404)

graycode.random_bitstring()

Generates a random bitlist of length \(n\).

**Examples**

```python
>>> from sympy.combinatorics.graycode import random_bitstring
>>> random_bitstring(3)
100
```

graycode.gray_to_bin()

Convert from Gray coding to binary coding.

We assume big endian encoding.

**Examples**

```python
>>> from sympy.combinatorics.graycode import gray_to_bin
>>> gray_to_bin('100')
'111'
```

See also:

`bin_to_gray` (page 406)

graycode.bin_to_gray()

Convert from binary coding to gray coding.

We assume big endian encoding.
Examples

```python
>>> from sympy.combinatorics.graycode import bin_to_gray
>>> bin_to_gray('111')
'100'
```

See also:

- `gray_to_bin` (page 406)
- `graycode.get_subset_from_bitstring(bitstring)`
  Gets the subset defined by the bitstring.

Examples

```python
>>> from sympy.combinatorics.graycode import get_subset_from_bitstring
>>> get_subset_from_bitstring(['a', 'b', 'c', 'd'], '0011')
['c', 'd']
>>> get_subset_from_bitstring(['c', 'a', 'c', 'c'], '1100')
['c', 'a']
```

See also:

- `graycode_subsets` (page 407)
- `graycode.graycode_subsets()`
  Generates the subsets as enumerated by a Gray code.

Examples

```python
>>> from sympy.combinatorics.graycode import graycode_subsets
>>> list(graycode_subsets(['a', 'b', 'c']))
[]
['c'],
['b', 'c'],
['b'],
['a', 'b'],
['a', 'b', 'c'],
['a', 'c'],
['a', 'b', 'c'],
['a'],
```

See also:

- `get_subset_from_bitstring` (page 407)
Named Groups

sympy.combinatorics.named_groups.SymmetricGroup(n)

Generates the symmetric group on n elements as a permutation group.

Explanation

The generators taken are the n-cycle (0 1 2 ... n-1) and the transposition (0 1) (in cycle notation). (See [1]). After the group is generated, some of its basic properties are set.

Examples

```python
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> G = SymmetricGroup(4)
>>> G.is_group
True
>>> G.order()
24
>>> list(G.generate_schreier_sims(af=True))
[[0, 1, 2, 3], [1, 2, 3, 0], [2, 3, 0, 1], [3, 1, 2, 0], [0, 2, 3, 1],
 [1, 3, 0, 2], [2, 0, 1, 3], [3, 2, 0, 1], [0, 3, 1, 2], [1, 0, 2, 3],
 [2, 1, 3, 0], [3, 0, 1, 2], [0, 1, 3, 2], [1, 2, 0, 3], [2, 3, 1, 0],
 [3, 1, 0, 2], [0, 2, 1, 3], [1, 3, 2, 0], [2, 0, 3, 1], [3, 2, 1, 0],
 [0, 3, 2, 1], [1, 0, 3, 2], [2, 1, 0, 3], [3, 0, 2, 1]]
```

See also:
CyclicGroup (page 408), DihedralGroup (page 409), AlternatingGroup (page 410)

References

[R51]

sympy.combinatorics.named_groups.CyclicGroup(n)

Generates the cyclic group of order n as a permutation group.

Explanation

The generator taken is the n-cycle (0 1 2 ... n-1) (in cycle notation). After the group is generated, some of its basic properties are set.
Examples

```python
>>> from sympy.combinatorics.named_groups import CyclicGroup
>>> G = CyclicGroup(6)
>>> G.is_group
True
>>> G.order()
6
>>> list(G.generate_schreier_sims(af=True))
[[0, 1, 2, 3, 4, 5], [1, 2, 3, 4, 5, 0], [2, 3, 4, 5, 0, 1],
 [3, 4, 5, 0, 1, 2], [4, 5, 0, 1, 2, 3], [5, 0, 1, 2, 3, 4]]
```

See also:

SymmetricGroup (page 408), DihedralGroup (page 409), AlternatingGroup (page 410)

sympy.combinatorics.named_groups.DihedralGroup(n)
Generates the dihedral group $D_n$ as a permutation group.

Explanation

The dihedral group $D_n$ is the group of symmetries of the regular n-gon. The generators taken are the n-cycle $a = (0 \ 1 \ 2 \ldots \ n-1)$ (a rotation of the n-gon) and $b = (0 \ n-1)(1 \ n-2)\ldots$ (a reflection of the n-gon) in cycle rotation. It is easy to see that these satisfy $a^n = b^2 = 1$ and $bab = a^{-1}$ so they indeed generate $D_n$ (See [1]). After the group is generated, some of its basic properties are set.

Examples

```python
>>> from sympy.combinatorics.named_groups import DihedralGroup
>>> G = DihedralGroup(5)
>>> G.is_group
True
>>> a = list(G.generate_dimino())
>>> [perm.cyclic_form for perm in a]
[[], [[0, 1, 2, 3, 4]], [[0, 2, 4, 1, 3]],
 [[0, 3, 1, 4, 2]], [[0, 4, 3, 2, 1]], [[0, 4], [1, 3]],
 [[1, 4], [2, 3]], [[0, 1], [2, 4]], [[0, 2], [3, 4]],
 [[0, 3], [1, 2]]]
```

See also:

SymmetricGroup (page 408), CyclicGroup (page 408), AlternatingGroup (page 410)

5.8. Topics 409
**References**

[R52]

sympy.combinatorics.named_groups.AlternatingGroup($n$)

Generates the alternating group on $n$ elements as a permutation group.

**Explanation**

For $n > 2$, the generators taken are $(0 \ 1 \ 2)$, $(0 \ 1 \ 2 \ldots \ n-1)$ for $n$ odd and $(0 \ 1 \ 2)$, $(1 \ 2 \ldots \ n-1)$ for $n$ even (See [1], p.31, ex.6.9.). After the group is generated, some of its basic properties are set. The cases $n = 1$, $2$ are handled separately.

**Examples**

```python
>>> from sympy.combinatorics.named_groups import AlternatingGroup
>>> G = AlternatingGroup(4)
>>> G.is_group
True
>>> a = list(G.generate_dimino())
>>> len(a)
12
>>> all(perm.is_even for perm in a)
True
```

See also:

SymmetricGroup (page 408), CyclicGroup (page 408), DihedralGroup (page 409)

**References**

[R53]

sympy.combinatorics.named_groups.AbelianGroup(*cyclic_orders)

Returns the direct product of cyclic groups with the given orders.

**Explanation**

According to the structure theorem for finite abelian groups ([1]), every finite abelian group can be written as the direct product of finitely many cyclic groups.
Examples

```python
>>> from sympy.combinatorics.named_groups import AbelianGroup
>>> AbelianGroup(3, 4)
PermutationGroup([[(6)(0 1 2),
                   (3 4 5 6)]])
>>> _.is_group
True
```

See also:

DirectProduct (page 423)

Galois Groups

Construct transitive subgroups of symmetric groups, useful in Galois theory. Besides constructing instances of the `PermutationGroup` (page 343) class to represent the transitive subgroups of $S_n$ for small $n$, this module provides names for these groups.

In some applications, it may be preferable to know the name of a group, rather than receive an instance of the `PermutationGroup` (page 343) class, and then have to do extra work to determine which group it is, by checking various properties.

Names are instances of `Enum` classes defined in this module. With a name in hand, the name’s `get_perm_group` method can then be used to retrieve a `PermutationGroup` (page 343).

The names used for groups in this module are taken from [1].

References

```python
class sympy.combinatorics.galois.S6TransitiveSubgroups(value)
    Names for the transitive subgroups of S6.
class sympy.combinatorics.galois.S5TransitiveSubgroups(value)
    Names for the transitive subgroups of S5.
class sympy.combinatorics.galois.S4TransitiveSubgroups(value)

class sympy.combinatorics.galois.S1TransitiveSubgroups(value)
    Names for the transitive subgroups of S1.
```
SymPy Documentation, Release 1.12.1

sympy.combinatorics.galois.four_group()
Return a representation of the Klein four-group as a transitive subgroup of S4.

sympy.combinatorics.galois.M20()
Return a representation of the metacyclic group M20, a transitive subgroup of S5 that is one of the possible Galois groups for polys of degree 5.

Notes
See [1], Page 323.

sympy.combinatorics.galois.S3_in_S6()
Return a representation of S3 as a transitive subgroup of S6.

Notes
The representation is found by viewing the group as the symmetries of a triangular prism.

sympy.combinatorics.galois.A4_in_S6()
Return a representation of A4 as a transitive subgroup of S6.

Notes
This was computed using find_transitive_subgroups_of_S6() (page 414).

sympy.combinatorics.galois.S4m()
Return a representation of the S4- transitive subgroup of S6.

Notes
This was computed using find_transitive_subgroups_of_S6() (page 414).

sympy.combinatorics.galois.S4p()
Return a representation of the S4+ transitive subgroup of S6.

Notes
This was computed using find_transitive_subgroups_of_S6() (page 414).

sympy.combinatorics.galois.A4xC2()
Return a representation of the (A4 x C2) transitive subgroup of S6.
Notes

This was computed using \texttt{find_transitive_subgroups_of_S6()} (page 414).

\texttt{sympy.combinatorics.galois.S4xC2()}

Return a representation of the (S4 x C2) transitive subgroup of S6.

Notes

This was computed using \texttt{find_transitive_subgroups_of_S6()} (page 414).

\texttt{sympy.combinatorics.galois.G18()}

Return a representation of the group G18, a transitive subgroup of S6 isomorphic to the semidirect product of C3^2 with C2.

Notes

This was computed using \texttt{find_transitive_subgroups_of_S6()} (page 414).

\texttt{sympy.combinatorics.galois.G36m()}

Return a representation of the group G36-, a transitive subgroup of S6 isomorphic to the semidirect product of C3^2 with C2^2.

Notes

This was computed using \texttt{find_transitive_subgroups_of_S6()} (page 414).

\texttt{sympy.combinatorics.galois.G36p()}

Return a representation of the group G36+, a transitive subgroup of S6 isomorphic to the semidirect product of C3^2 with C4.

Notes

This was computed using \texttt{find_transitive_subgroups_of_S6()} (page 414).

\texttt{sympy.combinatorics.galois.G72()}

Return a representation of the group G72, a transitive subgroup of S6 isomorphic to the semidirect product of C3^2 with D4.

Notes

See [1], Page 325.

\texttt{sympy.combinatorics.galois.PSL2F5()}

Return a representation of the group \( \text{PSL}_2(\mathbb{F}_5) \), as a transitive subgroup of S6, isomorphic to \( A_5 \).
Notes

This was computed using `find_transitive_subgroups_of_S6()` (page 414).

```
sympy.combinatorics.galois.PGL2F5()
```

Return a representation of the group $PGL_2(F_5)$, as a transitive subgroup of $S_6$, isomorphic to $S_5$.

Notes

See [1], Page 325.

```
sympy.combinatorics.galois.find_transitive_subgroups_of_S6(*targets,
        print_report=False)
```

Search for certain transitive subgroups of $S_6$.

The symmetric group $S_6$ has 16 different transitive subgroups, up to conjugacy. Some are more easily constructed than others. For example, the dihedral group $D_6$ is immediately found, but it is not at all obvious how to realize $S_4$ or $S_5$ transitively within $S_6$.

In some cases there are well-known constructions that can be used. For example, $S_5$ is isomorphic to $PGL_2(F_5)$, which acts in a natural way on the projective line $P^1(F_5)$, a set of order 6.

In absence of such special constructions however, we can simply search for generators. For example, transitive instances of $A_4$ and $S_4$ can be found within $S_6$ in this way.

Once we are engaged in such searches, it may then be easier (if less elegant) to find even those groups like $S_5$ that do have special constructions, by mere search.

This function locates generators for transitive instances in $S_6$ of the following subgroups:

- $A_4$
- $S_4^-$ ($S_4$ not contained within $A_6$)
- $S_4^+$ ($S_4$ contained within $A_6$)
- $A_4 \times C_2$
- $S_4 \times C_2$
- $G_{18} = C_3^2 \ltimes C_2$
- $G_{36} = C_3^2 \ltimes C_2^2$
- $G_{72} = C_3^2 \times C_4$
- $G_{72} = C_2^2 \ltimes D_4$
- $A_5$
- $S_5$

Note: Each of these groups also has a dedicated function in this module that returns the group immediately, using generators that were found by this search procedure.

The search procedure serves as a record of how these generators were found. Also, due to randomness in the generation of the elements of permutation groups, it can be called again, in order to (probably) get different generators for the same groups.

**Parameters**

- **targets** : list of $S6TransitiveSubgroups$ (page 411) values
The groups you want to find.

**print_report** : bool (default False)

If True, print to stdout the generators found for each group.

**Returns**

dict

mapping each name in targets to the *PermutationGroup* (page 343)
that was found

**Nilpotent, Abelian and Cyclic Numbers**

*sympy.combinatorics.group_numbers.is_nilpotent_number(n)*

Check whether \( n \) is a nilpotent number. A number \( n \) is said to be nilpotent if and only if every finite group of order \( n \) is nilpotent. For more information see [R48].

**Examples**

```python
>>> from sympy.combinatorics.group_numbers import is_nilpotent_number
>>> from sympy import randprime
>>> is_nilpotent_number(21)
False
>>> is_nilpotent_number(randprime(1, 30)**12)
True
```

**References**

[R48]

*sympy.combinatorics.group_numbers.is_abelian_number(n)*

Check whether \( n \) is an abelian number. A number \( n \) is said to be abelian if and only if every finite group of order \( n \) is abelian. For more information see [R49].

**Examples**

```python
>>> from sympy.combinatorics.group_numbers import is_abelian_number
>>> from sympy import randprime
>>> is_abelian_number(4)
True
>>> is_abelian_number(randprime(1, 2000)**2)
True
>>> is_abelian_number(60)
False
```
References

[R49]

sympy.combinatorics.group_numbers.is_cyclic_number(n)
Check whether n is a cyclic number. A number n is said to be cyclic if and only if every finite group of order n is cyclic. For more information see [R50].

Examples

```python
>>> from sympy.combinatorics.group_numbers import is_cyclic_number
>>> from sympy import randprime
>>> is_cyclic_number(15)
True
>>> is_cyclic_number(randprime(1, 2000)**2)
False
>>> is_cyclic_number(4)
False
```

[R50]

Utilities

sympy.combinatorics.util._base_ordering(base, degree)
Order \{0, 1, \ldots, n - 1\} so that base points come first and in order.

Parameters

- base: the base
- degree: the degree of the associated permutation group

Returns

A list base_ordering such that base_ordering[point] is the number of point in the ordering.

Examples

```python
>>> from sympy.combinatorics import SymmetricGroup
>>> from sympy.combinatorics.util import _base_ordering
>>> S = SymmetricGroup(4)
>>> S.schreier_sims()
>>> _base_ordering(S.base, S.degree)
[0, 1, 2, 3]
```
Notes

This is used in backtrack searches, when we define a relation $\ll$ on the underlying set for a permutation group of degree $n$, $\{0, 1, \ldots, n-1\}$, so that if $(b_1, b_2, \ldots, b_k)$ is a base we have $b_i \ll b_j$ whenever $i < j$ and $b_i \ll a$ for all $i \in \{1, 2, \ldots, k\}$ and $a$ is not in the base. The idea is developed and applied to backtracking algorithms in [1], pp.108-132. The points that are not in the base are taken in increasing order.

References

[R89] sympy.combinatorics.util._check_cycles_alt_sym(perm)
 Checks for cycles of prime length $p$ with $n/2 < p < n-2$.

Explanation

Here $n$ is the degree of the permutation. This is a helper function for the function is_alt_sym from sympy.combinatorics.perm_groups.

Examples

```python
>>> from sympy.combinatorics.util import _check_cycles_alt_sym
>>> from sympy.combinatorics import Permutation
>>> a = Permutation([[0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10], [11, 12]])
>>> _check_cycles_alt_sym(a)
False
>>> b = Permutation([[0, 1, 2, 3, 4, 5, 6], [7, 8, 9, 10]])
>>> _check_cycles_alt_sym(b)
True
```

See also:
sympy.combinatorics.perm_groups.PermutationGroup.is_alt_sym (page 365)
sympy.combinatorics.util._distribute_gens_by_base(base, gens)
Distribute the group elements gens by membership in basic stabilizers.

Parameters

- base : a sequence of points in $\{0, 1, \ldots, n-1\}$
- gens : a list of elements of a permutation group of degree $n$.

Returns

List of length $k$, where $k$ is the length of base. The $i$-th entry contains those elements in gens which fix the first $i$ elements of base (so that the $0$-th entry is equal to gens itself). If no element fixes the first $i$ elements of base, the $i$-th element is set to a list containing the identity element.
Explanation

Notice that for a base \((b_1, b_2, \ldots, b_k)\), the basic stabilizers are defined as \(G^{(i)} = G_{b_1, \ldots, b_{i-1}}\) for \(i \in \{1, 2, \ldots, k\}\).

Examples

```python
>>> from sympy.combinatorics.named_groups import DihedralGroup
>>> from sympy.combinatorics.util import _distribute_gens_by_base
>>> D = DihedralGroup(3)
>>> D.schreier_sims()
>>> D.strong_gens
[[0 1 2), (0 2), (1 2)]
>>> D.base
[0, 1]
>>> _distribute_gens_by_base(D.base, D.strong_gens)
[[[0 1 2), (0 2), (1 2)],
 [(1 2)]]
```

See also:

- _strong_gens_from_distr (page 422), _orbits_transversals_from_bsgs (page 419), _handle_precomputed_bsgs (page 418)

```python
sympy.combinatorics.util._handle_precomputed_bsgs(base, strong_gens,
transversals=None, basic_orbits=None, strong_gens_distr=None)
```

Calculate BSGS-related structures from those present.

Parameters
``
`base` - the base
`strong_gens` - the strong generators
`transversals` - basic transversals
`basic_orbits` - basic orbits
`strong_gens_distr` - strong generators distributed by membership in basic stabilizers
``

Returns
``
(transversals, basic_orbits, strong_gens_distr) where transversals
are the basic transversals, basic_orbits are the basic orbits, and
strong_gens_distr are the strong generators distributed by membership in basic stabilizers.
``
Explanation

The base and strong generating set must be provided; if any of the transversals, basic orbits or distributed strong generators are not provided, they will be calculated from the base and strong generating set.

Examples

```python
>>> from sympy.combinatorics.named_groups import DihedralGroup
>>> from sympy.combinatorics.util import _handle_precomputed_bsgs
>>> D = DihedralGroup(3)
>>> D.schreier_sims()
>>> _handle_precomputed_bsgs(D.base, D.strong_gens,
... basic_orbits=D.basic_orbits)

([{0: (2), 1: (0 1 2), 2: (0 2)}, {1: (2), 2: (1 2)}], [[0, 1, 2], [1, 2]], [[(0 1 2), (0 2), (1 2)], [(1 2)]])
```

See also:

_orbits_transversals_from_bsgs (page 419), _distribute_gens_by_base (page 417)

Compute basic orbits and transversals from a base and strong generating set.

**Parameters**

\`\`base\`\` - The base.

\`\`strong_gens_distr\`\` - Strong generators distributed by membership in basic stabilizers.

\`\`transversals_only\`\` - bool

A flag switching between returning only the transversals and both orbits and transversals.

\`\`slp\`\` -

If True, return a list of dictionaries containing the generator presentations of the elements of the transversals, i.e. the list of indices of generators from strong_gens_distr[i] such that their product is the relevant transversal element.

Explanation

The generators are provided as distributed across the basic stabilizers. If the optional argument transversals_only is set to True, only the transversals are returned.
Examples

```python
def with_from(sympy.combinatorics)
    >>> from sympy.combinatorics import SymmetricGroup
    >>> from sympy.combinatorics.util import _distribute_gens_by_base
    >>> S = SymmetricGroup(3)
    >>> S.schreier_sims()
    >>> strong_gens_distr = _distribute_gens_by_base(S.base, S.strong_gens)
    >>> (S.base, strong_gens_distr)
    ([0, 1], [[(0 1 2), (2)(0 1), (1 2)], [(1 2)]])
```

See also:

- `_distribute_gens_by_base` (page 417), `_handle_precomputed_bsgs` (page 418)

```
sympy.combinatorics.util._remove_gens(base, strong_gens, basic_orbits=None, strong_gens_distr=None)
```

Remove redundant generators from a strong generating set.

**Parameters**
- `base` - a base
- `strong_gens` - a strong generating set relative to `base`
- `basic_orbits` - basic orbits
- `strong_gens_distr` - strong generators distributed by membership in basic stabilizers

**Returns**
A strong generating set with respect to base which is a subset of `strong_gens`.

Examples

```python
def with_from(sympy.combinatorics)
    >>> from sympy.combinatorics import SymmetricGroup
    >>> from sympy.combinatorics.util import _remove_gens
    >>> from sympy.combinatorics.testutil import _verify_bsgs
    >>> S = SymmetricGroup(15)
    >>> base, strong_gens = S.schreier_sims_incremental()
    >>> new_gens = _remove_gens(base, strong_gens)
    >>> len(new_gens)
    14
    >>> _verify_bsgs(S, base, new_gens)
    True
```
Notes

This procedure is outlined in [1], p.95.

References

[R90]

sympy.combinatorics.util._strip(g, base, orbits, transversals)

Attempt to decompose a permutation using a (possibly partial) BSGS structure.

Parameters
``g`` - permutation to be decomposed
``base`` - sequence of points
``orbits`` - a list in which the ``i``-th entry is an orbit of ``base[i]``
under some subgroup of the pointwise stabilizer of `
`base[0], base[1], ..., base[i - 1]``. The groups themselves are im-
plicit
in this function since the only information we need is encoded in the
orbits
and transversals
``transversals`` - a list of orbit transversals associated with the orbits
``orbits``.

Explanation

This is done by treating the sequence base as an actual base, and the orbits orbits and
transversals transversals as basic orbits and transversals relative to it.

This process is called “sifting”. A sift is unsuccessful when a certain orbit element is not
found or when after the sift the decomposition does not end with the identity element.

The argument transversals is a list of dictionaries that provides transversal elements
for the orbits orbits.

Examples

```python
>>> from sympy.combinatorics import Permutation, SymmetricGroup
>>> from sympy.combinatorics.util import _strip
>>> S = SymmetricGroup(5)
>>> S.schreier_sims()
>>> g = Permutation([0, 2, 3, 1, 4])
>>> _strip(g, S.base, S.basic_orbits, S.basic_transversals)
((4), 5)
```
Notes

The algorithm is described in [1], pp. 89-90. The reason for returning both the current state of the element being decomposed and the level at which the sifting ends is that they provide important information for the randomized version of the Schreier-Sims algorithm.

sympy.combinatorics.perm_groups.PermutationGroup.schreier_sims (page 380),
sympy.combinatorics.perm_groups.PermutationGroup.schreier_sims_random (page 381)

References

[R91]
sympy.combinatorics.util._strong_gens_from_distr(strong_gens_distr)
Retrieve strong generating set from generators of basic stabilizers.
This is just the union of the generators of the first and second basic stabilizers.

Parameters

\`
``strong_gens_distr`` - strong generators distributed by membership in basic stabilizers
``

Examples

```python
def _strong_gens_from_distr(strong_gens_distr):
    return [tuple(g) for g in strong_gens_distr]

S = SymmetricGroup(3)
S.schreier_sims()
S.strong_gens
# [(0 1 2), (2)(0 1), (1 2)]
strong_gens_distr = _distribute_gens_by_base(S.base, S.strong_gens)
strong_gens_distr
# [(0 1 2), (2)(0 1), (1 2)]

See also:

_distribute_gens_by_base (page 417)
```
Group constructors

\texttt{sympy.combinatorics.group_constructs.DirectProduct(*groups)}

Returns the direct product of several groups as a permutation group.

**Explanation**

This is implemented much like the \texttt{\_mul\_} procedure for taking the direct product of two permutation groups, but the idea of shifting the generators is realized in the case of an arbitrary number of groups. A call to \texttt{DirectProduct(G1, G2, ..., Gn)} is generally expected to be faster than a call to \texttt{G1*G2*...*Gn} (and thus the need for this algorithm).

**Examples**

```python
>>> from sympy.combinatorics.group_constructs import DirectProduct
>>> from sympy.combinatorics.named_groups import CyclicGroup
>>> C = CyclicGroup(4)
>>> G = DirectProduct(C, C, C)
>>> G.order()
64
```

**See also:**

\texttt{sympy.combinatorics.perm_groups.PermutationGroup.__mul__} (page 344)

**Test Utilities**

\texttt{sympy.combinatorics.testutil._cmp_perm_lists(first, second)}

Compare two lists of permutations as sets.

**Explanation**

This is used for testing purposes. Since the array form of a permutation is currently a list, Permutation is not hashable and cannot be put into a set.

**Examples**

```python
>>> from sympy.combinatorics.permutations import Permutation
>>> from sympy.combinatorics.testutil import _cmp_perm_lists
>>> a = Permutation([0, 2, 3, 4, 1])
>>> b = Permutation([1, 2, 0, 4, 3])
>>> c = Permutation([3, 4, 0, 1, 2])
>>> ls1 = [a, b, c]
>>> ls2 = [b, c, a]
>>> _cmp_perm_lists(ls1, ls2)
True
```
Explanation

This is a naive implementation using the definition of a base and a strong generating set relative to it. There are other procedures for verifying a base and strong generating set, but this one will serve for more robust testing.

Examples

```python
>>> from sympy.combinatorics.named_groups import AlternatingGroup
>>> from sympy.combinatorics.testutil import _verify_bsgs
>>> A = AlternatingGroup(4)
>>> A.schreier_sims()
>>> _verify_bsgs(A, A.base, A.strong_gens)
True
```

See also:

- `sympy.combinatorics.perm_groups.PermutationGroup.schreier_sims` (page 380)

```
sympy.combinatorics.testutil._verify_centralizer(group, arg, centr=None)
```

Verify the centralizer of a group/set/element inside another group. This is used for testing .centralizer() from sympy.combinatorics.perm_groups

Examples

```python
>>> from sympy.combinatorics.named_groups import (SymmetricGroup, ...
... AlternatingGroup)
>>> from sympy.combinatorics.perm_groups import PermutationGroup
>>> from sympy.combinatorics.permutations import Permutation
>>> from sympy.combinatorics.testutil import _verify_centralizer
>>> S = SymmetricGroup(5)
>>> A = AlternatingGroup(5)
>>> centr = PermutationGroup([Permutation([0, 1, 2, 3, 4])])
>>> _verify_centralizer(S, A, centr)
True
```

See also:

- `_naive_list_centralizer` (page 423), `sympy.combinatorics.perm_groups.PermutationGroup.centralizer` (page 354), `_cmp_perm_lists` (page 423)

```
sympy.combinatorics.testutil._verify_normal_closure(group, arg, closure=None)
```
Tensor Canonicalization

`sympy.combinatorics.tensor_can.canonicalize(g, dummies, msym, *v)`

canonicalize tensor formed by tensors

**Parameters**

- **g**: permutation representing the tensor
- **dummies**: list representing the dummy indices
  - it can be a list of dummy indices of the same type or a list of lists of dummy indices, one list for each type of index; the dummy indices must come after the free indices, and put in order contravariant, covariant [d0, -d0, d1,-d1,...]
- **msym**: symmetry of the metric(s)
  - it can be an integer or a list; in the first case it is the symmetry of the dummy index metric; in the second case it is the list of the symmetries of the index metric for each type
- **v**: list, (base_i, gens_i, n_i, sym_i) for tensors of type i
- **base_i, gens_i**: BSGS for tensors of this type.
  - The BSGS should have minimal base under lexicographic ordering; if not, an attempt is made do get the minimal BSGS; in case of failure, canonicalize naive is used, which is much slower.
- **n_i**: number of tensors of type i.
- **sym_i**: symmetry under exchange of component tensors of type i.

**Both for msym and sym_i the cases are**

- None no symmetry
- 0 commuting
- 1 anticommuting

**Returns**

- 0 if the tensor is zero, else return the array form of the permutation representing the canonical form of the tensor.

**Algorithm**

First one uses canonical_free to get the minimum tensor under lexicographic order, using only the slot symmetries. If the component tensors have not minimal BSGS, it is attempted to find it; if the attempt fails canonicalize_naive is used instead.

Compute the residual slot symmetry keeping fixed the free indices using tensor_gens(base, gens, list_free_indices, sym).

Reduce the problem eliminating the free indices.

Then use double_coset_can_rep and lift back the result reintroducing the free indices.
Examples

one type of index with commuting metric;
$A_{ab}$ and $B_{ab}$ antisymmetric and commuting

$T = A_{d0d1} * B_{d0d2} * B_{d2d1}$

$ord = [d0, -d0, d1, -d1, d2, -d2]$ order of the indices

g = [1, 3, 0, 5, 4, 2, 6, 7]

$T_c = 0$

```python
>>> from sympy.combinatorics.tensor_can import get_symmetric_group_sgs,
... canonicalize, bsgs_direct_product
>>> from sympy.combinatorics import Permutation
>>> base2a, gens2a = get_symmetric_group_sgs(2, 1)
>>> t0 = (base2a, gens2a, 1, 0)
>>> t1 = (base2a, gens2a, 2, 0)
>>> g = Permutation([1, 3, 0, 5, 4, 2, 6, 7])
>>> canonicalize(g, range(6), 0, t0, t1)
0
```
same as above, but with $B_{ab}$ anticommuting

$T_c = -A_{d0d1} * B_{d0d2} * B_{d1d2}$

can = [0, 2, 1, 4, 3, 5, 7, 6]

```python
>>> t1 = (base2a, gens2a, 2, 1)
>>> canonicalize(g, range(6), 0, t0, t1)
[0, 2, 1, 4, 3, 5, 7, 6]
```
two types of indices $[a, b, c, d, e, f]$ and $[m, n]$, in this order, both with commuting metric $f^{abc}$ antisymmetric, commuting

$A_{ma}$ no symmetry, commuting

$T = f_{e}^{d} * A_{m}^{d} * A_{mb} * A_{na} * A_{ne}$

$ord = [c, f, a, -a, b, -b, d, -d, e, -e, m, -m, n, -n]$

g = [0, 7, 3, 1, 9, 5, 11, 6, 10, 4, 13, 2, 12, 8, 14, 15]
The canonical tensor is $T_c = -f^{cab} * f^{fde} * A_{m}^{a} * A_{md} * A_{n}^{b} * A_{ne}$
can = [0, 2, 4, 1, 6, 8, 10, 3, 11, 7, 12, 5, 13, 9, 15, 14]

```python
>>> base_f, gens_f = get_symmetric_group_sgs(3, 1)
>>> base_A, gens_A = bsgs_direct_product(base1, gens1, base1, gens1)
>>> t0 = (base_f, gens_f, 2, 0)
>>> t1 = (base_A, gens_A, 4, 0)
>>> dummies = [range(2, 10), range(10, 14)]
>>> g = Permutation([0, 7, 3, 1, 9, 5, 11, 6, 10, 4, 13, 2, 12, 8, 14, 15])
>>> canonicalize(g, dummies, [0, 0], t0, t1)
[0, 2, 4, 1, 6, 8, 10, 3, 11, 7, 12, 5, 13, 9, 15, 14]
```
Butler-Portugal algorithm for tensor canonicalization with dummy indices.

**Parameters**

- **dummies**: list of lists of dummy indices, one list for each type of index; the dummy indices are put in order contravariant, covariant [d0, -d0, d1, -d1, ...].
- **sym**: list of the symmetries of the index metric for each type.

**possible symmetries of the metrics**

- 0 symmetric
- 1 antisymmetric
- None no symmetry

- **b_S**: base of a minimal slot symmetry BSGS.
- **sgens**: generators of the slot symmetry BSGS.
- **S_transversals**: transversals for the slot BSGS.
- **g**: permutation representing the tensor.

**Returns**

Return 0 if the tensor is zero, else return the array form of the permutation representing the canonical form of the tensor.

**Notes**

A tensor with dummy indices can be represented in a number of equivalent ways which typically grows exponentially with the number of indices. To be able to establish if two tensors with many indices are equal becomes computationally very slow in absence of an efficient algorithm.

The Butler-Portugal algorithm [3] is an efficient algorithm to put tensors in canonical form, solving the above problem.

Portugal observed that a tensor can be represented by a permutation, and that the class of tensors equivalent to it under slot and dummy symmetries is equivalent to the double coset $D * g * S$ (Note: in this documentation we use the conventions for multiplication of permutations p, q with (p*q)(i) = p[q[i]] which is opposite to the one used in the Permutation class)

Using the algorithm by Butler to find a representative of the double coset one can find a canonical form for the tensor.
To see this correspondence, let $g$ be a permutation in array form; a tensor with indices $\text{ind}$ (the indices including both the contravariant and the covariant ones) can be written as

\[ t = T(\text{ind}[g[0]], \ldots, \text{ind}[g[n-1]]), \]

where $n = \text{len}(\text{ind})$; $g$ has size $n + 2$, the last two indices for the sign of the tensor (trick introduced in [4]).

A slot symmetry transformation $s$ is a permutation acting on the slots $t \rightarrow T(\text{ind}([g * s][0]), \ldots, \text{ind}([d * g][n-1]))$

A dummy symmetry transformation acts on $\text{ind} t \rightarrow T(\text{ind}([d * g][0]), \ldots, \text{ind}([d * g][n-1]))$

Being interested only in the transformations of the tensor under these symmetries, one can represent the tensor by $g$, which transforms as

\[ g - \rightarrow d * g * s, \text{ so it belongs to the coset } D * g * S, \text{ or in other words to the set of all permutations allowed by the slot and dummy symmetries.} \]

Let us explain the conventions by an example.

**Given a tensor $T^d_3 d_2 d_1 d_3$ with the slot symmetries**

\[ T^0 a_1 a_2 a_3 a_4 a_5 = -T^2 a_1 a_2 a_3 a_4 a_5 \]

\[ T^0 a_1 a_2 a_3 a_4 a_5 = -T^4 a_1 a_2 a_3 a_4 a_5 \]

and symmetric metric, find the tensor equivalent to it which is the lowest under the ordering of indices: lexicographic ordering $d_1, d_2, d_3$ and then contravariant before covariant index; that is the canonical form of the tensor.

The canonical form is $-T^d_1 d_2 d_3$ obtained using $T^0 a_1 a_2 a_3 a_4 a_5 = -T^2 a_1 a_2 a_3 a_4 a_5$.

To convert this problem into the input for this function, use the following ordering of the index names (- for covariant for short) $d_1, -d_1, d_2, -d_2, d_3, -d_3$

$T^d a_1 a_2 a_3 a_4 a_5$ corresponds to $g = [4, 2, 0, 1, 3, 5, 6, 7]$ where the last two indices are for the sign

\[ \text{sgens} = [\text{Permutation}(0, 2)(6, 7), \text{Permutation}(0, 4)(6, 7)] \]

\[ \text{sgens}[0] \text{ is the slot symmetry } -(0, 2) T^0 a_1 a_2 a_3 a_4 a_5 = -T^2 a_1 a_2 a_3 a_4 a_5 \]

\[ \text{sgens}[1] \text{ is the slot symmetry } -(0, 4) T^0 a_1 a_2 a_3 a_4 a_5 = -T^4 a_1 a_2 a_3 a_4 a_5 \]

The dummy symmetry group $D$ is generated by the strong base generators $[(0, 1), (2, 3), (4, 5), (0, 2)(1, 3), (0, 4)(1, 5)]$ where the first three interchange covariant and contravariant positions of the same index ($d_1 <-> -d_1$) and the last two interchange the dummy indices themselves ($d_1 <-> d_2$).

The dummy symmetry acts from the left $d = [1, 0, 2, 3, 4, 5, 6, 7]$ exchange $d_1 \leftrightarrow -d_1$

\[ T^d a_1 a_2 a_3 a_4 a_5 = T^d a_1 a_2 a_3 a_4 a_5 \]

\[ g = [4, 2, 0, 1, 3, 5, 6, 7] \rightarrow [4, 2, 1, 0, 3, 5, 6, 7] = a, \text{mul}(d, g) \text{ which differs from } a, \text{mul}(g, d). \]

The slot symmetry acts from the right $s = [2, 1, 0, 3, 4, 5, 7, 6]$ exchanges slots 0 and 2 and changes sign $T^d a_1 a_2 a_3 a_4 a_5 = T^d a_1 a_2 a_3 a_4 a_5$

\[ g = [4, 2, 0, 1, 3, 5, 6, 7] \rightarrow [0, 2, 4, 1, 3, 5, 7, 6] = a, \text{mul}(g, s) \]

**Example in which the tensor is zero, same slot symmetries as above: $T^d d_1 d_3 d_1 d_3 d_2$**

\[ = -T^d d_1 d_3 d_1 d_3 d_2 \text{ under slot symmetry } -(0, 4); \]

\[ = T^d d_1 d_3 d_1 d_2 d_2 \text{ under slot symmetry } -(0, 2); \]

\[ = T^d d_1 d_3 d_1 d_2 d_2 \text{ symmetric metric}; \]
= 0 since two of these lines have tensors differ only for the sign.

The double coset $D^g S$ consists of permutations $h = d * g * s$ corresponding to equivalent tensors; if there are two $h$ which are the same apart from the sign, return zero; otherwise choose as representative the tensor with indices ordered lexicographically according to $[d_1, -d_1, d_2, -d_2, d_3, -d_3]$ that is $\text{rep} = \min(D^g S) = \min([d^g s \text{ for } d \in D \text{ for } s \in S])$

The indices are fixed one by one; first choose the lowest index for slot 0, then the lowest remaining index for slot 1, etc. Doing this one obtains a chain of stabilizers $S \to S_{b_0} \to S_{b_0, b_1} \to \ldots$ and $D \to D_{p_0} \to D_{p_0, p_1} \to \ldots$

where $[b_0, b_1, \ldots] = \text{range}(b)$ is a base of the symmetric group; the strong base $b_S$ of $S$ is an ordered sublist of it; therefore it is sufficient to compute once the strong base generators of $S$ using the Schreier-Sims algorithm; the stabilizers of the strong base generators are the strong base generators of the stabilizer subgroup.

d_base = [p_0, p_1, \ldots] is not in general in lexicographic order, so that one must recompute the strong base generators each time; however this is trivial, there is no need to use the Schreier-Sims algorithm for $D$.

The algorithm keeps a TAB of elements $(s_i, d_i, h_i)$ where $h_i = d_i \times g \times s_i$ satisfying $h_i[j] = p_j$ for $0 \leq j < i$ starting from $s_0 = id, d_0 = id, h_0 = g$.

The equations $h_0[0] = p_0, h_0[1] = p_1, \ldots$ are solved in this order, choosing each time the lowest possible value of $p_i$.

For $j < i$ $d_i * g * s_i * S_{b_0, \ldots, b_i-1} * b_j = D_{p_0, \ldots, p_i-1} * p_j$ so that for $dx$ in $D_{p_0, \ldots, p_i-1}$ and $sx$ in $S_{base[0], \ldots, base[i-1]}$ one has $dx * d_i * g * s_i * sx * b_j = p_j$

Search for $dx, sx$ such that this equation holds for $j = i$; it can be written as $s_i * sx * b_j = J, dx * d_i * g * J = p_j, sx * b_j = s_i * s_j * s_k * b_j = 1 * J$; $sx = \text{trace}(s_i * s_j * s_k - 1, S_{b_0, \ldots, b_i-1}) dx * s_j * p_j = d_i * g * J; dx = \text{trace}(d_i * g * J, D_{p_0, \ldots, p_i-1})$

$s_{i+1} = s_i * \text{trace}(s_i * s_j * s_k - 1, S_{b_0, \ldots, b_i-1}) d_{i+1} = \text{trace}(d_i * g * J, D_{p_0, \ldots, p_i-1}) * s_j - 1 * d_i; h_{i+1} * b_i = d_{i+1} * g * s_i * b_i = p_i$

$h_n * b_j = p_j$ for all $j$, so that $h_n$ is the solution.

Add the found $(s, d, h)$ to TAB1.

At the end of the iteration sort TAB1 with respect to the $h$; if there are two consecutive $h$ in TAB1 which differ only for the sign, the tensor is zero, so return 0; if there are two consecutive $h$ which are equal, keep only one.

Then stabilize the slot generators under $i$ and the dummy generators under $p_i$.

Assign $TAB = TAB1$ at the end of the iteration step.

At the end $TAB$ contains a unique $(s, d, h)$, since all the slots of the tensor $h$ have been fixed to have the minimum value according to the symmetries. The algorithm returns $h$.

It is important that the slot BSGS has lexicographic minimal base, otherwise there is an $i$ which does not belong to the slot base for which $p_i$ is fixed by the dummy symmetry only, while $i$ is not invariant from the slot stabilizer, so $p_i$ is not in general the minimal value.

This algorithm differs slightly from the original algorithm [3]:

the canonical form is minimal lexicographically, and the BSGS has minimal base under lexicographic order. Equal tensors $h$ are eliminated from TAB.
Examples

```python
>>> from sympy.combinatorics.permutations import Permutation
>>> from sympy.combinatorics.tensor_can import double_coset_can_rep, get_transversals
>>> gens = [Permutation(x) for x in [[2, 1, 0, 3, 4, 5, 7, 6], [4, 1, 2, 3, 0, 5, 7, 6]]]
>>> base = [0, 2]
>>> g = Permutation([4, 2, 0, 1, 3, 5, 6, 7])
>>> transversals = get_transversals(base, gens)
>>> double_coset_can_rep([list(range(6))], [0], base, gens, transversals, g)
[0, 1, 2, 3, 4, 5, 7, 6]

```
Examples

```python
>>> from sympy.combinatorics.tensor_can import (get_symmetric_group_sgs,
bsgs_direct_product)
>>> base1, gens1 = get_symmetric_group_sgs(1)
>>> base2, gens2 = get_symmetric_group_sgs(2)
>>> bsgs_direct_product(base1, gens1, base2, gens2)
([1], [(4)(1 2)])
```

Finitely Presented Groups

Introduction

This module presents the functionality designed for computing with finitely-presented groups (fp-groups for short). The name of the corresponding SymPy object is FpGroup. The functions or classes described here are studied under computational group theory. All code examples assume:

```python
>>> from sympy.combinatorics.free_groups import free_group, vfree_group,
xfree_group
>>> from sympy.combinatorics.fp_groups import FpGroup, CosetTable, coset_enumeration_r
```

Overview of Facilities

The facilities provided for fp-groups fall into a number of natural groupings

- The construction of fp-groups using a free group and a list of words in generators of that free group.
- Index determination using the famous Todd-Coxeter procedure.
- The construction of all subgroups having index less than some (small) specified positive integer, using the Low-Index Subgroups algorithm.
- Algorithms for computing presentations of a subgroup of finite index in a group defined by finite presentation.

For a description of fundamental algorithms of finitely presented groups we often make use of Handbook of Computational Group Theory.

The Construction of Finitely Presented Groups

Finitely presented groups are constructed by factoring a free group by a set of relators. The set of relators is taken in as a list of words in generators of free group in SymPy, using a list provides ordering to the relators. If the list of relators is empty, the associated free group is returned.

Example of construction of a finitely-presented group. The symmetric group of degree 4 may be represented as a two generator group with presentation \( \langle a, b \mid a^2, b^3, (ab)^4 \rangle \). Giving the relations as a list of relators, group in SymPy would be specified as:
```python
>>> F, a, b = free_group("a, b")
>>> G = FpGroup(F, [a**2, b**3, (a*b)**4])
>>> G
<fp group on the generators (a, b)>
```

Currently groups with relators having presentation like \( \langle r, s, t \mid r^2, s^2, t^2, rst = str = trs \rangle \) will have to be specified as:

```python
>>> F, r, s, t = free_group("r, s, t")
>>> G = FpGroup(F, [r**2, s**2, t**2, r*s*t**-1*t**-1*s**-1, s*t*r*s**-1*r**-1*t**-1])
```

Obviously this is not a unique way to make that particular group, but the point is that in case of equality with non-identity the user has to manually do that.

## Free Groups and Words

### Construction of a Free Group

`free_group("gen0, gen1, ..., gen_(n-1)")` constructs a free group \( F \) on \( n \) generators, where \( n \) is a positive integer. The \( i \)-th generator of \( F \) may be obtained using the method `.generators[i]`, \( i = 0, ..., n - 1 \).

```python
>>> F, x, y = free_group("x, y")
```

creates a free group \( F \) of rank 2 and assigns the variables \( x \) and \( y \) to the two generators.

```python
>>> F = vfree_group("x, y")
>>> F
<free group on the generators (x, y)>
```

creates a free group \( F \) of rank 2, with tuple of generators \( F\)\generators, and inserts \( x \) and \( y \) as generators into the global namespace.

```python
>>> F = xfree_group("x, y")
>>> F
(<free group on the generators (x, y)>, (x, y))
>>> x**2
x**2
```

creates a free groups \( F[0] \) of rank 2, with tuple of generators \( F[1] \).

### Construction of words

This section is applicable to words of `FreeGroup` as well as `FpGroup`. When we say `word` in SymPy, it actually means a reduced word, since the words are automatically reduced. Given a group \( G \) defined on \( n \) generators \( x_1, x_2, x_3, ..., x_n \), a word is constructed as \( s_1^{r_1} s_2^{r_2} ... s_k^{r_k} \) where \( s_i \in \{x_1, x_2, ..., x_n\}, r_i \in \mathbb{Z} \) for all \( k \).

Each word can be constructed in a variety of ways, since after reduction they may be equivalent.
Coset Enumeration: The Todd-Coxeter Algorithm

This section describes the use of coset enumeration techniques in SymPy. The algorithm used for coset enumeration procedure is Todd-Coxeter algorithm and is developed in SymPy using [Ho05] and [CDHW73]. The reader should consult [CDHW73] and [Hav91] for a general description of the algorithm.

We have two strategies of coset enumeration relator-based and coset-table based and the two have been implemented as coset_enumeration_r, coset_enumeration_c respectively. The two strategies differ in the way they make new definitions for the cosets.

Though from the user point of view it is suggested to rather use the .coset_enumeration method of FpGroup and specify the strategy argument.

strategy:
(default="relator_based") specifies the strategy of coset enumeration to be used, possible values are "relator_based" or "coset_table_based".

CosetTable

Class used to manipulate the information regarding the coset enumeration of the finitely presented group $G$ on the cosets of the subgroup $H$.

Basically a coset table CosetTable($G, H$), is the permutation representation of the finitely presented group on the cosets of a subgroup. Most of the set theoretic and group functions use the regular representation of $G$, i.e., the coset table of $G$ over the trivial subgroup.

The actual mathematical coset table is obtained using .table attribute and is a list of lists. For each generator $g$ of $G$ it contains a column and the next column corresponds to $g**-1$ and so on for other generators, so in total it has $2*G.rank()$ columns. Each column is simply a list of integers. If $l$ is the generator list for the generator $g$ and if $l[i] = j$ then generator $g$ takes the coset $i$ to the coset $j$ by multiplication from the right.

For finitely presented groups, a coset table is computed by a Todd-Coxeter coset enumeration. Note that you may influence the performance of that enumeration by changing the values of the variable CosetTable.coset_table_max_limit.

Attributes of CosetTable

For CosetTable($G, H$) where $G$ is the group and $H$ is the subgroup.

- $n$: A non-negative integer, non-mutable attribute, dependently calculated as the maximum among the live-cosets (i.e. $\Omega$).
- table: A list of lists, mutable attribute, mathematically represents the coset table.
- omega: A list, dependent on the internal attribute $p$. $\Omega$ represents the list of live-cosets. A standard coset-table has its $\Omega = \{0, 1, \ldots, index - 1\}$ where $index$ is the index of subgroup $H$ in $G$.

For experienced users we have a number of parameters that can be used to manipulate the algorithm, like

- coset_table_max_limit (default value = 4096000): manipulate the maximum number of cosets allowed in coset enumeration, i.e. the number of rows allowed in coset table. A coset enumeration will not finish if the subgroup does not have finite index, and even if it has it may take many more intermediate cosets than the actual index of the subgroup.
is. To avoid a coset enumeration “running away” therefore SymPy has a “safety stop” built-in. This is controlled by this variable. To change it, use \textit{max\_cosets} keyword. For example:

```python
>>> F, a, b = free_group("a, b")
>>> Cox = FpGroup(F, [a**6, b**6, (a*b)**2, (a**2*b**2)**2, (a**3*b**3)**5])
>>> C_r = coset_enumeration_r(Cox, [a], max\_cosets=50)
Traceback (most recent call last):
  ... 
ValueError: the coset enumeration has defined more than 50 cosets
```

- \textit{max\_stack\_size} (default value = 500): manipulate the maximum size of deduction\_stack above or equal to which the stack is emptied.

### Compression and Standardization

For any two entries \(i, j\) with \(i < j\) in coset table, the first occurrence of \(i\) in a coset table precedes the first occurrence of \(j\) with respect to the usual row-wise ordering of the table entries. We call such a table a standard coset table. To standardize a \texttt{CosetTable} we use the \texttt{.standardize} method.

**Note** the method alters the given table, it does not create a copy.

### Subgroups of Finite Index

The functionality in this section are concerned with the construction of subgroups of finite index. We describe a method for computing all subgroups whose index does not exceed some (modest) integer bound.

#### Low Index Subgroups

\texttt{low\_index\_subgroups}(G, N): Given a finitely presented group \(G = \langle X | R \rangle\) (can be a free group), and \(N\) a positive integer; determine the conjugacy classes of subgroups of \(G\) whose indices is less than or equal to \(N\).

For example to find all subgroups of \(G = \langle a, b \mid a^2 = b^3 = (ab)^4 = 1 \rangle\) having index \(\leq 4\), can be found as follows:

```python
>>> from sympy.combinatorics.fp_groups import low_index_subgroups
>>> F, a, b = free_group("a, b")
>>> G = FpGroup(F, [a**2, b**3, (a*b)**4])
>>> l = low_index_subgroups(G, 4)
>>> for coset_table in l:
...    print(coset_table.table)
...
[[0, 0, 0, 0], [0, 0, 1, 2], [1, 1, 2, 0], [3, 3, 0, 1], [2, 2, 3, 3]]
[[0, 0, 1, 2], [2, 2, 2, 0], [1, 1, 0, 1]]
[[1, 1, 0, 0], [0, 0, 1, 1]]
```
This returns the coset tables of subgroups of satisfying the property that index, \( \text{index} \), of subgroup in group is \( \leq n \).

**Constructing a presentation for a subgroup**

In this section we discuss finding the presentation of a subgroup in a finitely presentation group. While the subgroup is currently allowed as input only in the form of a list of generators for the subgroup, you can expect the functionality of a coset table as input for subgroup in the group in near future.

There are two ways to construct a set of defining relations for subgroup from those of \( G \). First is on a set of Schreier generators, known generally as Reidemeister-Schreier algorithm or on the given list of generators of \( H \).

**Reidemeister Schreier algorithm**

called using `reidemeister_presentation(G, Y)` where \( G \) is the group and \( Y \) is a list of generators for subgroup \( H \) whose presentation we want to find.

```python
>>> from sympy.combinatorics.fp_groups import reidemeister_presentation
>>> F, x, y = free_group("x, y")
>>> f = FpGroup(F, [x**3, y**5, (x*y)**2])
>>> H = [x*y, x**-1*y**-1*x*y*x]
>>> p1 = reidemeister_presentation(f, H)
>>> p1
((y_1, y_2), (y_1**2, y_2**3, y_2*y_1*y_2*y_1*y_2**2*y_1))
```

**Bibliography**

**Polycyclic Groups**

**Introduction**

This module presents the functionality designed for computing with polycyclic groups(\texttt{PcGroup} for short). The name of the corresponding SymPy object is \texttt{PolycyclicGroup}. The functions or classes described here are studied under \textit{Computational Group Theory}.

**Overview of functionalities**

- The construction of \texttt{PolycyclicGroup} from a given \texttt{PermutationGroup}.
- Computation of polycyclic generating sequence(\texttt{pcgs} for short) and polycyclic series(\texttt{pc_series}).
- Computation of relative order for polycyclic series.
- Implementation of class \texttt{Collector} which can be treated as a base for polycyclic groups.
- Implementation of polycyclic group presentation(\texttt{pc_presentation} for short).
• Computation of exponent vector, depth and leading exponent for a given element of a polycyclic group.

For a description of fundamental algorithms of polycyclic groups, we often make use of *Handbook of Computational Group Theory*.

**The Construction of Polycyclic Groups**

Given a Permutation Group, A Polycyclic Group is constructed by computing the corresponding polycyclic generating sequence, polycyclic series and it's relative order.

**Attributes of PolycyclicGroup**

- `pc_sequence`: Polycyclic sequence is formed by collecting all the missing generators between the adjacent groups in the derived series of given permutation group.
- `pc_series`: Polycyclic series is formed by adding all the missing generators of `der[i+1]` in `der[i]`, where `der` represents derived series.
- `relative_order`: A list, computed by the ratio of adjacent groups in `pc_series`.
- `collector`: By default, it is None. Collector class provides the polycyclic presentation.

```python
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> G = SymmetricGroup(4)
>>> PcGroup = G.polycyclic_group()
>>> len(PcGroup.pcg)
4
>>> pc_series = PcGroup.pc_series
>>> pc_series[0].equals(G)  # use equals, not literal `==`
True
>>> gen = pc_series[len(pc_series) - 1].generators[0]
>>> gen.is_identity
True
>>> PcGroup.relative_order
[2, 3, 2, 2]
```

**The Construction of Collector**

Collector is one of the attributes of class PolycyclicGroup.

**Attributes of Collector**

Collector posses all the attributes of PolycyclicGroup, In addition there are few more attributes which are defined below:

- `free_group`: free_group provides the mapping of polycyclic generating sequence with the free group elements.
- `pc_presentation`: Provides the presentation of polycyclic groups with the help of power and conjugate relators.
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> G = SymmetricGroup(3)
>>> PcGroup = G.polycyclic_group()
>>> Collector = PcGroup.collector
>>> Collector.free_group
<free group on the generators (x0, x1)>
>>> Collector.pc_presentation
{x0**2: (), x1**3: (), x0**-1*x1*x0: x1**2}

Computation of Minimal Uncollected Subword

A word $V$ defined on generators in the free_group of pc_group is a minimal uncollected subword of the word $W$ if $V$ is a subword of $W$ and it has one of the following form:

- $v = x_{i+1}a_i x_i$
- $v = x_{i+1}a_i x_i^{-1}$
- $v = x_i a_j$

$a_j \notin \{0, \ldots, \text{relative_order}[j] - 1\}$.

Computation of Subword Index

For a given word and it’s subword, subword_index computes the starting and ending index of the subword in the word.
Computation of Collected Word

A word $W$ is called collected, if $W = x_{i_1}^{a_1} \cdots x_{i_r}^{a_r}$ with $i_1 < i_2 < \ldots < i_r$ and $a_j$ is in $\{1, \ldots, s_j-1\}$, where $s_j$ represents the respective relative order.

```python
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> from sympy.combinatorics.perm_groups import PermutationGroup
>>> from sympy.combinatorics.free_groups import free_group

>>> G = SymmetricGroup(4)
>>> PcGroup = G.polycyclic_group()
>>> collector = PcGroup.collector

>>> F, x0, x1, x2, x3 = free_group("x0, x1, x2, x3")

>>> word = x3*x2*x1*x0

>>> collected_word = collector.collected_word(word)

>>> G1 = PermutationGroup()

>>> for w in word:
...     sym = w[0]
...     perm = free_to_perm[sym]
...     G1 = PermutationGroup([perm] + G1.generators)

>>> G2 = PermutationGroup()

>>> for w in collected_word:
...     sym = w[0]
...     perm = free_to_perm[sym]
...     G2 = PermutationGroup([perm] + G2.generators)

The two are not identical but they are equivalent:

```python
>>> G1 == G2
False

>>> G1.equals(G2)
True
```

Computation of Polycyclic Presentation

The computation of presentation starts from the bottom of the pcgs and polycyclic series. Storing all the previous generators from pcgs and then taking the last generator as the generator which acts as a conjugator and conjugates all the previous generators in the list.

To get a clear picture, start with an example of SymmetricGroup(4). For S(4) there are 4 generators in pcgs say $[x_0, x_1, x_2, x_3]$ and the relative order vector is $[2, 3, 2, 2]$. Starting from bottom of this sequence the presentation is computed in order as below.

using only $[x_3]$ from pcgs and pc_series[4] compute:

- $x_3^2$

using only $[x_3]$ from pcgs and pc_series[3] compute:

- $x_3^2$
- $x_2^{-1} x_3 x_2$
SymPy Documentation, Release 1.12.1

using \([x_3, x_2]\) from pcgs and pc_series[2] compute:

- \(x_1^3\)
- \(x_1^{-1}x_3x_1\)
- \(x_1^{-1}x_2x_1\)

using \([x_3, x_2, x_1]\) from pcgs and pc_series[1] compute:

- \(x_0^2\)
- \(x_0^{-1}x_3x_0\)
- \(x_0^{-1}x_2x_0\)
- \(x_0^{-1}x_1x_0\)

One thing to note is same group can have different pcgs due to varying derived_series which, results in different polycyclic presentations.

```python
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> from sympy.combinatorics.permutations import Permutation
>>> G = SymmetricGroup(4)
>>> PcGroup = G.polycyclic_group()
>>> collector = PcGroup.collector
>>> pcgs = PcGroup.pcgs
>>> len(pcgs)
4
>>> free_group = collector.free_group
>>> pc_presentation = collector.pc_presentation
>>> free_to_perm = {}
>>> for s, g in zip(free_group.symbols, pcgs):
...     free_to_perm[s] = g
>>> for k, v in pc_presentation.items():
...     k_array = k.array_form
...     if v != ():
...         v_array = v.array_form
...         lhs = Permutation()
...         for gen in k_array:
...             s = gen[0]
...             e = gen[1]
...             lhs = lhs*free_to_perm[s]**e
...         if v == ():
...             assert lhs.is_identity
...             continue
...         rhs = Permutation()
...         for gen in v_array:
...             s = gen[0]
...             e = gen[1]
...             rhs = rhs*free_to_perm[s]**e
...         assert lhs == rhs
```
Computation of Exponent Vector

Any generator of the polycyclic group can be represented with the help of its polycyclic generating sequence. Hence, the length of exponent vector is equal to the length of the pcgs.

A given generator \( g \) of the polycyclic group, can be represented as \( g = x_1^{e_1} \cdots x_n^{e_n} \), where \( x_i \) represents polycyclic generators and \( n \) is the number of generators in the free group equal to the length of pcgs.

```python
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> from sympy.combinatorics.permutations import Permutation
>>> G = SymmetricGroup(4)
>>> PcGroup = G.polycyclic_group()
>>> collector = PcGroup.collector
>>> pcgs = PcGroup.pcgs
>>> collector.exponent_vector(G[0])
[1, 0, 0, 0]
>>> exp = collector.exponent_vector(G[1])
>>> g = Permutation()
>>> for i in range(len(exp)):
...     g = g*pcgs[i]**exp[i] if exp[i] else g
>>> assert g == G[1]
```

Depth of Polycyclic generator

Depth of a given polycyclic generator is defined as the index of the first non-zero entry in the exponent vector.

```python
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> G = SymmetricGroup(3)
>>> PcGroup = G.polycyclic_group()
>>> collector = PcGroup.collector
>>> collector.depth(G[0])
2
>>> collector.depth(G[1])
1
```

Computation of Leading Exponent

Leading exponent represents the exponent of polycyclic generator at the above depth.

```python
>>> from sympy.combinatorics.named_groups import SymmetricGroup
>>> G = SymmetricGroup(3)
>>> PcGroup = G.polycyclic_group()
>>> collector = PcGroup.collector
>>> collector.leading_exponent(G[1])
1
```
Bibliography

Functions

All functions support the methods documented below, inherited from `sympy.core.function.Function` (page 1096).

```python
class sympy.core.function.Function(*args)
    Base class for applied mathematical functions.
    
    It also serves as a constructor for undefined function classes.
    
    See the Writing Custom Functions (page 102) guide for details on how to subclass Function and what methods can be defined.
```

Examples

Undefined Functions

To create an undefined function, pass a string of the function name to `Function`.

```python
>>> from sympy import Function, Symbol
>>> x = Symbol('x')
>>> f = Function('f')
>>> g = Function('g')(x)
>>> f
f
>>> f(x)
f(x)
>>> g
g(x)
>>> f(x).diff(x)
Derivative(f(x), x)
>>> g.diff(x)
Derivative(g(x), x)
```

Assumptions can be passed to `Function` the same as with a `Symbol` (page 1028). Alternatively, you can use a `Symbol` with assumptions for the function name and the function will inherit the name and assumptions associated with the `Symbol`:

```python
>>> f_real = Function('f', real=True)
>>> f_real(x).is_real
True
>>> f_real_inherit = Function(Symbol('f', real=True))
>>> f_real_inherit(x).is_real
True
```

Note that assumptions on a function are unrelated to the assumptions on the variables it is called on. If you want to add a relationship, subclass `Function` and define custom assumptions handler methods. See the Assumptions (page 111) section of the Writing Custom Functions (page 102) guide for more details.

Custom Function Subclasses

The Writing Custom Functions (page 102) guide has several Complete Examples (page 122) of how to subclass `Function` to create a custom function.
as_base_exp()
    Returns the method as the 2-tuple (base, exponent).

fdiff(argindex=1)
    Returns the first derivative of the function.

classmethod is_singular(a)
    Tests whether the argument is an essential singularity or a branch point, or the functions is non-holomorphic.

Contents

Elementary

This module implements elementary functions such as trigonometric, hyperbolic, and sqrt, as well as functions like Abs, Max, Min etc.

Complex Functions

class sympy.functions.elementary.complexes.re(arg)
    Returns real part of expression. This function performs only elementary analysis and so it will fail to decompose properly more complicated expressions. If completely simplified result is needed then use Basic.as_real_imag() or perform complex expansion on instance of this function.

    Parameters
        arg : Expr
            Real or complex expression.

    Returns
        expr : Expr
            Real part of expression.

Examples

>>> from sympy import re, im, I, E, symbols
>>> x, y = symbols('x y', real=True)
>>> re(2*E)
2*E
>>> re(2*I + 17)
17
>>> re(2*I)
0
>>> re(im(x) + x*I + 2)
2
>>> re(5 + I + 2)
7

See also:

im (page 443)
as_real_imag(*deep=True, **hints*)

Returns the real number with a zero imaginary part.

class sympy.functions.elementary.complexes.im(arg)

Returns imaginary part of expression. This function performs only elementary analysis and so it will fail to decompose properly more complicated expressions. If completely simplified result is needed then use Basic.as_real_imag() or perform complex expansion on instance of this function.

**Parameters**

- **arg**: Expr
  
  Real or complex expression.

**Returns**

- **expr**: Expr
  
  Imaginary part of expression.

**Examples**

```python
>>> from sympy import re, im, E, I
>>> from sympy import re, im, E, I
>>> from sympy import re, im, E, I
>>> im(2*E)
0
>>> im(2*I + 17)
2
>>> im(x*I)
re(x)
>>> im(re(x) + y)
im(y)
>>> im(2 + 3*I)
3
```

**See also:**

* re (page 442)

as_real_imag(*deep=True, **hints*)

Return the imaginary part with a zero real part.

class sympy.functions.elementary.complexes.sign(arg)

Returns the complex sign of an expression:

**Parameters**

- **arg**: Expr
  
  Real or imaginary expression.

**Returns**

- **expr**: Expr
  
  Complex sign of expression.
**Explanation**

If the expression is real the sign will be:
- $1$ if expression is positive
- $0$ if expression is equal to zero
- $-1$ if expression is negative

If the expression is imaginary the sign will be:
- $I$ if $\text{im}(\text{expression})$ is positive
- $-I$ if $\text{im}(\text{expression})$ is negative

Otherwise an unevaluated expression will be returned. When evaluated, the result (in general) will be $\cos(\text{arg}(\text{expr})) + I\sin(\text{arg}(\text{expr}))$.

**Examples**

```python
>>> from sympy import sign, I

>>> sign(-1)
-1
```
```
>>> sign(0)
0
```
```
>>> sign(-3*I)
-I
```
```
>>> sign(1 + I)
sign(1 + I)
```
```
>>> _.evalf()
0.707106781186548 + 0.707106781186548*I
```

**See also:**

`Abs` (page 444), `conjugate` (page 446)

**class** sympy.functions.elementary.complexes.Abs(arg)

Return the absolute value of the argument.

**Parameters**

- `arg` : Expr

  Real or complex expression.

**Returns**

- `expr` : Expr

  Absolute value returned can be an expression or integer depending on input `arg`.  

Explanation

This is an extension of the built-in function abs() to accept symbolic values. If you pass a SymPy expression to the built-in abs(), it will pass it automatically to Abs().

Examples

```python
>>> from sympy import Abs, Symbol, S, I

>>> Abs(-1)
1

>>> x = Symbol('x', real=True)

>>> Abs(-x)
Abs(x)

>>> Abs(x**2)
x**2

>>> abs(-x) # The Python built-in
Abs(x)

>>> Abs(3*x + 2*I)
sqrt(9*x**2 + 4)

>>> Abs(8*I)
8
```

Note that the Python built-in will return either an Expr or int depending on the argument:

```python
>>> type(abs(-1))
<... 'int'>

>>> type(abs(S.NegativeOne))
<class 'sympy.core.numbers.One'>
```

Abs will always return a SymPy object.

See also:

* sign (page 443), conjugate (page 446)

**fdiff**(argindex=1)

Get the first derivative of the argument to Abs().

**class** sympy.functions.elementary.complexes.arg(arg)

Returns the argument (in radians) of a complex number. The argument is evaluated in consistent convention with atan2 where the branch-cut is taken along the negative real axis and arg(z) is in the interval $(-\pi, \pi]$. For a positive number; the argument is always 0; the argument of a negative number is $\pi$; and the argument of 0 is undefined and returns nan. So the arg function will never nest greater than 3 levels since at the 4th application, the result must be nan; for a real number, nan is returned on the 3rd application.

**Parameters**

arg : Expr

Real or complex expression.

**Returns**

value : Expr

Returns arc tangent of arg measured in radians.
**Examples**

```python
>>> from sympy import arg, I, sqrt, Dummy
>>> from sympy.abc import x
>>> arg(2.0)
0
>>> arg(I)
pi/2
>>> arg(sqrt(2) + I*sqrt(2))
pi/4
>>> arg(sqrt(3)/2 + I/2)
pi/6
>>> arg(4 + 3*I)
atan(3/4)
>>> arg(0.8 + 0.6*I)
0.643501108793284
>>> arg(arg(arg(arg(x))))
nan
>>> real = Dummy(real=True)
>>> arg(arg(arg(real)))
nan
```

**class** `sympy.functions.elementary.complexes.conjugate(arg)`

Returns the complex conjugate of an argument. In mathematics, the complex conjugate of a complex number is given by changing the sign of the imaginary part. Thus, the conjugate of the complex number \( a + ib \) (where \( a \) and \( b \) are real numbers) is \( a - ib \).

**Parameters**

- **arg**: Expr

  Real or complex expression.

**Returns**

- **arg**: Expr

  Complex conjugate of arg as real, imaginary or mixed expression.

**Examples**

```python
>>> from sympy import conjugate, I
>>> conjugate(2)
2
>>> conjugate(I)
-I
>>> conjugate(3 + 2*I)
3 - 2*I
>>> conjugate(5 - I)
5 + I
```

**See also:**

- `sign` (page 443), `Abs` (page 444)
References

[R248]

class sympy.functions.elementary.complexes.polar_lift(arg)
Lift argument to the Riemann surface of the logarithm, using the standard branch.

Parameters
arg : Expr
    Real or complex expression.

Examples

>>> from sympy import Symbol, polar_lift, I
>>> p = Symbol('p', polar=True)
>>> x = Symbol('x')
>>> polar_lift(4)
4*exp_polar(0)
>>> polar_lift(-4)
4*exp_polar(I*pi)
>>> polar_lift(-I)
exp_polar(-I*pi/2)
>>> polar_lift(I + 2)
polar_lift(2 + I)

See also:
sympy.functions.elementary.exponential.exp_polar (page 471),
periodic_argument (page 447)

class sympy.functions.elementary.complexes.periodic_argument(ar, period)
Represent the argument on a quotient of the Riemann surface of the logarithm. That is, given a period $P$, always return a value in $(-P/2, P/2]$, by using exp($P*I$) = 1.

Parameters
ar : Expr
    A polar number.

period : Expr
    The period $P$. 
Examples

```python
>>> from sympy import exp_polar, periodic_argument
>>> from sympy import I, pi
>>> periodic_argument(exp_polar(10*I*pi), 2*pi)
0
>>> periodic_argument(exp_polar(5*I*pi), 4*pi)
pi
>>> from sympy import exp_polar, periodic_argument
>>> from sympy import I, pi
>>> periodic_argument(exp_polar(5*I*pi), 2*pi)
pi
>>> periodic_argument(exp_polar(5*I*pi), 3*pi)
-pi
>>> periodic_argument(exp_polar(5*I*pi), pi)
0
```

See also:

- `sympy.functions.elementary.exponential.exp_polar` (page 471)
- `polar_lift` (page 447)
  Lift argument to the Riemann surface of the logarithm
- `principal_branch` (page 448)

class sympy.functions.elementary.complexes.principal_branch(x, period)
Represent a polar number reduced to its principal branch on a quotient of the Riemann surface of the logarithm.

Parameters

- `x` : Expr
  A polar number.
- `period` : Expr
  Positive real number or infinity.

Explanation

This is a function of two arguments. The first argument is a polar number $z$, and the second one a positive real number or infinity, $p$. The result is $z \mod \exp_polar(I*p)$.

Examples

```python
>>> from sympy import exp_polar, principal_branch, oo, I, pi
>>> from sympy.abc import z
>>> principal_branch(z, oo)
z
>>> principal_branch(exp_polar(2*pi*I)*3, 2*pi)
3*exp_polar(0)
>>> principal_branch(exp_polar(2*pi*I)*3*z, 2*pi)
3*principal_branch(z, 2*pi)
```
**See also:**

- `sympy.functions.elementary.exponential.exp_polar` (page 471)
- **polar_lift** (page 447)
  - Lift argument to the Riemann surface of the logarithm
- `periodic_argument` (page 447)

---

**Trigonometric**

**Trigonometric Functions**

```python
class sympy.functions.elementary.trigonometric.sin(arg)
```

The sine function.

- Returns the sine of x (measured in radians).

**Explanation**

This function will evaluate automatically in the case \( x/\pi \) is some rational number [R252]. For example, if \( x \) is a multiple of \( \pi, \pi/2, \pi/3, \pi/4, \) and \( \pi/6 \).

**Examples**

```python
>>> from sympy import sin, pi
>>> from sympy.abc import x
>>> sin(x**2).diff(x)
2*x*cos(x**2)
>>> sin(1).diff(x)
0
>>> sin(pi)
0
>>> sin(pi/2)
1
>>> sin(pi/6)
1/2
>>> sin(pi/12)
-sqrt(2)/4 + sqrt(6)/4
```

**See also:**

class sympy.functions.elementary.trigonometric.cos(arg)
The cosine function.
Returns the cosine of x (measured in radians).

Explanation

See \texttt{sin()} (page 449) for notes about automatic evaluation.

Examples

\begin{verbatim}
>>> from sympy import cos, pi
>>> from sympy.abc import x
>>> cos(x**2).diff(x)
-2*x*sin(x**2)
>>> cos(1).diff(x)
0
>>> cos(pi)
-1
>>> cos(pi/2)
0
>>> cos(2*pi/3)
-1/2
>>> cos(pi/12)
\sqrt{2}/4 + \sqrt{6}/4
\end{verbatim}

class sympy.functions.elementary.trigonometric.tan(arg)
The tangent function.
Returns the tangent of x (measured in radians).
Explanation

See \texttt{sin} (page 449) for notes about automatic evaluation.

Examples

```python
>>> from sympy import tan, pi
>>> from sympy.abc import x
>>> tan(x**2).diff(x)
2*x*(tan(x**2)**2 + 1)
>>> tan(1).diff(x)
0
>>> tan(pi/8).expand()
-1 + sqrt(2)
```

\texttt{inverse(argindex=1)}

    Returns the inverse of this function.

class sympy.functions.elementary.trigonometric.\texttt{cot}(arg)

    The cotangent function.

    Returns the cotangent of \texttt{x} (measured in radians).

Explanation

See \texttt{sin} (page 449) for notes about automatic evaluation.

Examples

```python
>>> from sympy import cot, pi
>>> from sympy.abc import x
>>> cot(x**2).diff(x)
2*x*(-cot(x**2)**2 - 1)
>>> cot(1).diff(x)
0
>>> cot(pi/12)
sqrt(3) + 2
```

inverse\((\text{argindex}=1)\)

Returns the inverse of this function.

class sympy.functions.elementary.trigonometric.sec\((arg)\)

The secant function.

Returns the secant of \( x \) (measured in radians).

Explanation

See \( \sin \) (page 449) for notes about automatic evaluation.

Examples

```python
>>> from sympy import sec
>>> from sympy.abc import x
>>> sec(x**2).diff(x)
2*x*tan(x**2)*sec(x**2)
>>> sec(1).diff(x)
0
```

References

[R262], [R263], [R264]

class sympy.functions.elementary.trigonometric.csc\((arg)\)

The cosecant function.

Returns the cosecant of \( x \) (measured in radians).
Explanation

See :math:`\sin()` (page 449) for notes about automatic evaluation.

Examples

```python
>>> from sympy import csc
>>> from sympy import x
>>> csc(x**2).diff(x)
-2*x*cot(x**2)*csc(x**2)
>>> csc(1).diff(x)
0
```

.. class:: sympy.functions.elementary.trigonometric.sinc(arg)

    Represents an unnormalized sinc function:

    .. math::
        \text{sinc}(x) = \begin{cases}
            \frac{\sin x}{x} & x \neq 0 \\
            1 & x = 0
        \end{cases}

Examples

```python
>>> from sympy import sinc, oo, jn
>>> from sympy import x
>>> sinc(x)
sinc(x)
```

- Automated Evaluation

```python
>>> sinc(0)
1
>>> sinc(oo)
0
```

- Differentiation

```python
>>> sinc(x).diff()
\cos(x)/x - \sin(x)/x**2
```

- Series Expansion

5.8. Topics
sinc(x).series()
1 - x**2/6 + x**4/120 + O(x**6)

Trigonometric Inverses

class sympy.functions.elementary.trigonometric.asin(arg)
The inverse sine function.
Returns the arcsine of x in radians.

Explanation

asin(x) will evaluate automatically in the cases \( x \in \{\infty, -\infty, 0, 1, -1\} \) and for some instances when the result is a rational multiple of \( \pi \) (see the eval class method).
A purely imaginary argument will lead to an asinh expression.

Examples

from sympy import asin, oo
asin(1)
pi/2
asin(-1)
-pi/2
asin(-oo)
oo*I
asin(oo)
-oo*I

[R269], [R270], [R271]

**inverse(argindex=1)**

Returns the inverse of this function.

```python
class sympy.functions.elementary.trigonometric.acos(arg)
```

The inverse cosine function.

### Explanation

Returns the arc cosine of x (measured in radians).

\( \text{acos}(x) \) will evaluate automatically in the cases \( x \in \{ \infty, -\infty, 0, 1, -1 \} \) and for some instances when the result is a rational multiple of \( \pi \) (see the eval class method).

\( \text{acos}(\text{zoo}) \) evaluates to \( \text{zoo} \) (see note in \textit{sympy.functions.elementary.trigonometric.asec} (page 457))

A purely imaginary argument will be rewritten to asinh.

### Examples

```python
>>> from sympy import acos, oo

>>> acos(1)
0

>>> acos(0)
\pi/2

>>> acos(oo)
\infty*I
```

**inverse(argindex=1)**

Returns the inverse of this function.

```python
class sympy.functions.elementary.trigonometric.atan(arg)
```

The inverse tangent function.

Returns the arc tangent of x (measured in radians).
**Explanation**

atan(x) will evaluate automatically in the cases \( x \in \{\infty, -\infty, 0, 1, -1\} \) and for some instances when the result is a rational multiple of \( \pi \) (see the eval class method).

**Examples**

```python
code
>>> from sympy import atan, oo

>>> atan(0)
0

>>> atan(1)
pi/4

>>> atan(oo)
pi/2
```

**See also:**

sin (page 449), csc (page 452), cos (page 450), sec (page 452), tan (page 450), cot (page 451), asin (page 454), acsc (page 458), acos (page 455), asec (page 457), acot (page 456), atan2 (page 459)

**References**

[R275], [R276], [R277]

**inverse(argindex=1)**

Returns the inverse of this function.

**class sympy.functions.elementary.trigonometric.acot(arg)**

The inverse cotangent function.

Returns the arc cotangent of x (measured in radians).

**Explanation**

acot(x) will evaluate automatically in the cases \( x \in \{\infty, -\infty, 0, 1, -1\} \) and for some instances when the result is a rational multiple of \( \pi \) (see the eval class method).

A purely imaginary argument will lead to an acot expression.

acot(x) has a branch cut along \((-i, i)\), hence it is discontinuous at 0. Its range for real x is \((-\pi/2, \pi/2]\).
Examples

```python
>>> from sympy import acot, sqrt
>>> acot(0)
pi/2
>>> acot(1)
pi/4
>>> acot(sqrt(3) - 2)
-5*pi/12
```

See also:

\( \sin \) (page 449), \( \csc \) (page 452), \( \cos \) (page 450), \( \sec \) (page 452), \( \tan \) (page 450), \( \cot \) (page 451), \( \arcsin \) (page 454), \( \arccsc \) (page 458), \( \arccos \) (page 455), \( \arccsc \) (page 457), \( \arctan \) (page 455), \( \arctan2 \) (page 459)

References

[R278], [R279]

`inverse`(argindex=1)

Returns the inverse of this function.

```python
class sympy.functions.elementary.trigonometric.asec(arg)
```

The inverse secant function.

Returns the arc secant of x (measured in radians).

Explanation

asec(x) will evaluate automatically in the cases \( x \in \{\infty, -\infty, 0, 1, -1\} \) and for some instances when the result is a rational multiple of \( \pi \) (see the eval class method).

asec(x) has branch cut in the interval \([-1, 1]\). For complex arguments, it can be defined [R283] as

\[
\sec^{-1}(z) = -i \log \left( \frac{\sqrt{1 - z^2} + 1}{z} \right)
\]

At \( x = 0 \), for positive branch cut, the limit evaluates to zoo. For negative branch cut, the limit

\[
\lim_{z \to 0} -i \log \left( \frac{-\sqrt{1 - z^2} + 1}{z} \right)
\]

simplifies to \(-i \log (z/2 + O(z^3))\) which ultimately evaluates to zoo.

As \( \arccos(x) = \arccsc(1/x) \), a similar argument can be given for \( \arccos(x) \).
Examples

```python
>>> from sympy import asec, oo
>>> asec(1)
0
>>> asec(-1)
pi
>>> asec(0)
zoo
>>> asec(-oo)
pi/2
```

References

[R280], [R281], [R282], [R283]

`inverse(argindex=1)`

Returns the inverse of this function.

class sympy.functions.elementary.trigonometric.acsc(arg)

The inverse cosecant function.

Returns the arc cosecant of \(x\) (measured in radians).

Explanation

\(\text{acsc}(x)\) will evaluate automatically in the cases \(x \in \{\infty, -\infty, 0, 1, -1\}\) and for some instances when the result is a rational multiple of \(\pi\) (see the `eval` class method).

Examples

```python
>>> from sympy import acsc, oo
>>> acsc(1)
pi/2
>>> acsc(-1)
-pi/2
>>> acsc(oo)
0
>>> acsc(-oo) == acsc(oo)
True
>>> acsc(0)
zoo
```
See also:

\(\sin\) (page 449), \(\csc\) (page 452), \(\cos\) (page 450), \(\sec\) (page 452), \(\tan\) (page 450), \(\cot\) (page 451), \(\arcsin\) (page 454), \(\arccos\) (page 455), \(\arccsc\) (page 457), \(\arctan\) (page 455), \(\arccot\) (page 456), \(\arctan^2\) (page 459)

References

[R284], [R285], [R286]

inverse\((argindex=1)\)

Returns the inverse of this function.

class sympy.functions.elementary.trigonometric.atan2\((y, x)\)

The function \(\text{atan2}(y, x)\) computes \(\arctan\left(\frac{y}{x}\right)\) taking two arguments \(y\) and \(x\). Signs of both \(y\) and \(x\) are considered to determine the appropriate quadrant of \(\arctan\left(\frac{y}{x}\right)\). The range is \((-\pi, \pi]\). The complete definition reads as follows:

\[
\text{atan2}(y, x) = \begin{cases} 
\arctan\left(\frac{y}{x}\right) & x > 0 \\
\arctan\left(\frac{y}{x}\right) + \pi & y \geq 0, x < 0 \\
\arctan\left(\frac{y}{x}\right) - \pi & y < 0, x < 0 \\
\frac{\pi}{2} & y > 0, x = 0 \\
\frac{-\pi}{2} & y < 0, x = 0 \\
\text{undefined} & y = 0, x = 0
\end{cases}
\]

Attention: Note the role reversal of both arguments. The \(y\)-coordinate is the first argument and the \(x\)-coordinate the second.

If either \(x\) or \(y\) is complex:

\[
\text{atan2}(y, x) = -i \log\left(\frac{x + iy}{\sqrt{x^2 + y^2}}\right)
\]

Examples

Going counter-clock wise around the origin we find the following angles:

```python
>>> from sympy import atan2
>>> atan2(0, 1) 0
>>> atan2(1, 1) pi/4
>>> atan2(1, 0) pi/2
>>> atan2(1, -1) 3*pi/4
>>> atan2(0, -1) pi
>>> atan2(-1, -1) -3*pi/4
>>> atan2(-1, 0) -pi/2
```
which are all correct. Compare this to the results of the ordinary `atan` function for the
point \((x, y) = (-1, 1)\)

```
>>> from sympy import atan, S
>>> atan(S(1)/-1)
-pi/4
>>> atan2(1, -1)
3*pi/4
```

where only the `atan2` function returns what we expect. We can differentiate the function
with respect to both arguments:

```
>>> from sympy import diff
code
```

We can express the `atan2` function in terms of complex logarithms:

```
>>> from sympy import log
code
```

and in terms of \((atan)\):

```
>>> from sympy import atan
code
```

but note that this form is undefined on the negative real axis.

Hyperbolic Functions

```python
class sympy.functions.elementary.hyperbolic.HyperbolicFunction(*args)
    Base class for hyperbolic functions.

See also:
    sinh (page 461), cosh (page 461), tanh (page 462), coth (page 462)
```

```python
class sympy.functions.elementary.hyperbolic.sinh(arg)
sinh(x) is the hyperbolic sine of x.
    The hyperbolic sine function is \( \frac{e^x - e^{-x}}{2} \).
```

Examples

```python
>>> from sympy import sinh
>>> from sympy.abc import x
>>> sinh(x)
```

See also:
    cosh (page 461), tanh (page 462), asinh (page 463)

```python
as_real_imag(deep=True, **hints)
    Returns this function as a complex coordinate.
```

```python
fdiff(argindex=1)
    Returns the first derivative of this function.
```

```python
inverse(argindex=1)
    Returns the inverse of this function.
```

```python
static taylor_term(n, x, *previous_terms)
    Returns the next term in the Taylor series expansion.
```

```python
class sympy.functions.elementary.hyperbolic.cosh(arg)
cosh(x) is the hyperbolic cosine of x.
    The hyperbolic cosine function is \( \frac{e^x + e^{-x}}{2} \).
```
Examples

```python
>>> from sympy import cosh
>>> from sympy import x
>>> cosh(x)
cosh(x)
```

See also:

sinh (page 461), tanh (page 462), acosh (page 464)

class sympy.functions.elementary.hyperbolic.tanh(arg)
tanh(x) is the hyperbolic tangent of x.
The hyperbolic tangent function is \(\frac{\sinh(x)}{\cosh(x)}\).

Examples

```python
>>> from sympy import tanh
>>> from sympy import x
>>> tanh(x)
tanh(x)
```

See also:

sinh (page 461), cosh (page 461), atanh (page 464)

inverse(argindex=1)
   Returns the inverse of this function.

class sympy.functions.elementary.hyperbolic.coth(arg)
coth(x) is the hyperbolic cotangent of x.
The hyperbolic cotangent function is \(\frac{\cosh(x)}{\sinh(x)}\).

Examples

```python
>>> from sympy import coth
>>> from sympy import x
>>> coth(x)
coth(x)
```

See also:

sinh (page 461), cosh (page 461), acoth (page 464)

inverse(argindex=1)
   Returns the inverse of this function.

class sympy.functions.elementary.hyperbolic.sech(arg)
sech(x) is the hyperbolic secant of x.
The hyperbolic secant function is \(\frac{2}{e^x+e^{-x}}\)
Examples

```python
>>> from sympy import sech
>>> from sympy.abc import x
>>> sech(x)
sech(x)
```

See also:

- `sinh` (page 461), `cosh` (page 461), `tanh` (page 462), `coth` (page 462), `csch` (page 463), `asinh` (page 463), `acosh` (page 464)

```python
>>> from sympy import csch
>>> from sympy.abc import x
>>> csch(x)
csch(x)
```

See also:

- `sinh` (page 461), `cosh` (page 461), `tanh` (page 462), `sech` (page 462), `asinh` (page 463), `acosh` (page 464)

```python
>>> from sympy import asinh
>>> from sympy.abc import x
>>> asinh(x)
```

Hyperbolic Inverses

```python
>>> from sympy import asinh
>>> from sympy.abc import x
>>> asinh(x).diff(x)
1/sqrt(x**2 + 1)
>>> asinh(1)
log(1 + sqrt(2))
```
See also:

\(\text{acosh}\) (page 464), \(\text{atanh}\) (page 464), \(\text{sinh}\) (page 461)

\(\text{inverse}(\text{argindex}=1)\)

Returns the inverse of this function.

\textbf{class sympy.functions.elementary.hyperbolic.\texttt{acosh}(\texttt{arg})}

\(\text{acosh}(x)\) is the inverse hyperbolic cosine of \(x\).

The inverse hyperbolic cosine function.

\textbf{Examples}

```python
>>> from sympy import acosh
>>> from sympy.abc import x
>>> acosh(x).diff(x)
1/(sqrt(x - 1)*sqrt(x + 1))

0
```

See also:

\(\text{asinh}\) (page 463), \(\text{atanh}\) (page 464), \(\text{cosh}\) (page 461)

\(\text{inverse}(\text{argindex}=1)\)

Returns the inverse of this function.

\textbf{class sympy.functions.elementary.hyperbolic.\texttt{atanh}(\texttt{arg})}

\(\text{atanh}(x)\) is the inverse hyperbolic tangent of \(x\).

The inverse hyperbolic tangent function.

\textbf{Examples}

```python
>>> from sympy import atanh
>>> from sympy.abc import x
>>> atanh(x).diff(x)
1/(1 - x**2)
```

See also:

\(\text{asinh}\) (page 463), \(\text{acosh}\) (page 464), \(\text{tanh}\) (page 462)

\(\text{inverse}(\text{argindex}=1)\)

Returns the inverse of this function.

\textbf{class sympy.functions.elementary.hyperbolic.\texttt{acoth}(\texttt{arg})}

\(\text{acoth}(x)\) is the inverse hyperbolic cotangent of \(x\).

The inverse hyperbolic cotangent function.
**Examples**

```python
>>> from sympy import acoth
>>> from sympy import x
>>> acoth(x).diff(x)
1/(1 - x**2)
```

**See also:**

\(\text{asinh} \) (page 463), \(\text{acosh} \) (page 464), \(\text{coth} \) (page 462)

**inverse**\((\text{argindex}=1)\)

Returns the inverse of this function.

**class** sympy.functions.elementary.hyperbolic.asech\((\text{arg})\)

\(\text{asech}(x)\) is the inverse hyperbolic secant of \(x\).

The inverse hyperbolic secant function.

**Examples**

```python
>>> from sympy import asech, sqrt, S
>>> from sympy import x
>>> asech(x).diff(x)
-1/(x*sqrt(1 - x**2))
>>> asech(1).diff(x)
0
>>> asech(1)
0
>>> asech(S(2))
I*pi/3
>>> asech(-sqrt(2))
3*I*pi/4
>>> asech((sqrt(6) - sqrt(2)))
I*pi/12
```

**See also:**

\(\text{asinh} \) (page 463), \(\text{atanh} \) (page 464), \(\text{cosh} \) (page 461), \(\text{acoth} \) (page 464)

**References**

[R290], [R291], [R292]

**inverse**\((\text{argindex}=1)\)

Returns the inverse of this function.

**class** sympy.functions.elementary.hyperbolic.acsch\((\text{arg})\)

\(\text{acsch}(x)\) is the inverse hyperbolic cosecant of \(x\).

The inverse hyperbolic cosecant function.
Examples

```python
>>> from sympy import acsch, sqrt, I
>>> from sympy.abc import x
>>> acsch(x).diff(x)
-1/(x**2*sqrt(1 + x**(-2)))
>>> acsch(1).diff(x)
0
>>> acsch(1)
log(1 + sqrt(2))
>>> acsch(I)
-I*pi/2
>>> acsch(-2*I)
I*pi/6
>>> acsch(I*(sqrt(6) - sqrt(2)))
-5*I*pi/12
```

See also:

`asinh` (page 463)

References

[R293], [R294], [R295]

inverse(argindex=1)

Returns the inverse of this function.

Integer Functions

class sympy.functions.elementary.integers.ceiling(arg)

Ceiling is a univariate function which returns the smallest integer value not less than its argument. This implementation generalizes ceiling to complex numbers by taking the ceiling of the real and imaginary parts separately.

Examples

```python
>>> from sympy import ceiling, E, I, S, Float, Rational
>>> ceiling(17)
17
>>> ceiling(Rational(23, 10))
3
>>> ceiling(2*E)
6
>>> ceiling(-Float(0.567))
0
>>> ceiling(I/2)
I
>>> ceiling(S(5)/2 + 5*I/2)
3 + 3*I
```
class sympy.functions.elementary.integers.floor(arg)

Floor is a univariate function which returns the largest integer value not greater than its argument. This implementation generalizes floor to complex numbers by taking the floor of the real and imaginary parts separately.

Examples

```python
>>> from sympy import floor, E, I, S, Float, Rational
>>> floor(17)
17
>>> floor(Rational(23, 10))
2
>>> floor(2*E)
5
>>> floor(-Float(0.567))
-1
>>> floor(-I/2)
-I
>>> floor(S(5)/2 + 5*I/2)
2 + 2*I
```

See also:

sympy.functions.elementary.integers.ceiling (page 466)

References

[R298], [R299]
Examples

```python
from sympy import Symbol, frac, Rational, floor, I

frac(Rational(4, 3))
1/3
frac(-Rational(4, 3))
2/3
```

returns zero for integer arguments

```python
n = Symbol('n', integer=True)
frac(n)
0
```

rewrite as floor

```python
x = Symbol('x')
frac(x).rewrite(floor)
x - floor(x)
```

for complex arguments

```python
r = Symbol('r', real=True)
t = Symbol('t', real=True)
frac(t + I*r)
I*frac(r) + frac(t)
```

- `sympy.functions.elementary.integers.floor` (page 467), `sympy.functions.elementary.integers.ceiling` (page 466)

References

[R300], [R301]

Exponential

class sympy.functions.elementary.exponential.exp(arg)

The exponential function, \( e^x \).

Parameters

- arg : Expr
Examples

```python
>>> from sympy import exp, I, pi
>>> from sympy.abc import x
>>> exp(x)
exp(x)
>>> exp(x).diff()
exp(x)
>>> exp(I*pi)
-1
```

See also:

- `log` (page 470)
- `as_real_imag`(deep=True, **hints)

Returns this function as a 2-tuple representing a complex number.

Examples

```python
>>> from sympy import exp, I
>>> from sympy.abc import x
>>> exp(x).as_real_imag()
(exp(re(x))*cos(im(x)), exp(re(x))*sin(im(x)))
>>> exp(1).as_real_imag()
(E, 0)
>>> exp(I).as_real_imag()
(cos(1), sin(1))
>>> exp(1+I).as_real_imag()
(E*cos(1), E*sin(1))
```

See also:

- `sympy.functions.elementary.complexes.re` (page 442), `sympy.functions.elementary.complexes.im` (page 443)

property base

Returns the base of the exponential function.

```
defdiff(argindex=1)
```

Returns the first derivative of this function.

```
def static taylor_term(n, x, *previous_terms)
```

Calculates the next term in the Taylor series expansion.

```
class sympy.functions.elementary.exponential.LambertW(x, k=) None
```

The Lambert W function $W(z)$ is defined as the inverse function of $w \exp(w)$ [R302].
Explanation

In other words, the value of \( W(z) \) is such that \( z = W(z) \exp(W(z)) \) for any complex number \( z \). The Lambert W function is a multivalued function with infinitely many branches \( W_k(z) \), indexed by \( k \in \mathbb{Z} \). Each branch gives a different solution \( w \) of the equation \( z = w \exp(w) \).

The Lambert W function has two partially real branches: the principal branch \((k = 0)\) is real for real \( z > -1/e \), and the \( k = -1 \) branch is real for \(-1/e < z < 0\). All branches except \( k = 0 \) have a logarithmic singularity at \( z = 0 \).

Examples

```python
>>> from sympy import LambertW
>>> LambertW(1.2)
0.635564016364870
>>> LambertW(1.2, -1).n()
-1.34747534407696 - 4.41624341514535*I
>>> LambertW(-1).is_real
False
```

References

[R302]

\[ \text{fdiff(argindex=1)} \]

Return the first derivative of this function.

class sympy.functions.elementary.exponential.log(arg, base=None)
The natural logarithm function \( \ln(x) \) or \( \log(x) \).

Explanation

Logarithms are taken with the natural base, \( e \). To get a logarithm of a different base \( b \), use \( \log(x, b) \), which is essentially short-hand for \( \log(x)/\log(b) \).

\( \log \) represents the principal branch of the natural logarithm. As such it has a branch cut along the negative real axis and returns values having a complex argument in \((-\pi, \pi]\).

Examples

```python
>>> from sympy import log, sqrt, S, I
>>> log(8, 2)
3
>>> log(S(8)/3, 2)
-log(3)/log(2) + 3
>>> log(-1 + I*sqrt(3))
log(2) + 2*I*pi/3
```

See also:

exp (page 468)
as_base_exp()

Returns this function in the form (base, exponent).

as_real_imag(deep=True, **hints)

Returns this function as a complex coordinate.

Examples

```python
>>> from sympy import I, log
>>> from sympy.abc import x
>>> log(x).as_real_imag()
(log(Abs(x)), arg(x))
>>> log(I).as_real_imag()
(0, pi/2)
>>> log(1 + I).as_real_imag()
(log(sqrt(2)), pi/4)
>>> log(I*x).as_real_imag()
(log(Abs(x)), arg(I*x))
```

fdiff(argindex=1)

Returns the first derivative of the function.

inverse(argindex=1)

Returns $e^x$, the inverse function of $\log(x)$.

static taylor_term(n, x, *previous_terms)

Returns the next term in the Taylor series expansion of $\log(1 + x)$.

class sympy.functions.elementary.exponential.exp_polar(*args)

Represent a polar number (see g-function Sphinx documentation).

Explanation

exp_polar represents the function $Exp : \mathbb{C} \rightarrow S$, sending the complex number $z = a + bi$ to the polar number $r = e^{x(a)}, \theta = b$. It is one of the main functions to construct polar numbers.

Examples

```python
>>> from sympy import exp_polar, pi, I, exp
```

The main difference is that polar numbers do not “wrap around” at $2\pi$:

```python
>>> exp(2*pi*I)
1
>>> exp_polar(2*pi*I)
exp_polar(2*pi*I)
```

apart from that they behave mostly like classical complex numbers.
>>> exp_polar(2)*exp_polar(3)
exp_polar(5)

See also:
sympy.simplify.powsimp.powsimp (page 736), polar_lift (page 447), periodic_argument (page 447), principal_branch (page 448)

Piecewise
class sympy.functions.elementary.piecewise.ExprCondPair(expr, cond)
    Represents an expression, condition pair.
    
    property cond
        Returns the condition of this pair.
    
    property expr
        Returns the expression of this pair.

class sympy.functions.elementary.piecewise.Piecewise(*_args)
    Represents a piecewise function.

Usage:
    Piecewise( (expr,cond), (expr,cond), ... )
    
    • Each argument is a 2-tuple defining an expression and condition
    • The conds are evaluated in turn returning the first that is True. If any of
      the evaluated conds are not explicitly False, e.g. $x < 1$, the function is
      returned in symbolic form.
    • If the function is evaluated at a place where all conditions are False, nan
      will be returned.
    • Pairs where the cond is explicitly False, will be removed and no pair
      appearing after a True condition will ever be retained. If a single pair
      with a True condition remains, it will be returned, even when evaluation
      is False.

Examples

>>> from sympy import Piecewise, log, piecewise_fold
>>> from sympy.abc import x, y
>>> f = x**2
>>> g = log(x)
>>> p = Piecewise((0, x < -1), (f, x <= 1), (g, True))
>>> p.subs(x,1)
1
>>> p.subs(x,5)
log(5)

Booleans can contain Piecewise elements:
>>> cond = (x < y).subs(x, Piecewise((2, x < 0), (3, True))); cond
Piecewise((2 * x - 1, x < 0), (x, x < 1), (2*x, True)) < y

The folded version of this results in a Piecewise whose expressions are Booleans:

>>> folded_cond = piecewise_fold(cond); folded_cond
Piecewise((2 < y, x < 0), (3 < y, True))

When a Boolean containing Piecewise (like cond) or a Piecewise with Boolean expressions (like folded_cond) is used as a condition, it is converted to an equivalent ITE (page 1216) object:

>>> Piecewise((1, folded_cond))
Piecewise((1, ITE(x < 0, y > 2, y > 3)))

When a condition is an ITE, it will be converted to a simplified Boolean expression:

>>> piecewise_fold(_)
Piecewise((1, ((x >= 0) | (y > 2)) & ((y > 3) | (x < 0))))

See also:
piecewise_fold (page 476), piecewise_exclusive (page 475), ITE (page 1216)

_eval_integral(x, _first=True, **kwargs)
    Return the indefinite integral of the Piecewise such that subsequent substitution of x with a value will give the value of the integral (not including the constant of integration) up to that point. To only integrate the individual parts of Piecewise, use the piecewise_integrate method.

Examples

>>> from sympy import Piecewise
>>> from sympy.abc import x
>>> p = Piecewise((0, x < 0), (1, x < 1), (2, True))
>>> p.integrate(x)
Piecewise((0, x < 0), (x, x < 1), (2*x - 1, True))
>>> p.piecewise_integrate(x)
Piecewise((0, x < 0), (x, x < 1), (2*x, True))

See also:
Piecewise.piecewise_integrate (page 474)

as_expr_set_pairs(domain=None)
    Return tuples for each argument of self that give the expression and the interval in which it is valid which is contained within the given domain. If a condition cannot be converted to a set, an error will be raised. The variable of the conditions is assumed to be real; sets of real values are returned.
Examples

```python
>>> from sympy import Piecewise, Interval
>>> from sympy.abc import x
>>> p = Piecewise(
... (1, x < 2),
... (2, (x > 0) & (x < 4)),
... (3, True))
>>> p.as_expr_set_pairs()
[(1, Interval.open(-oo, 2)),
 (2, Interval.Ropen(2, 4)),
 (3, Interval(4, oo))]
>>> p.as_expr_set_pairs(Interval(0, 3))
[(1, Interval.Ropen(0, 2)),
 (2, Interval(2, 3))]
```

doit(**hints)
Evaluate this piecewise function.

classmethod eval(*_args)
Either return a modified version of the args or, if no modifications were made, return None.

Modifications that are made here:
1. relationals are made canonical
2. any False conditions are dropped
3. any repeat of a previous condition is ignored
4. any args past one with a true condition are dropped

If there are no args left, nan will be returned. If there is a single arg with a True condition, its corresponding expression will be returned.

Examples

```python
>>> from sympy import Piecewise
>>> from sympy.abc import x
>>> cond = -x < -1
>>> args = [(1, cond), (4, cond), (3, False), (2, True), (5, x < 1)]
>>> Piecewise(*args, evaluate=False)
Piecewise((1, -x < -1), (4, -x < -1), (2, True))
>>> Piecewise(*args)
Piecewise((1, x > 1), (2, True))
```

piecewise_integrate(x, **kwargs)
Return the Piecewise with each expression being replaced with its antiderivative. To obtain a continuous antiderivative, use the `integrate()` (page 657) function or method.
Examples

```python
>>> from sympy import Piecewise
>>> from sympy.abc import x
>>> p = Piecewise((0, x < 0), (1, x < 1), (2, True))
>>> p.piecewise_integrate(x)
Piecewise((0, x < 0), (x, x < 1), (2*x, True))
```

Note that this does not give a continuous function, e.g. at \(x = 1\) the 3rd condition applies and the antiderivative there is \(2x\) so the value of the antiderivative is 2:

```python
>>> anti = __
>>> anti.subs(x, 1)
2
```

The continuous derivative accounts for the integral up to the point of interest, however:

```python
>>> p.integrate(x)
Piecewise((0, x < 0), (x, x < 1), (2*x - 1, True))
```

```python
>>> _.subs(x, 1)
1
```

See also:

Piecewise._eval_integral (page 473)

sympy.functions.elementary.piecewise.piecewise_exclusive(expr, *, skip_nan=False, deep=True)

Rewrite Piecewise (page 472) with mutually exclusive conditions.

Parameters

expr: a SymPy expression.

Any Piecewise (page 472) in the expression will be rewritten.

skip_nan: `bool` (default `False`)

If skip_nan is set to True then a final NaN (page 1047) case will not be included.

deep: `bool` (default `True`)

If deep is True then piecewise_exclusive() (page 475) will rewrite any Piecewise (page 472) subexpressions in expr rather than just rewriting expr itself.

Returns

An expression equivalent to expr but where all Piecewise (page 472) have been rewritten with mutually exclusive conditions.
Explanation

SymPy represents the conditions of a `Piecewise` (page 472) in an “if-elif”-fashion, allowing more than one condition to be simultaneously True. The interpretation is that the first condition that is True is the case that holds. While this is a useful representation computationally it is not how a piecewise formula is typically shown in a mathematical text. The `piecewise_exclusive()` (page 475) function can be used to rewrite any `Piecewise` (page 472) with more typical mutually exclusive conditions.

Note that further manipulation of the resulting `Piecewise` (page 472), e.g. simplifying it, will most likely make it non-exclusive. Hence, this is primarily a function to be used in conjunction with printing the Piecewise or if one would like to reorder the expression-condition pairs.

If it is not possible to determine that all possibilities are covered by the different cases of the `Piecewise` (page 472) then a final `Nan` (page 1047) case will be included explicitly. This can be prevented by passing `skip_nan=True`.

Examples

```python
>>> from sympy import piecewise_exclusive, Symbol, Piecewise, S
>>> x = Symbol('x', real=True)
>>> p = Piecewise((0, x < 0), (S.Half, x <= 0), (1, True))
>>> piecewise_exclusive(p)
Piecewise((0, x < 0), (1/2, Eq(x, 0)), (1, x > 0))
>>> piecewise_exclusive(Piecewise((2, x > 1)))
Piecewise((2, x > 1), (nan, x <= 1))
>>> piecewise_exclusive(Piecewise((2, x > 1)), skip_nan=True)
Piecewise((2, x > 1))
```

See also:

`Piecewise` (page 472), `piecewise_fold` (page 476)

`sympy.functions.elementary.piecewise.piecewise_fold(expr, evaluate=True)`

Takes an expression containing a piecewise function and returns the expression in piecewise form. In addition, any ITE conditions are rewritten in negation normal form and simplified.

The final Piecewise is evaluated (default) but if the raw form is desired, send `evaluate=False`; if trivial evaluation is desired, send `evaluate=None` and duplicate conditions and processing of True and False will be handled.

Examples

```python
>>> from sympy import Piecewise, piecewise_fold, S
>>> from sympy.abc import x
>>> p = Piecewise((x, x < 1), (1, S(1) <= x))
>>> piecewise_fold(x**p)
Piecewise((x**2, x < 1), (x, True))
```

See also:

`Piecewise` (page 472), `piecewise_exclusive` (page 475)
Miscellaneous

class sympy.functions.elementary.miscellaneous.IdentityFunction

The identity function

Examples

```python
>>> from sympy import Id, Symbol
>>> x = Symbol('x')
>>> Id(x)
```

class sympy.functions.elementary.miscellaneous.Min(*args)

Return, if possible, the minimum value of the list. It is named Min and not min to avoid conflicts with the built-in function min.

Examples

```python
>>> from sympy import Min, Symbol, oo
>>> from sympy.abc import x, y
>>> p = Symbol('p', positive=True)
>>> n = Symbol('n', negative=True)

>>> Min(x, -2)
Min(-2, x)
>>> Min(x, -2).subs(x, 3)
-2
>>> Min(p, -3)
-3
>>> Min(x, y)
Min(x, y)
>>> Min(n, 8, p, -7, p, oo)
Min(-7, n)
```

See also:

Max (page 477)

find maximum values

class sympy.functions.elementary.miscellaneous.Max(*args)

Return, if possible, the maximum value of the list.

When number of arguments is equal one, then return this argument.

When number of arguments is equal two, then return, if possible, the value from \(a, b\) that is \(\geq\) the other.

In common case, when the length of list greater than 2, the task is more complicated. Return only the arguments, which are greater than others, if it is possible to determine directional relation.

If is not possible to determine such a relation, return a partially evaluated result.
Assumptions are used to make the decision too.
Also, only comparable arguments are permitted.
It is named Max and not max to avoid conflicts with the built-in function max.

**Examples**

```python
>>> from sympy import Max, Symbol, oo
>>> from sympy.abc import x, y, z
>>> p = Symbol('p', positive=True)
>>> n = Symbol('n', negative=True)

>>> Max(x, -2)
Max(-2, x)
>>> Max(x, -2).subs(x, 3)
3
>>> Max(p, -2)
p
>>> Max(x, y)
Max(x, y)
>>> Max(x, y) == Max(y, x)
True
>>> Max(x, Max(y, z))
Max(x, y, z)
>>> Max(n, 8, p, 7, -oo)
Max(8, p)
>>> Max(1, x, oo)
oo
```

- Algorithm

The task can be considered as searching of supremums in the directed complete partial orders [R303].
The source values are sequentially allocated by the isolated subsets in which supremums are searched and result as Max arguments.
If the resulted supremum is single, then it is returned.
The isolated subsets are the sets of values which are only the comparable with each other in the current set. E.g. natural numbers are comparable with each other, but not comparable with the $x$ symbol. Another example: the symbol $x$ with negative assumption is comparable with a natural number.
Also there are “least” elements, which are comparable with all others, and have a zero property (maximum or minimum for all elements). For example, in case of $\infty$, the allocation operation is terminated and only this value is returned.

**Assumption:**
- if $A > B > C$ then $A > C$
- if $A = B$ then $B$ can be removed

**See also:**
**Min** (page 477)
find minimum values

**References**

[R303], [R304]
sympy.functions.elementary.miscellaneous.\texttt{root}(arg, n, k=0, evaluate=None)

Returns the $k$-th $n$-th root of arg.

**Parameters**

- $k$ : int, optional
  Should be an integer in \{0, 1, ..., $n-1$\}. Defaults to the principal root if 0.

- evaluate : bool, optional
  The parameter determines if the expression should be evaluated. If None, its value is taken from \texttt{global\_parameters.evaluate}.

**Examples**

```python
>>> from sympy import root, Rational
>>> from sympy.abc import x, n

>>> root(x, 2)
sqrt(x)

>>> root(x, 3)
x**(1/3)

>>> root(x, n)
x**(1/n)

>>> root(x, -Rational(2, 3))
x**(-3/2)
```

To get the $k$-th $n$-th root, specify $k$:

```python
>>> root(-2, 3, 2)
-(-1)**(2/3)*2**(1/3)
```

To get all $n$ $n$-th roots you can use the \texttt{rootof} function. The following examples show the roots of unity for $n$ equal 2, 3 and 4:

```python
>>> from sympy import rootof

>>> [rootof(x**2 - 1, i) for i in range(2)]
[-1, 1]
```
SymPy, like other symbolic algebra systems, returns the complex root of negative numbers. This is the principal root and differs from the text-book result that one might be expecting. For example, the cube root of -8 does not come back as -2:

```
>>> root(-8, 3)
2*(-1)**(1/3)
```

The `real_root` function can be used to either make the principal result real (or simply to return the real root directly):

```
>>> from sympy import real_root
>>> real_root(_)
-2
>>> real_root(-32, 5)
-2
```

Alternatively, the \(n/2\)-th n-th root of a negative number can be computed with `root`:

```
>>> root(-32, 5, 5/2)
-2
```

See also:

- `sympy.polys.rootoftools.rootof` (page 2507), `sympy.core.power.integer_nthroot` (page 1057), `sqrt` (page 480), `real_root` (page 483)

References

[R305], [R306], [R307], [R308], [R309]
Examples

```python
>>> from sympy import sqrt, Symbol, S
>>> x = Symbol('x')
```

```python
>>> sqrt(x)
sqrt(x)
```

```python
>>> sqrt(x)**2
x
```

Note that sqrt(x**2) does not simplify to x.

```python
>>> sqrt(x**2)
sqrt(x**2)
```

This is because the two are not equal to each other in general. For example, consider x == -1:

```python
>>> from sympy import Eq
>>> Eq(sqrt(x**2), x).subs(x, -1)
False
```

This is because sqrt computes the principal square root, so the square may put the argument in a different branch. This identity does hold if x is positive:

```python
>>> y = Symbol('y', positive=True)
>>> sqrt(y**2)
y
```

You can force this simplification by using the powdenest() function with the force option set to True:

```python
>>> from sympy import powdenest
>>> sqrt(x**2)
sqrt(x**2)
>>> powdenest(sqrt(x**2), force=True)
x
```

To get both branches of the square root you can use the rootof function:

```python
>>> from sympy import rootof
>>> [rootof(x**2-3, i) for i in (0,1)]
[-sqrt(3), sqrt(3)]
```

Although sqrt is printed, there is no sqrt function so looking for sqrt in an expression will fail:

```python
>>> from sympy.utilities.misc import func_name
>>> func_name(sqrt(x))
'Pow'
>>> sqrt(x).has(sqrt)
False
```
To find $\sqrt{\cdot}$ look for Pow with an exponent of 1/2:

```python
>>> (x + 1/sqrt(x)).find(lambda i: i.is_Pow and abs(i.exp) is S.Half)
{1/sqrt(x)}
```

**See also:**

`sympy.polys.rootoftools.rootof` (page 2507), `root` (page 479), `real_root` (page 483)

**References**

[R310], [R311]

`sympy.functions.elementary.miscellaneous.cbrt(arg, evaluate=None)`

Returns the principal cube root.

**Parameters**

- `arg`
- `evaluate` : bool, optional

The parameter determines if the expression should be evaluated. If None, its value is taken from `global_parameters.evaluate`.

**Examples**

```python
>>> from sympy import cbrt, Symbol

>>> x = Symbol('x')

>>> cbrt(x)
x**(1/3)

>>> cbrt(x)**3
x
```

Note that $cbrt(x**3)$ does not simplify to $x$.

```python
>>> cbrt(x**3)
(x**3)**(1/3)
```

This is because the two are not equal to each other in general. For example, consider $x = -1$:

```python
>>> from sympy import Eq

>>> Eq(cbrt(x**3), x).subs(x, -1)
False
```

This is because `cbrt` computes the principal cube root, this identity does hold if $x$ is positive:

```python
>>> y = Symbol('y', positive=True)

>>> cbrt(y**3)
y
```

**See also:**

`sympy.polys.rootoftools.rootof` (page 2507), `root` (page 479), `real_root` (page 483)

References

[R312], [R313]

```
sympy.functions.elementary.miscellaneous.real_root(arg, n=None, evaluate=None)
```

Return the real n’th-root of arg if possible.

**Parameters**

- `n` : int or None, optional
  
  If n is None, then all instances of \((-n)^{1/\text{odd}}\) will be changed to \(-n^{1/\text{odd}}\). This will only create a real root of a principal root. The presence of other factors may cause the result to not be real.

- `evaluate` : bool, optional
  
  The parameter determines if the expression should be evaluated. If None, its value is taken from global_parameters.evaluate.

**Examples**

```
>>> from sympy import root, real_root

>>> real_root(-8, 3)
-2
```

If one creates a non-principal root and applies real_root, the result will not be real (so use with caution):

```
>>> root(-8, 3, 2)
-2*(-1)**(2/3)
```

**See also:**

- `sympy.polys.rootoftools.rootof` (page 2507), `sympy.core.power.integer_nthroot` (page 1057), `root` (page 479), `sqrt` (page 480)

**Combinatorial**

This module implements various combinatorial functions.

```
class sympy.functions.combinatorial.numbers.bell(n, k_sym=None, symbols=None)
```

Bell numbers / Bell polynomials

The Bell numbers satisfy \(B_0 = 1\) and

\[
B_n = \sum_{k=0}^{n-1} \binom{n-1}{k} B_k.
\]
They are also given by:

\[ B_n = \frac{1}{e} \sum_{k=0}^{\infty} \frac{k^n}{k!}. \]

The Bell polynomials are given by \( B_0(x) = 1 \) and

\[ B_n(x) = x \sum_{k=1}^{n-1} \binom{n-1}{k-1} B_{k-1}(x). \]

The second kind of Bell polynomials (are sometimes called “partial” Bell polynomials or incomplete Bell polynomials) are defined as

\[
B_{n,k}(x_1, x_2, \ldots, x_{n-k+1}) = \sum_{\substack{j_1+j_2+\cdots+j_{n-k+1}=n \\ j_1!j_2!\cdots j_{n-k+1}!}} \frac{n!}{j_1!j_2!\cdots j_{n-k+1}!} \frac{x_1^{j_1} x_2^{j_2} \cdots x_{n-k+1}^{j_{n-k+1}}}{(n-k+1)!}. \]

- \( \text{bell}(n) \) gives the \( n \text{th} \) Bell number, \( B_n \).
- \( \text{bell}(n, x) \) gives the \( n \text{th} \) Bell polynomial, \( B_n(x) \).
- \( \text{bell}(n, k, (x_1, x_2, \ldots)) \) gives Bell polynomials of the second kind, \( B_{n,k}(x_1, x_2, \ldots, x_{n-k+1}) \).

**Notes**

Not to be confused with Bernoulli numbers and Bernoulli polynomials, which use the same notation.

**Examples**

```python
>>> from sympy import bell, Symbol, symbols

>>> [bell(n) for n in range(11)]
[1, 1, 2, 5, 15, 52, 203, 877, 4140, 21147, 115975]

>>> bell(30)
84674901451180332450147

>>> bell(4, Symbol('t'))
t**4 + 6*t**3 + 7*t**2 + t

>>> bell(6, 2, symbols('x:6')[1:])
6*x1*x5 + 15*x2*x4 + 10*x3**2
```

**See also:**

class sympy.functions.combinatorial.numbers.bernoulli(n, x=None)

Bernoulli numbers / Bernoulli polynomials / Bernoulli function

The Bernoulli numbers are a sequence of rational numbers defined by $B_0 = 1$ and the recursive relation ($n > 0$):

$$n + 1 = \sum_{k=0}^{n} \binom{n+1}{k} B_k$$

They are also commonly defined by their exponential generating function, which is $\frac{x}{\exp(x) - 1}$. For odd indices $> 1$, the Bernoulli numbers are zero.

The Bernoulli polynomials satisfy the analogous formula:

$$B_n(x) = \sum_{k=0}^{n} (-1)^k \binom{n}{k} B_k x^{n-k}$$

Bernoulli numbers and Bernoulli polynomials are related as $B_n(1) = B_n$.

The generalized Bernoulli function $B(s, a)$ is defined for any complex $s$ and $a$, except where $a$ is a nonpositive integer and $s$ is not a nonnegative integer. It is an entire function of $s$ for fixed $a$, related to the Hurwitz zeta function by

$$B(s, a) = \begin{cases} -s\zeta(1-s, a) & s \neq 0 \\ 1 & s = 0 \end{cases}$$

When $s$ is a nonnegative integer this function reduces to the Bernoulli polynomials: $B(n, x) = B_n(x)$. When $a$ is omitted it is assumed to be 1, yielding the (ordinary) Bernoulli function which interpolates the Bernoulli numbers and is related to the Riemann zeta function.

We compute Bernoulli numbers using Ramanujan’s formula:

$$B_n = \frac{A(n) - S(n)}{\binom{n+3}{n}}$$

where:

$$A(n) = \begin{cases} \frac{n+3}{6} & n \equiv 0 \text{ or } 2 \pmod{6} \\ -\frac{n+3}{6} & n \equiv 4 \pmod{6} \end{cases}$$

and:

$$S(n) = \sum_{k=1}^{\lfloor n/6 \rfloor} \binom{n+3}{n-6k} B_{n-6k}$$

This formula is similar to the sum given in the definition, but cuts $\frac{2}{3}$ of the terms. For Bernoulli polynomials, we use Appell sequences.

For $n$ a nonnegative integer and $s, a, x$ arbitrary complex numbers,

- bernoulli(n) gives the nth Bernoulli number, $B_n$
- bernoulli(s) gives the Bernoulli function $B(s)$

5.8. Topics
• bernoulli(n, x) gives the nth Bernoulli polynomial in x, B_n(x)
• bernoulli(s, a) gives the generalized Bernoulli function B(s,a)

Changed in version 1.12: bernoulli(1) gives +\frac{1}{2} instead of −\frac{1}{2}. This choice of value confers several theoretical advantages [R205], including the extension to complex parameters described above which this function now implements. The previous behavior, defined only for nonnegative integers n, can be obtained with (-1)**n*bernoulli(n).

Examples

```python
>>> from sympy import bernoulli
>>> from sympy.abc import x
>>> [bernoulli(n) for n in range(11)]
[1, 1/2, 1/6, 0, -1/30, 0, 1/42, 0, -1/30, 0, 5/66]
>>> bernoulli(1000001)
0
>>> bernoulli(3, x)
x**3 - 3*x**2/2 + x/2
```

References

[R201], [R202], [R203], [R204], [R205], [R206]

class sympy.functions.combinatorial.factorials.binomial(n, k)

Implementation of the binomial coefficient. It can be defined in two ways depending on its desired interpretation:

\[
\binom{n}{k} = \frac{n!}{k!(n-k)!} \quad \text{or} \quad \binom{n}{k} = \frac{(n)_k}{k!}
\]

First, in a strict combinatorial sense it defines the number of ways we can choose k elements from a set of n elements. In this case both arguments are nonnegative integers and binomial is computed using an efficient algorithm based on prime factorization.

The other definition is generalization for arbitrary n, however k must also be nonnegative. This case is very useful when evaluating summations.

For the sake of convenience, for negative integer k this function will return zero no matter the other argument.

To expand the binomial when n is a symbol, use either expand_func() or expand(func=True). The former will keep the polynomial in factored form while the latter will expand the polynomial itself. See examples for details.
Examples

```python
>>> from sympy import Symbol, Rational, binomial, expand_func
>>> n = Symbol('n', integer=True, positive=True)

>>> binomial(15, 8)
6435

>>> binomial(n, -1)
0

Rows of Pascal’s triangle can be generated with the binomial function:

```python
>>> for N in range(8):
...     print([binomial(N, i) for i in range(N + 1)])
...
[1]
[1, 1]
[1, 2, 1]
[1, 3, 3, 1]
[1, 4, 6, 4, 1]
[1, 5, 10, 10, 5, 1]
[1, 6, 15, 20, 15, 6, 1]
[1, 7, 21, 35, 35, 21, 7, 1]
```

As can a given diagonal, e.g. the 4th diagonal:

```python
>>> N = -4
>>> [binomial(N, i) for i in range(1 - N)]
[1, -4, 10, -20, 35]

>>> binomial(Rational(5, 4), 3)
-5/128
>>> binomial(Rational(-5, 4), 3)
-195/128

>>> binomial(n, 3)
binomial(n, 3)

>>> binomial(n, 3).expand(func=True)
n**3/6 - n**2/2 + n/3

>>> expand_func(binomial(n, 3))
n*(n - 2)*(n - 1)/6
```
References

[R207]
class sympy.functions.combinatorial.numbers.catalan(n)

Catalan numbers
The \( n^{th} \) catalan number is given by:

\[
C_n = \frac{1}{n+1} \binom{2n}{n}
\]

- catalan(n) gives the \( n^{th} \) Catalan number, \( C_n \)

Examples

```python
>>> from sympy import (Symbol, binomial, gamma, hyper, ...
...                     catalan, diff, combsimp, Rational, I)
```

```python
>>> [catalan(i) for i in range(1,10)]
[1, 2, 5, 14, 42, 132, 429, 1430, 4862]
```

```python
>>> n = Symbol("n", integer=True)
```

```python
>>> catalan(n)
catalan(n)
```

Catalan numbers can be transformed into several other, identical expressions involving other mathematical functions

```python
>>> catalan(n).rewrite(binomial)
binomial(2*n, n)/(n + 1)
```

```python
>>> catalan(n).rewrite(gamma)
4**n*gamma(n + 1/2)/(sqrt(pi)*gamma(n + 2))
```

```python
>>> catalan(n).rewrite(hyper)
hyper((1 - n, -n), (2,), 1)
```

For some non-integer values of \( n \) we can get closed form expressions by rewriting in terms of gamma functions:

```python
>>> catalan(Rational(1, 2)).rewrite(gamma)
8/(3*pi)
```

We can differentiate the Catalan numbers \( C(n) \) interpreted as a continuous real function in \( n \):

```python
>>> diff(catalan(n), n)
(polygamma(0, n + 1/2) - polygamma(0, n + 2) + log(4))*catalan(n)
```

As a more advanced example consider the following ratio between consecutive numbers:
The Catalan numbers can be generalized to complex numbers:

```python
>>> catalan(I).rewrite(gamma)
4**I*gamma(1/2 + I)/(sqrt(pi)*gamma(2 + I))
```

and evaluated with arbitrary precision:

```python
>>> catalan(I).evalf(20)
0.39764993382373624267 - 0.020884341620842555705*I
```

References

[R208], [R209], [R210], [R211]

class sympy.functions.combinatorial.numbers.euler(n, x=None)
Euler numbers / Euler polynomials / Euler function

The Euler numbers are given by:

\[
E_{2n} = \sum_{k=1}^{2n+1} \left( \sum_{j=0}^{k} \frac{(-1)^{j}(k-2j)^{2n+1}}{2k!k!} \right)
\]

\[
E_{2n+1} = 0
\]

Euler numbers and Euler polynomials are related by

\[
E_n = 2^n E_n \left( \frac{1}{2} \right).
\]

We compute symbolic Euler polynomials using Appell sequences, but numerical evaluation of the Euler polynomial is computed more efficiently (and more accurately) using the mpmath library.

The Euler polynomials are special cases of the generalized Euler function, related to the Genocchi function as

\[
E(s, a) = -\frac{\zeta(s+1, a)}{s+1}
\]

with the limit of \( \psi \left( \frac{s+1}{2} \right) - \psi \left( \frac{s}{2} \right) \) being taken when \( s = -1 \). The (ordinary) Euler function interpolating the Euler numbers is then obtained as \( E(s) = 2^s E \left( s, \frac{1}{2} \right) \).

- euler(n) gives the nth Euler number \( E_n \).
- euler(s) gives the Euler function \( E(s) \).
- euler(n, x) gives the nth Euler polynomial \( E_n(x) \).
- euler(s, a) gives the generalized Euler function \( E(s, a) \).
Examples

```python
>>> from sympy import euler, Symbol, S
>>> [euler(n) for n in range(10)]
[1, 0, -1, 0, 5, 0, -61, 0, 1385, 0]
>>> [2**n*euler(n,1) for n in range(10)]
[1, 1, 0, -2, 0, 16, 0, -272, 0, 7936]
>>> n = Symbol("n")
>>> euler(n + 2*n)
euler(3*n)

>>> x = Symbol("x")
>>> euler(n, x)
euler(n, x)

>>> euler(0, x)
1
>>> euler(1, x)
x - 1/2
>>> euler(2, x)
x**2 - x
>>> euler(3, x)
x**3 - 3*x**2/2 + 1/4
>>> euler(4, x)
x**4 - 2*x**3 + x

>>> euler(12, S.Half)
2702765/4096
>>> euler(12)
2702765
```

See also:

andre (page 499), bell (page 483), bernoulli (page 485), catalan (page 488), fibonacci (page 494), harmonic (page 495), lucas (page 497), genocchi (page 498), partition (page 500), tribonacci (page 494), sympy.polys.appellseqs.euler_poly (page 2520)

References

[R212], [R213], [R214], [R215]

class sympy.functions.combinatorial.factorials.factorial(n)
Implementation of factorial function over nonnegative integers. By convention (consistent with the gamma function and the binomial coefficients), factorial of a negative integer is complex infinity.

The factorial is very important in combinatorics where it gives the number of ways in which \( n \) objects can be permuted. It also arises in calculus, probability, number theory, etc.

There is strict relation of factorial with gamma function. In fact \( n! = \text{gamma}(n + 1) \) for nonnegative integers. Rewrite of this kind is very useful in case of combinatorial simplification.
Computation of the factorial is done using two algorithms. For small arguments a pre-computed look up table is used. However for bigger input algorithm Prime-Swing is used. It is the fastest algorithm known and computes $n!$ via prime factorization of special class of numbers, called here the ‘Swing Numbers’.

### Examples

```python
>>> from sympy import Symbol, factorial, S
>>> n = Symbol('n', integer=True)

>>> factorial(0)
1
>>> factorial(7)
5040
>>> factorial(-2)
zoo
>>> factorial(n)
factorial(n)
>>> factorial(2*n)
factorial(2*n)
>>> factorial(S(1)/2)
factorial(1/2)
```

See also:

*factorial2* (page 492), *RisingFactorial* (page 500), *FallingFactorial* (page 493)

class sympy.functions.combinatorial.factorials.subfactorial(arg)
The subfactorial counts the derangements of $n$ items and is defined for non-negative integers as:

\[
!n = \begin{cases} 
1 & n = 0 \\
0 & n = 1 \\
(n - 1)!(n - 1)! + !(n - 2) & n > 1 
\end{cases}
\]

It can also be written as \(\text{int}(\text{round}(n!/\exp(1)))\) but the recursive definition with caching is implemented for this function.

An interesting analytic expression is the following [R217]

\[
!x = \Gamma(x + 1, -1)/e
\]

which is valid for non-negative integers $x$. The above formula is not very useful in case of non-integers. $\Gamma(x + 1, -1)$ is single-valued only for integral arguments $x$, elsewhere on the positive real axis it has an infinite number of branches none of which are real.
Examples

```python
>>> from sympy import subfactorial
>>> from sympy import subfactorial
>>> subfactorial(n + 1)
subfactorial(n + 1)
>>> subfactorial(5)
44
```

`factorial` (page 490), `uppergamma` (page 523), `sympy.utilities.iterables.generate_derangements` (page 2146)

References

[R216], [R217]

class sympy.functions.combinatorial.factorials.factorial2(arg)
The double factorial n!!, not to be confused with (n!)!
The double factorial is defined for nonnegative integers and for odd negative integers as:

\[
n!! = \begin{cases} 
1 & n = 0 \\
(n-2)(n-4)\ldots1 & n \text{ positive odd} \\
n(n-2)(n-4)\ldots2 & n \text{ positive even} \\
(n+2)!!/(n+2) & n \text{ negative odd}
\end{cases}
\]

Examples

```python
>>> from sympy import factorial2, var
>>> n = var('n')
>>> n
n
>>> factorial2(n + 1)
factorial2(n + 1)
>>> factorial2(5)
15
>>> factorial2(-1)
1
>>> factorial2(-5)
1/3
```

See also:

`factorial` (page 490), `RisingFactorial` (page 500), `FallingFactorial` (page 493)
References

[R218]

class sympy.functions.combinatorial.factorials.FallingFactorial(x, k)

Falling factorial (related to rising factorial) is a double valued function arising in concrete mathematics, hypergeometric functions and series expansions. It is defined by

\[
ff(x, \, k) = (x)_k = x \cdot (x-1) \cdots (x-k+1)
\]

where \( x \) can be arbitrary expression and \( k \) is an integer. For more information check “Concrete mathematics” by Graham, pp. 66 or [R219].

When \( x \) is a \( Poly \) instance of degree \( \geq 1 \) with single variable, \( (x)_k = x(y) \cdot x(y-1) \cdots x(y-k+1) \), where \( y \) is the variable of \( x \). This is as described in

```python
>>> from sympy import ff, Poly, Symbol
>>> from sympy.abc import x
>>> n = Symbol('n', integer=True)
```

```python
>>> ff(x, 0)
1
>>> ff(5, 5)
120
>>> ff(x, 5) == x*(x - 1)*(x - 2)*(x - 3)*(x - 4)
True
>>> ff(Poly(x**2, x), 2)
Poly(x**4 - 2*x**3 + x**2, x, domain='ZZ')
>>> ff(n, n)
factorial(n)
```

Rewriting is complicated unless the relationship between the arguments is known, but falling factorial can be rewritten in terms of gamma, factorial and binomial and rising factorial.

```python
>>> from sympy import factorial, rf, gamma, binomial, Symbol
>>> n = Symbol('n', integer=True, positive=True)
>>> F = ff(n, n - 2)
>>> for i in (rf, ff, factorial, binomial, gamma):
...     F.rewrite(i)
...     RisingFactorial(3, n - 2)
     FallingFactorial(n, n - 2)
     factorial(n)/2
     binomial(n, n - 2)*factorial(n - 2)
     gamma(n + 1)/2
```

See also:

factorial (page 490), factorial2 (page 492), RisingFactorial (page 500)
class sympy.functions.combinatorial.numbers.fibonacci(n, sym=None)

Fibonacci numbers / Fibonacci polynomials

The Fibonacci numbers are the integer sequence defined by the initial terms \( F_0 = 0 \), \( F_1 = 1 \) and the two-term recurrence relation \( F_n = F_{n-1} + F_{n-2} \). This definition extended to arbitrary real and complex arguments using the formula

\[
F_z = \frac{\phi^z - \cos(\pi z)\phi^{-z}}{\sqrt{5}}
\]

The Fibonacci polynomials are defined by \( F_1(x) = 1 \), \( F_2(x) = x \), and \( F_n(x) = x \cdot F_{n-1}(x) + F_{n-2}(x) \) for \( n > 2 \). For all positive integers \( n \), \( F_n(1) = F_n \).

- fibonacci(n) gives the \( n^{th} \) Fibonacci number, \( F_n \)
- fibonacci(n, x) gives the \( n^{th} \) Fibonacci polynomial in \( x \), \( F_n(x) \)

Examples

```python
>>> from sympy import fibonacci, Symbol

>>> [fibonacci(x) for x in range(11)]
[0, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55]

>>> fibonacci(5, Symbol('t'))
t**4 + 3*t**2 + 1
```

See also:

References

[R222], [R223]

class sympy.functions.combinatorial.numbers.tribonacci(n, sym=None)

Tribonacci numbers / Tribonacci polynomials

The Tribonacci numbers are the integer sequence defined by the initial terms \( T_0 = 0 \), \( T_1 = 1 \), \( T_2 = 1 \) and the three-term recurrence relation \( T_n = T_{n-1} + T_{n-2} + T_{n-3} \).

The Tribonacci polynomials are defined by \( T_0(x) = 0 \), \( T_1(x) = 1 \), \( T_2(x) = x^2 \), and \( T_n(x) = x^2 T_{n-1}(x) + x T_{n-2}(x) + T_{n-3}(x) \) for \( n > 2 \). For all positive integers \( n \), \( T_n(1) = T_n \).

- tribonacci(n) gives the \( n^{th} \) Tribonacci number, \( T_n \)
- tribonacci(n, x) gives the \( n^{th} \) Tribonacci polynomial in \( x \), \( T_n(x) \)
Examples

```python
>>> from sympy import tribonacci, Symbol

>>> [tribonacci(x) for x in range(11)]
[0, 1, 1, 2, 4, 7, 13, 24, 44, 81, 149]

>>> tribonacci(5, Symbol('t'))
t**8 + 3*t**5 + 3*t**2
```

See also:

References

[R224], [R225], [R226]

class sympy.functions.combinatorial.numbers.harmonic(n, m=None)
Harmonic numbers

The nth harmonic number is given by $H_n = 1 + \frac{1}{2} + \frac{1}{3} + \ldots + \frac{1}{n}$.

More generally:

$$H_{n,m} = \sum_{k=1}^{n} \frac{1}{k^m}$$

As $n \to \infty$, $H_{n,m} \to \zeta(m)$, the Riemann zeta function.

- harmonic(n) gives the nth harmonic number, $H_n$
- harmonic(n, m) gives the nth generalized harmonic number of order $m$, $H_{n,m}$, where harmonic(n) == harmonic(n, 1)

This function can be extended to complex $n$ and $m$ where $n$ is not a negative integer or $m$ is a nonpositive integer as

$$H_{n,m} = \begin{cases} 
\zeta(m) - \zeta(m, n + 1) & m \neq 1 \\
\psi(n + 1) + \gamma & m = 1
\end{cases}$$

Examples

```python
>>> from sympy import harmonic, oo

>>> [harmonic(n) for n in range(6)]
[0, 1, 3/2, 11/6, 25/12, 137/60]

>>> [harmonic(n, 2) for n in range(6)]
[0, 1, 5/4, 49/36, 205/144, 5269/3600]

>>> harmonic(oo, 2)
pi**2/6
```
```python
>>> from sympy import Symbol, Sum
>>> n = Symbol("n")

>>> harmonic(n).rewrite(Sum)
Sum(1/_k, (_k, 1, n))

We can evaluate harmonic numbers for all integral and positive rational arguments:

```python
>>> from sympy import S, expand_func, simplify

>>> harmonic(8)
761/280

>>> harmonic(11)
83711/27720

>>> H = harmonic(1/S(3))

>>> H
harmonic(1/3)

>>> He = expand_func(H)

>>> He
-log(6) - sqrt(3)*pi/6 + 2*Sum(log(sin(_k*pi/3))*cos(2*_k*pi/3), (_k, 1, _-1))
  + 3*Sum(1/(3*_k + 1), (_k, 0, 0))

>>> He.doit()
-log(6) - sqrt(3)*pi/6 - log(sqrt(3)/2) + 3

>>> H = harmonic(25/S(7))

>>> He = simplify(expand_func(H).doit())

>>> He
log(sin(2*pi/7)**(2*cos(16*pi/7))/(14*sin(pi/7)**(2*cos(pi/7)))*cos(pi/14)**(2*sin(pi/14))) + pi*tan(pi/14)/2 + 30247/9900

>>> He.n(40)
1.98369745523298067469851942390639915940

>>> harmonic(25/S(7)).n(40)
1.98369745523298067469851942390639915940

We can rewrite harmonic numbers in terms of polygamma functions:

```python
>>> from sympy import digamma, polygamma
>>> m = Symbol("m", integer=True, positive=True)

>>> harmonic(n).rewrite(digamma)
polygamma(0, n + 1) + EulerGamma

>>> harmonic(n).rewrite(polygamma)
polygamma(0, n + 1) + EulerGamma

>>> harmonic(n, 3).rewrite(polygamma)
polygamma(2, n + 1)/2 + zeta(3)

>>> simplify(harmonic(n, m).rewrite(polygamma))
Piecewise((polygamma(0, n + 1) + EulerGamma, Eq(m, 1)),
(-(-1)**m*polygamma(m - 1, n + 1)/factorial(m - 1) + zeta(m), True))
```
Integer offsets in the argument can be pulled out:

```python
>>> from sympy import expand_func

>>> expand_func(harmonic(n+4))
harmonic(n) + 1/(n + 4) + 1/(n + 3) + 1/(n + 2) + 1/(n + 1)

>>> expand_func(harmonic(n-4))
harmonic(n) - 1/(n - 1) - 1/(n - 2) - 1/(n - 3) - 1/n
```

Some limits can be computed as well:

```python
>>> from sympy import limit, oo

>>> limit(harmonic(n), n, oo)
oo

>>> limit(harmonic(n, 2), n, oo)
pi**2/6

>>> limit(harmonic(n, 3), n, oo)
zeta(3)
```

For $m > 1$, $H_{n,m}$ tends to $\zeta(m)$ in the limit of infinite $n$:

```python
>>> m = Symbol("m", positive=True)
>>> limit(harmonic(n, m+1), n, oo)
zeta(m + 1)
```

**class** `sympy.functions.combinatorial.numbers.lucas(n)`

Lucas numbers

Lucas numbers satisfy a recurrence relation similar to that of the Fibonacci sequence, in which each term is the sum of the preceding two. They are generated by choosing the initial values $L_0 = 2$ and $L_1 = 1$.

- *lucas(n)* gives the $n^{th}$ Lucas number
Examples

```python
>>> from sympy import lucas

>>> [lucas(x) for x in range(11)]
[2, 1, 3, 4, 7, 11, 18, 29, 47, 76, 123]
```

class sympy.functions.combinatorial.numbers.genocchi(n, x=None)

Genocchi numbers / Genocchi polynomials / Genocchi function

The Genocchi numbers are a sequence of integers $G_n$ that satisfy the relation:

$$
\frac{-2t}{1+e^{-t}} = \sum_{n=0}^{\infty} \frac{G_n t^n}{n!}
$$

They are related to the Bernoulli numbers by

$$
G_n = 2(1 - 2^n)B_n
$$

and generalize like the Bernoulli numbers to the Genocchi polynomials and function as

$$
G(s, a) = 2 \left( B(s, a) - 2^s B \left( s, \frac{a+1}{2} \right) \right)
$$

Changed in version 1.12: genocchi(1) gives $-1$ instead of 1.

Examples

```python
>>> from sympy import genocchi, Symbol

>>> [genocchi(n) for n in range(9)]
[0, -1, -1, 0, 1, 0, -3, 0, 17]

>>> n = Symbol('n', integer=True, positive=True)
>>> genocchi(2*n + 1)
0

>>> x = Symbol('x')
>>> genocchi(4, x)
-4*x**3 + 6*x**2 - 1
```

- harmonic (page 495)
- lucas (page 497)
- partition (page 500)
- tribonacci (page 494)
- sympy.polys.appellseqs.genocchi_poly (page 2519)
class sympy.functions.combinatorial.numbers.andre(n)

Andre numbers / Andre function

The Andre number $A_n$ is Luschny’s name for half the number of alternating permutations on $n$ elements, where a permutation is alternating if adjacent elements alternately compare “greater” and “smaller” going from left to right. For example, $2 < 3 > 1 < 4$ is an alternating permutation.

This sequence is A000111 in the OEIS, which assigns the names up/down numbers and Euler zigzag numbers. It satisfies a recurrence relation similar to that for the Catalan numbers, with $A_0 = 1$ and

$$2A_{n+1} = \sum_{k=0}^{n} \binom{n}{k} A_k A_{n-k}$$

The Bernoulli and Euler numbers are signed transformations of the odd- and even-indexed elements of this sequence respectively:

$$B_{2k} = \frac{2kA_{2k-1}}{(-4)^k - (-16)^k}$$

$$E_{2k} = (-1)^k A_{2k}$$

Like the Bernoulli and Euler numbers, the Andre numbers are interpolated by the entire Andre function:

$$A(s) = (-i)^{s+1} \text{Li}_{-s}(i) + i^{s+1} \text{Li}_{-s}(-i) = \frac{2\Gamma(s+1)}{(2\pi)^{s+1}} (\zeta(s+1,1/4) - \zeta(s+1,3/4) \cos \pi s)$$

Examples

```python
>>> from sympy import andre, euler, bernoulli
>>> [andre(n) for n in range(11)]
[1, 1, 1, 2, 5, 16, 61, 272, 1385, 7936, 50521]
>>> [(1)**k * andre(2**k) for k in range(7)]
[1, -1, 5, -61, 1385, -50521, 2702765]
>>> [euler(2**k) for k in range(7)]
[1, -1, 5, -61, 1385, -50521, 2702765]
>>> [andre(2**k-1) * (2**k) / ((-4)**k - (-16)**k) for k in range(1, 8)]
[1/6, -1/30, 1/42, -1/30, 5/66, -691/2730, 7/6]
>>> [bernoulli(2**k) for k in range(1, 8)]
[1/6, -1/30, 1/42, -1/30, 5/66, -691/2730, 7/6]
```

See also:

bernoulli (page 485), catalan (page 488), euler (page 489), sympy.polys. appellseqs.andre_poly (page 2520)
class sympy.functions.combinatorial.numbers.partition(n)

Partition numbers

The Partition numbers are a sequence of integers $p_n$ that represent the number of distinct ways of representing $n$ as a sum of natural numbers (with order irrelevant). The generating function for $p_n$ is given by:

$$
\sum_{n=0}^{\infty} p_n x^n = \prod_{k=1}^{\infty} (1 - x^k)^{-1}
$$

Examples

```python
>>> from sympy import partition, Symbol
>>> [partition(n) for n in range(9)]
[1, 1, 2, 3, 5, 7, 11, 15, 22]
>>> n = Symbol('n', integer=True, negative=True)
>>> partition(n)
```

See also:

References

[R238], [R239]

class sympy.functions.combinatorial.factorials.MultiFactorial(*args)

class sympy.functions.combinatorial.factorials.RisingFactorial(x, k)

Rising factorial (also called Pochhammer symbol [R240]) is a double valued function arising in concrete mathematics, hypergeometric functions and series expansions. It is defined by:

$$
rf(y, k) = (x)^k = x \cdot (x+1) \cdots (x+k-1)
$$

where $x$ can be arbitrary expression and $k$ is an integer. For more information check “Concrete mathematics” by Graham, pp. 66 or visit https://mathworld.wolfram.com/RisingFactorial.html page.

When $x$ is a .Poly instance of degree $\geq 1$ with a single variable, $(x)^k = x(y) \cdot x(y+1) \cdots x(y+k-1)$, where $y$ is the variable of $x$. This is as described in [R241].
Examples

```python
>>> from sympy import rf, Poly
>>> from sympy.abc import x

>>> rf(x, 0)
1
>>> rf(1, 5)
120
>>> rf(x, 5) == x*(1 + x)*(2 + x)*(3 + x)*(4 + x)
True
>>> rf(Poly(x**3, x), 2)
Poly(x**6 + 3*x**5 + 3*x**4 + x**3, x, domain='ZZ')
```

Rewriting is complicated unless the relationship between the arguments is known, but rising factorial can be rewritten in terms of gamma, factorial, binomial, and falling factorial.

```python
>>> from sympy import Symbol, factorial, ff, binomial, gamma

>>> n = Symbol('n', integer=True, positive=True)
>>> R = rf(n, n + 2)

>>> for i in (rf, ff, factorial, binomial, gamma):
...     R.rewrite(i)

RisingFactorial(n, n + 2)
FallingFactorial(2*n + 1, n + 2)
factorial(2*n + 1)/factorial(n - 1)
binomial(2*n + 1, n + 2)*factorial(n + 2)
gamma(2*n + 2)/gamma(n)
```

SymPy Documentation, Release 1.12.1

5.8. Topics 501

sympy.functions.combinatorial.numbers.stirling(n, k, d=None, kind=2, signed=False)

Return Stirling number $S(n,k)$ of the first or second (default) kind.

The sum of all Stirling numbers of the second kind for $k = 1$ through $n$ is bell(n). The recurrence relationship for these numbers is:

\[
\begin{align*}
\{0\} &= 1; \\
\{n\} &= 0; \\
\{n + 1\} &= j\{n\} + \binom{n}{k - 1}
\end{align*}
\]

where $j$ is:

$n$ for Stirling numbers of the first kind, $-n$ for signed Stirling numbers of the first kind, $k$ for Stirling numbers of the second kind.
The first kind of Stirling number counts the number of permutations of \( n \) distinct items that have \( k \) cycles; the second kind counts the ways in which \( n \) distinct items can be partitioned into \( k \) parts. If \( d \) is given, the “reduced Stirling number of the second kind” is returned: 

\[
S_{d}(n, k) = S(n - d + 1, k - d + 1)
\]

with \( n \geq k \geq d \). (This counts the ways to partition \( n \) consecutive integers into \( k \) groups with no pairwise difference less than \( d \). See example below.)

To obtain the signed Stirling numbers of the first kind, use keyword signed=True. Using this keyword automatically sets kind to 1.

**Examples**

```python
>>> from sympy.functions.combinatorial.numbers import stirling, bell
>>> from sympy.combinatorics import Permutation
>>> from sympy.utilities.iterables import multiset_partitions,

First kind (unsigned by default):

```python
>>> [stirling(6, i, kind=1) for i in range(7)]
[0, 120, 274, 225, 85, 15, 1]
```  
```python
>>> perms = list(permutations(range(4)))
>>> [sum(Permutation(p).cycles == i for p in perms) for i in range(5)]
[0, 6, 11, 6, 1]
```  
```python
>>> [stirling(4, i, kind=1) for i in range(5)]
[0, 6, 11, 6, 1]
```  
First kind (signed):

```python
>>> [stirling(4, i, signed=True) for i in range(5)]
[0, -6, 11, -6, 1]
```  
Second kind:

```python
>>> [stirling(10, i) for i in range(12)]
[0, 1, 511, 9330, 34105, 42525, 22827, 5880, 750, 45, 1, 0]
```  
```python
>>> sum(_) == bell(10)
True
>>> len(list(multiset_partitions(range(4), 2))) == stirling(4, 2)
True
```  
Reduced second kind:

```python
>>> from sympy import subsets, oo
>>> def delta(p):
...    if len(p) == 1:
...        return oo
...    return min(abs(i[0] - i[1]) for i in subsets(p, 2))
>>> parts = multiset_partitions(range(5), 3)
>>> d = 2
>>> sum(1 for p in parts if all(delta(i) >= d for i in p))
7
>>> stirling(5, 3, 2)
7
```
See also:

*sympy.utilities.iterables.multiset_partitions* (page 2154)

References

[R242], [R243]

Enumeration

Three functions are available. Each of them attempts to efficiently compute a given combinatorial quantity for a given set or multiset which can be entered as an integer, sequence or multiset (dictionary with elements as keys and multiplicities as values). The k parameter indicates the number of elements to pick (or the number of partitions to make). When k is None, the sum of the enumeration for all k (from 0 through the number of items represented by n) is returned. A replacement parameter is recognized for combinations and permutations; this indicates that any item may appear with multiplicity as high as the number of items in the original set.

```python
>>> from sympy.functions.combinatorial.numbers import nC
>>> nC(3, 2)
3
>>> nC('abc', 2)
3
>>> nC('aab', 2)
2
```

When replacement is True, each item can have multiplicity equal to the length represented by n:
>>> nC('aabc', replacement=True)
35
>>> [len(list(multiset_combinations('aaaabbbcccc', i))) for i in
range(5)]
[1, 3, 6, 10, 15]
>>> sum(_)
35

If there are \( k \) items with multiplicities \( m_1, m_2, \ldots, m_k \) then the total of all combinations of length 0 through \( k \) is the product, \((m_1 + 1)*(m_2 + 1)*\ldots*(m_k + 1)\). When the multiplicity of each item is 1 (i.e., \( k \) unique items) then there are \( 2**k \) combinations. For example, if there are 4 unique items, the total number of combinations is 16:

>>> sum(nC(4, i) for i in range(5))
16

See also:

sympy.utilities.iterables.multiset_combinations (page 2153)

References

[R244], [R245]
sympy.functions.combinatorial.numbers.nP(n, k=None, replacement=False)
Return the number of permutations of \( n \) items taken \( k \) at a time.
Possible values for \( n \):
- integer - set of length \( n \)
- sequence - converted to a multiset internally
- multiset - \{element: multiplicity\}
If \( k \) is None then the total of all permutations of length 0 through the number of items represented by \( n \) will be returned.
If replacement is True then a given item can appear more than once in the \( k \) items. (For example, for ‘ab’ permutations of 2 would include ‘aa’, ‘ab’, ‘ba’ and ‘bb’.) The multiplicity of elements in \( n \) is ignored when replacement is True but the total number of elements is considered since no element can appear more times than the number of elements in \( n \).

Examples

>>> from sympy.functions.combinatorial.numbers import nP
>>> from sympy.utilities.iterables import multiset_permutations, multiset
>>> nP(3, 2)
6
>>> nP('abc', 2) == nP(multiset('abc'), 2) == 6
True
>>> nP('aab', 2)
3
(continues on next page)
When replacement is True, each item can have multiplicity equal to the length represented by n:

```
>>> nP('aabc', replacement=True)
121
>>> [len(list(multiset_permutations('aaaabbbcccc', i))) for i in range(5)]
[1, 3, 9, 27, 81]
>>> sum(_)
121
```

See also:

`sympy.utilities.iterables.multiset_permutations` (page 2156)

References

[R246]

`sympy.functions.combinatorial.numbers.nT(n, k=None)`

Return the number of k-sized partitions of n items.

Possible values for n:
- integer - n identical items
- sequence - converted to a multiset internally
- multiset - {element: multiplicity}

Note: the convention for nT is different than that of nC and nP in that here an integer indicates n identical items instead of a set of length n; this is in keeping with the partitions function which treats its integer-n input like a list of n 1s. One can use `range(n)` for n to indicate n distinct items.

If k is None then the total number of ways to partition the elements represented in n will be returned.

Examples

```
>>> from sympy.functions.combinatorial.numbers import nT
```

Partitions of the given multiset:

```
>>> [nT('aabbc', i) for i in range(1, 7)]
[1, 8, 11, 5, 1, 0]
```
>>> \texttt{nT('aabbc') == sum(_)}
True

>>> \texttt{[nT("mississippi", i) for i in range(1, 12)]}
[1, 74, 609, 1521, 1768, 1224, 579, 197, 50, 9, 1]

Partitions when all items are identical:

>>> \texttt{[nT(5, i) for i in range(1, 6)]}
[1, 2, 2, 1, 1]

When all items are different:

>>> \texttt{[nT(range(5), i) for i in range(1, 6)]}
[1, 15, 25, 10, 1]

Partitions of an integer expressed as a sum of positive integers:

>>> \texttt{from sympy import partition}

>>> \texttt{partition(4)}
5

>>> \texttt{nT(4, 1) + nT(4, 2) + nT(4, 3) + nT(4, 4)}
5

>>> \texttt{nT('1**4')}
5

See also:

[R247]

Special

Dirac Delta and Related Discontinuous Functions

\texttt{class sympy.functions.special.delta_functions.DiracDelta}(\texttt{arg}, \texttt{k=0})

The DiracDelta function and its derivatives.
Explanation

DiracDelta is not an ordinary function. It can be rigorously defined either as a distribution or as a measure.

DiracDelta only makes sense in definite integrals, and in particular, integrals of the form \( \int f(x) \text{DiracDelta}(x - x_0) \, dx \), where it equals \( f(x_0) \) if \( a \leq x_0 \leq b \) and 0 otherwise. Formally, DiracDelta acts in some ways like a function that is 0 everywhere except at 0, but in many ways it also does not. It can often be useful to treat DiracDelta in formal ways, building up and manipulating expressions with delta functions (which may eventually be integrated), but care must be taken to not treat it as a real function. SymPy's oo is similar. It only truly makes sense formally in certain contexts (such as integration limits), but SymPy allows its use everywhere, and it tries to be consistent with operations on it (like 1/oo), but it is easy to get into trouble and get wrong results if oo is treated too much like a number. Similarly, if DiracDelta is treated too much like a function, it is easy to get wrong or nonsensical results.

DiracDelta function has the following properties:

1) \( \frac{d}{dx} \delta(x) = \delta(x) \)
2) \( \int_{-\infty}^{\infty} \delta(x-a) f(x) \, dx = f(a) \) and \( \int_{a-\varepsilon}^{a+\varepsilon} \delta(x-a) f(x) \, dx = f(a) \)
3) \( \delta(x) = 0 \) for all \( x \neq 0 \)
4) \( \delta(g(x)) = \sum \frac{\delta(x-x_i)}{||g'(x)||} \) where \( x_i \) are the roots of \( g \)
5) \( \delta(-x) = \delta(x) \)

Derivatives of k-th order of DiracDelta have the following properties:
6) \( \delta(x,k) = 0 \) for all \( x \neq 0 \)
7) \( \delta(-x,k) = -\delta(x,k) \) for odd \( k \)
8) \( \delta(-x,k) = \delta(x,k) \) for even \( k \)

Examples

```python
>>> from sympy import DiracDelta, diff, pi
>>> from sympy.abc import x, y

>>> DiracDelta(x)
DiracDelta(x)
>>> DiracDelta(1)
0
>>> DiracDelta(-1)
0
>>> DiracDelta(pi)
0
>>> DiracDelta(x - 4).subs(x, 4)
DiracDelta(0)
>>> diff(DiracDelta(x))
DiracDelta(x, 1)
>>> diff(DiracDelta(x - 1), x, 2)
DiracDelta(x - 1, 2)
```

classmethod eval(arg, k=0)
Returns a simplified form or a value of DiracDelta depending on the argument passed by the DiracDelta object.

Parameters
k : integer
order of derivative
arg : argument passed to DiracDelta

Explanation
The eval() method is automatically called when the DiracDelta class is about to be instantiated and it returns either some simplified instance or the unevaluated instance depending on the argument passed. In other words, eval() method is not needed to be called explicitly, it is being called and evaluated once the object is called.

Examples

```python
>>> from sympy import DiracDelta, S
>>> from sympy.abc import x

>>> DiracDelta(x)
DiracDelta(x)

>>> DiracDelta(-x, 1)
-DiracDelta(x, 1)
```
```python
>>> DiracDelta(1)
0

>>> DiracDelta(5, 1)
0

>>> DiracDelta(0)
DiracDelta(0)

>>> DiracDelta(-1)
0

>>> DiracDelta(S.NaN)
nan

>>> DiracDelta(x - 100).subs(x, 5)
0

>>> DiracDelta(x - 100).subs(x, 100)
DiracDelta(0)
```

**fdiff(argindex=1)**

Returns the first derivative of a DiracDelta Function.

**Parameters**

- **argindex**: integer
  - degree of derivative

**Explanation**

The difference between diff() and fdiff() is: diff() is the user-level function and fdiff() is an object method. fdiff() is a convenience method available in the Function class. It returns the derivative of the function without considering the chain rule. diff(function, x) calls Function._eval_derivative which in turn calls fdiff() internally to compute the derivative of the function.

**Examples**

```python
>>> from sympy import DiracDelta, diff

>>> from sympy.abc import x

>>> DiracDelta(x).fdiff()
DiracDelta(x, 1)

>>> DiracDelta(x, 1).fdiff()
DiracDelta(x, 2)
```
is_simple(x)
Tells whether the argument(args[0]) of DiracDelta is a linear expression in x.

Parameters
x : can be a symbol

Examples

```python
>>> from sympy import DiracDelta, cos
>>> from sympy.abc import x, y

>>> DiracDelta(x*y).is_simple(x)
True
>>> DiracDelta(x*y).is_simple(y)
True

>>> DiracDelta(x**2 + x - 2).is_simple(x)
False

>>> DiracDelta(cos(x)).is_simple(x)
False
```

See also:
sympy.simplify.simplify.simplify (page 719), DiracDelta (page 506)

class sympy.functions.special.delta_functions.Heaviside(arg, H0=1/2)
Heaviside step function.

Explanation

The Heaviside step function has the following properties:

1) \( \frac{d}{dx} \theta(x) = \delta(x) \)

2) \( \theta(x) = \begin{cases} 0 & \text{for } x < 0 \\ \frac{1}{2} & \text{for } x = 0 \\ 1 & \text{for } x > 0 \end{cases} \)

3) \( \frac{d}{dx} \max(x, 0) = \theta(x) \)

Heaviside(x) is printed as \( \theta(x) \) with the SymPy LaTeX printer.

The value at 0 is set differently in different fields. SymPy uses 1/2, which is a convention from electronics and signal processing, and is consistent with solving improper integrals by Fourier transform and convolution.
To specify a different value of Heaviside at x=0, a second argument can be given. Using `Heaviside(x, nan)` gives an expression that will evaluate to nan for x=0.

Changed in version 1.9: Heaviside(0) now returns 1/2 (before: undefined)

**Examples**

```python
>>> from sympy import Heaviside, nan
>>> from sympy.abc import x
>>> Heaviside(9)
1
>>> Heaviside(-9)
0
>>> Heaviside(0)
1/2
>>> Heaviside(0, nan)
nan
>>> (Heaviside(x) + 1).replace(Heaviside(x), Heaviside(x, 1))
Heaviside(x, 1) + 1
```

See also:

`DiracDelta` (page 506)

**References**

[R315], [R316]

```python
classmethod eval(arg, H0=1/2)
```

Returns a simplified form or a value of Heaviside depending on the argument passed by the Heaviside object.

**Parameters**

- `arg`: argument passed by Heaviside object
- `H0`: value of Heaviside(0)

**Explanation**

The `eval()` method is automatically called when the `Heaviside` class is about to be instantiated and it returns either some simplified instance or the unevaluated instance depending on the argument passed. In other words, `eval()` method is not needed to be called explicitly, it is being called and evaluated once the object is called.
Examples

```python
from sympy import Heaviside, S
from sympy.abc import x

Heaviside(x)
Heaviside(x)

Heaviside(19)
1

Heaviside(0)
1/2

Heaviside(0, 1)
1

Heaviside(-5)
0

Heaviside(S.NaN)
nan

Heaviside(x - 100).subs(x, 5)
0

Heaviside(x - 100).subs(x, 105)
1
```

**fdiff(argindex=1)**

Returns the first derivative of a Heaviside Function.

**Parameters**

- **argindex**: integer
  - order of derivative

**Examples**

```python
from sympy import Heaviside, diff
from sympy.abc import x

Heaviside(x).fdiff()
DiracDelta(x)

Heaviside(x**2 - 1).fdiff()
DiracDelta(x**2 - 1)
```
property pargs
    Args without default S.Half

class sympy.functions.special.singularity_functions.SingularityFunction(`variable`, `offset`, `exponent`)

Singularity functions are a class of discontinuous functions.

Explanation

Singularity functions take a variable, an offset, and an exponent as arguments. These functions are represented using Macaulay brackets as:

\[ \text{SingularityFunction}(x, a, n) := <x - a>^n \]

The singularity function will automatically evaluate to \( \text{Derivative}(\text{DiracDelta}(x - a), x, -n - 1) \) if \( n < 0 \) and \( (x - a)^n \text{Heaviside}(x - a) \) if \( n \geq 0 \).

Examples

```python
>>> from sympy import SingularityFunction, diff, Piecewise, DiracDelta, Heaviside, Symbol
>>> from sympy.abc import x, a, n
>>> y = Symbol('y', positive=True)
>>> n = Symbol('n', nonnegative=True)
>>> SingularityFunction(y, -10, n)
(y + 10)**n
>>> SingularityFunction(y, 10, n)
0
>>> SingularityFunction(x, 4, -1).subs(x, 4)
oo
>>> SingularityFunction(x, 10, -2).subs(x, 10)
0
>>> SingularityFunction(4, 1, 5)
243
>>> diff(SingularityFunction(x, 1, 5) + SingularityFunction(x, 1, 4), x)
4*SingularityFunction(x, 1, 3) + 5*SingularityFunction(x, 1, 4)
>>> diff(SingularityFunction(x, 4, 0), x, 2)
SingularityFunction(x, 4, -2)
>>> SingularityFunction(x, 4, 5).rewrite(Piecewise)
Piecewise(((x - 4)**5, x > 4), (0, True))
>>> expr = SingularityFunction(x, a, n)
>>> y = Symbol('y', positive=True)
>>> n = Symbol('n', nonnegative=True)
```

(continues on next page)
>>> expr.subs({x: y, a: -10, n: n})
(y + 10)**n

The methods rewrite(DiracDelta), rewrite(Heaviside), and rewrite('HeavisideDiracDelta') returns the same output. One can use any of these methods according to their choice.

>>> expr = SingularityFunction(x, 4, 5) + SingularityFunction(x, -3, -1)
    - SingularityFunction(x, 0, -2)
>>> expr.rewrite(Heaviside)
(x - 4)**5*Heaviside(x - 4) + DiracDelta(x + 3) - DiracDelta(x, 1)
>>> expr.rewrite(DiracDelta)
(x - 4)**5*Heaviside(x - 4) + DiracDelta(x + 3) - DiracDelta(x, 1)
>>> expr.rewrite('HeavisideDiracDelta')
(x - 4)**5*Heaviside(x - 4) + DiracDelta(x + 3) - DiracDelta(x, 1)

classmethod eval(variable, offset, exponent)

Returns a simplified form or a value of Singularity Function depending on the argument passed by the object.

Explanation

The eval() method is automatically called when the SingularityFunction class is about to be instantiated and it returns either some simplified instance or the unevaluated instance depending on the argument passed. In other words, eval() method is not needed to be called explicitly, it is being called and evaluated once the object is called.

Examples

```python
>>> from sympy import SingularityFunction, Symbol, nan
>>> from sympy.abc import x, a, n
>>> SingularityFunction(x, a, n)
SingularityFunction(x, a, n)
>>> SingularityFunction(5, 3, 2)
4
>>> SingularityFunction(x, a, nan)
nan
>>> SingularityFunction(x, 3, 0).subs(x, 3)
1
>>> SingularityFunction(4, 1, 5)
```
>>> x = Symbol('x', positive = True)
>>> a = Symbol('a', negative = True)
>>> n = Symbol('n', nonnegative = True)
>>> SingularityFunction(x, a, n)
(-a + x)**n

>>> x = Symbol('x', negative = True)
>>> a = Symbol('a', positive = True)
>>> n = Symbol('n', nonnegative = True)
>>> SingularityFunction(x, a, n)
0

\textbf{fdiff}(\texttt{argindex}=1)

Returns the first derivative of a DiracDelta Function.

\textbf{Explanation}

The difference between \texttt{diff()} and \texttt{fdiff()} is: \texttt{diff()} is the user-level function and \texttt{fdiff()} is an object method. \texttt{fdiff()} is a convenience method available in the Function class. It returns the derivative of the function without considering the chain rule. \texttt{diff(function, x)} calls Function\_eval\_derivative which in turn calls \texttt{fdiff()} internally to compute the derivative of the function.

\textbf{Gamma, Beta and Related Functions}

\texttt{class sympy.functions.special.gamma_functions.gamma}(\texttt{arg})

The gamma function

\[
\Gamma(x) := \int_0^{\infty} t^{x-1} e^{-t} dt.
\]

\textbf{Explanation}

The gamma function implements the function which passes through the values of the factorial function (i.e., \(\Gamma(n) = (n-1)!\) when \(n\) is an integer). More generally, \(\Gamma(z)\) is defined in the whole complex plane except at the negative integers where there are simple poles.

\textbf{Examples}

```python
>>> from sympy import S, I, pi, gamma
>>> from sympy.abc import x
```

Several special values are known:

```python
>>> gamma(1)
1
>>> gamma(4)
6
```
The gamma function obeys the mirror symmetry:

```python
from sympy import conjugate
conjugate(gamma(x)) == gamma(conjugate(x))
```

Differentiation with respect to \(x\) is supported:

```python
from sympy import diff
diff(gamma(x), x) == gamma(x)*polygamma(0, x)
```

Series expansion is also supported:

```python
from sympy import series
series(gamma(x), x, 0, 3)
```

We can numerically evaluate the gamma function to arbitrary precision on the whole complex plane:

```python
gamma(pi).evalf(40)
gamma(1+I).evalf(20)
```

See also:

  Trigamma function.
- `beta` [page 526]
  Euler Beta function.
class sympy.functions.special.gamma_functions.loggamma(z)
The loggamma function implements the logarithm of the gamma function (i.e., \(\log(\Gamma(x))\)).

Examples

Several special values are known. For numerical integral arguments we have:

```python
>>> from sympy import loggamma
>>> loggamma(-2)
oo
>>> loggamma(0)
oo
>>> loggamma(1)
0
>>> loggamma(2)
0
>>> loggamma(3)
log(2)
```

And for symbolic values:

```python
>>> from sympy import Symbol
>>> n = Symbol("n", integer=True, positive=True)
>>> loggamma(n)
log(gamma(n))
>>> loggamma(-n)
oo
```

For half-integral values:

```python
>>> from sympy import S
>>> loggamma(S(5)/2)
log(3*sqrt(pi)/4)
>>> loggamma(n/2)
log(2**(1 - n)*sqrt(pi)*gamma(n)/gamma(n/2 + 1/2))
```

And general rational arguments:

```python
>>> from sympy import expand_func
>>> L = loggamma(S(16)/3)
>>> expand_func(L).doit()
-5*log(3) + loggamma(1/3) + log(4) + log(7) + log(10) + log(13)
>>> L = loggamma(S(19)/4)
>>> expand_func(L).doit()
-4*log(4) + loggamma(3/4) + log(3) + log(7) + log(11) + log(15)
>>> L = loggamma(S(23)/7)
>>> expand_func(L).doit()
-3*log(7) + log(2) + loggamma(2/7) + log(9) + log(16)
```

The loggamma function has the following limits towards infinity:
The `loggamma` function obeys the mirror symmetry if $x \in \mathbb{C} \setminus \{-\infty, 0\}$:

```
from sympy.abc import x
from sympy import conjugate
conjugate(loggamma(x))
```

Differentiation with respect to $x$ is supported:

```
from sympy import diff
diff(loggamma(x), x)
```

Series expansion is also supported:

```
from sympy import series
series(loggamma(x), x, 0, 4).cancel()
```

We can numerically evaluate the `loggamma` function to arbitrary precision on the whole complex plane:

```
from sympy import I
loggamma(5).evalf(30)
3.17805383034794561964694160130
loggamma(I).evalf(20)
-0.65092319930185633889 - 1.8724366472624298171*I
```

  Trigamma function.
- `beta` (page 526)
  Euler Beta function.
class sympy.functions.special.gamma_functions.polygamma(n, z)

The function polygamma(n, z) returns log(gamma(z)).diff(n + 1).

Explanation

It is a meromorphic function on \( \mathbb{C} \) and defined as the \((n+1)\)-th derivative of the logarithm of the gamma function:

\[
\psi^{(n)}(z) := \frac{d^{n+1}}{dz^{n+1}} \log \Gamma(z).
\]

For \( n \) not a nonnegative integer the generalization by Espinosa and Moll [R330] is used:

\[
\psi(s, z) = \zeta'(s + 1, z) + (\gamma + \psi(-s))\zeta(s + 1, z)
\]

Examples

Several special values are known:

```python
>>> from sympy import S, polygamma
>>> polygamma(0, 1)
-EulerGamma
>>> polygamma(0, 1/S(2))
-2*log(2) - EulerGamma
>>> polygamma(0, 1/S(3))
-log(3) - sqrt(3)*pi/6 - EulerGamma - log(sqrt(3))
>>> polygamma(0, 1/S(4))
-pi/2 - log(4) - log(2) - EulerGamma
>>> polygamma(0, 2)
1 - EulerGamma
>>> polygamma(0, 23)
19093197/5173168 - EulerGamma
```

```python
>>> from sympy import oo, I
>>> polygamma(0, oo)
oo
>>> polygamma(0, -oo)
oo
>>> polygamma(0, I*oo)
oo
>>> polygamma(0, -I*oo)
```

Differentiation with respect to \( x \) is supported:
```python
from sympy import *

x = Symbol("x")

diff(polygamma(0, x), x)
diff(polygamma(0, x), x, 2)
diff(polygamma(0, x), x, 3)
diff(polygamma(1, x), x)
diff(polygamma(1, x), x, 2)
diff(polygamma(2, x), x)
diff(polygamma(2, x), x, 2)
diff(polygamma(2, x), x, 3)
diff(polygamma(2, x), x, 4)

n = Symbol("n")

diff(polygamma(n, x), x)
diff(polygamma(n, x), x, 2)

We can rewrite polygamma functions in terms of harmonic numbers:

```python
from sympy import harmonic

polygamma(0, x).rewrite(harmonic)

2*harmonic(x - 1, 3) - 2*zeta(3)

ni = Symbol("n", integer=True)
polygamma(ni, x).rewrite(harmonic)

(-1)**(n + 1)*(-harmonic(x - 1, n + 1) + zeta(n + 1))*factorial(n)

class sympy.functions.special.gamma_functions.digamma(z)
The digamma function is the first derivative of the loggamma function
\[ \psi(x) := \frac{d}{dz} \log \Gamma(z) = \frac{\Gamma'(z)}{\Gamma(z)}. \]

In this case, \( \text{digamma}(z) = \text{polygamma}(0, z) \).

Examples

```python
>>> from sympy import digamma
>>> digamma(0)
zoo
>>> from sympy import Symbol
>>> z = Symbol('z')
>>> digamma(z)
polygamma(0, z)
```

To retain digamma as it is:

```python
>>> digamma(0, evaluate=False)
digamma(0)
>>> digamma(z, evaluate=False)
digamma(z)
```

**class sympy.functions.special.gamma_functions.uppergamma(a, z)**

The upper incomplete gamma function.

**Explanation**

It can be defined as the meromorphic continuation of

\[
\Gamma(s, x) := \int_x^\infty t^{s-1} e^{-t} dt = \Gamma(s) - \gamma(s, x).
\]

where \(\gamma(s, x)\) is the lower incomplete gamma function, \texttt{lowergamma} (page 524). This can be shown to be the same as

\[
\Gamma(s, x) = \Gamma(s) - \frac{x^s}{s} \, _1F_1\left(s, s+1, -x\right),
\]

where \(_1F_1\) is the (confluent) hypergeometric function.

The upper incomplete gamma function is also essentially equivalent to the generalized exponential integral:

\[
E_n(x) = \int_1^\infty \frac{e^{-xt}}{t^n} \, dt = x^{n-1} \Gamma(1-n, x).
\]

**Examples**

```python
>>> from sympy import uppergamma, S
>>> from sympy.abc import s, x
>>> uppergamma(s, x)
uppergamma(s, x)
>>> uppergamma(3, x)
2*(x**2/2 + x + 1)*exp(-x)
>>> uppergamma(-S(1)/2, x)
-2*sqrt(pi)*erfc(sqrt(x)) + 2*exp(-x)/sqrt(x)
>>> uppergamma(-2, x)
expint(3, x)/x**2
```

class sympy.functions.special.gamma_functions.lowergamma(a, x)
The lower incomplete gamma function.

Explanation

It can be defined as the meromorphic continuation of
\[
\gamma(s, x) := \int_0^x t^{s-1}e^{-t}dt = \Gamma(s) - \Gamma(s, x).
\]

This can be shown to be the same as
\[
\gamma(s, x) = \frac{x^s}{s} \, _1F_1\left(s \left| \frac{s}{s+1} \right| -x \right),
\]

where \( _1F_1 \) is the (confluent) hypergeometric function.

Examples

```python
>>> from sympy import lowergamma, S
>>> from sympy.abc import s, x
>>> lowergamma(s, x)
lowergamma(s, x)
>>> lowergamma(3, x)
-2*(x**2/2 + x + 1)*exp(-x) + 2
>>> lowergamma(-S(1)/2, x)
-2*sqrt(pi)*erf(sqrt(x)) - 2*exp(-x)/sqrt(x)
```

See also:

gamma (page 515)

Upper incomplete gamma function.

polygamma (page 519)
Polygamma function.

loggamma (page 517)
Log Gamma function.
sympy.functions.special.gamma_functions.multigamma(x, p)

The multivariate gamma function is a generalization of the gamma function

\[ \Gamma_p(z) = \pi^{p(p-1)/4} \prod_{k=1}^{p} \Gamma[z + (1 - k)/2]. \]

In a special case, \( \text{multigamma}(x, 1) = \text{gamma}(x) \).

**Parameters**

- \( p \): order or dimension of the multivariate gamma function

**Examples**

```python
>>> from sympy import S, multigamma
>>> from sympy import Symbol
>>> x = Symbol('x')
>>> p = Symbol('p', positive=True, integer=True)

>>> multigamma(x, p)
pi**(p*(p - 1)/4)*Product(gamma(-_k/2 + x + 1/2), (_k, 1, p))

Several special values are known:

>>> multigamma(1, 1)
1
>>> multigamma(4, 1)
6
>>> multigamma(S(3)/2, 1)
sqrt(pi)/2

Writing multigamma in terms of the gamma function:

>>> multigamma(x, 1)
gamma(x)

>>> multigamma(x, 2)
sqrt(pi)*gamma(x)*gamma(x - 1/2)

>>> multigamma(x, 3)
pi**(3/2)*gamma(x)*gamma(x - 1)*gamma(x - 1/2)
```

References

[R348]
class sympy.functions.special.beta_functions.beta(x, y=None)
The beta integral is called the Eulerian integral of the first kind by Legendre:

\[ B(x, y) = \int_0^1 t^{x-1}(1 - t)^{y-1} dt. \]

Explanation

The Beta function or Euler’s first integral is closely associated with the gamma function. The Beta function is often used in probability theory and mathematical statistics. It satisfies properties like:

\[
B(a, 1) = \frac{1}{a} \\
B(a, b) = B(b, a) \\
B(a, b) = \frac{\Gamma(a)\Gamma(b)}{\Gamma(a + b)}
\]

Therefore for integral values of \( a \) and \( b \):

\[
B = \frac{(a - 1)!(b - 1)!}{(a + b - 1)!}
\]

A special case of the Beta function when \( x = y \) is the Central Beta function. It satisfies properties like:

\[
B(x) = 2^{1-2x}B(x, \frac{1}{2})B(x) = 2^{1-2x}\cos(x)B(\frac{1}{2} - x, x)B(x) = \int_0^1 \frac{t^x}{(1 + t)^{2x}} dtB(x) = \frac{2}{x} \prod_{n=1}^{\infty} \frac{n(n + 2x)}{(n + x)^2}
\]

Examples

```python
>>> from sympy import I, pi
>>> from sympy.abc import x, y
```

The Beta function obeys the mirror symmetry:

```python
>>> from sympy import beta, conjugate
>>> conjugate(beta(x, y))
beta(conjugate(x), conjugate(y))
```

Differentiation with respect to both \( x \) and \( y \) is supported:
>>> from sympy import beta, diff
>>> diff(beta(x, y), x)
(polygamma(0, x) - polygamma(0, x + y))*beta(x, y)

>>> diff(beta(x, y), y)
(polygamma(0, y) - polygamma(0, x + y))*beta(x, y)

>>> diff(beta(x), x)
2*(polygamma(0, x) - polygamma(0, 2*x))*beta(x, x)

We can numerically evaluate the Beta function to arbitrary precision for any complex numbers \(x\) and \(y\):

```python
>>> from sympy import beta
>>> beta(pi).evalf(40)
0.02671848900111377452242355235388489324562
```

```python
>>> beta(1 + I).evalf(20)
-0.2112723729365330143 - 0.7655283165378005676*I
```

Error Functions and Fresnel Integrals

class sympy.functions.special.error_functions.erf(arg)
The Gauss error function.

Explanation

This function is defined as:

\[ \text{erf}(x) = \frac{2}{\sqrt{\pi}} \int_{0}^{x} e^{-t^2} dt. \]

Examples

```python
>>> from sympy import I, oo, erf
>>> from sympy.abc import z

Several special values are known:

>>> erf(0)
0
>>> erf(oo)
1
>>> erf(-oo)
-1
>>> erf(I*oo)
oo*I
>>> erf(-I*oo)
-oo*I

In general one can pull out factors of -1 and I from the argument:

>>> erf(-z)
-erf(z)

The error function obeys the mirror symmetry:

```from sympy import conjugate
>>> conjugate(erf(z))
erf(conjugate(z))
```  

Differentiation with respect to \( z \) is supported:

```from sympy import diff
>>> diff(erf(z), z)
2*exp(-z**2)/sqrt(pi)
```  

We can numerically evaluate the error function to arbitrary precision on the whole complex plane:

```python
>>> erf(4).evalf(30)
0.999999984582742099719981147840
```
```python
>>> erf(-4*I).evalf(30)
-1296959.73071763923152794095062*I
```

```python
class sympy.functions.special.error_functions.erfc(arg)
```
Complementary Error Function.

**Explanation**

The function is defined as:

\[
erfc(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-t^2} \, dt
\]

**Examples**

```python
>>> from sympy import I, oo, erfc
>>> from sympy.abc import z
```

Several special values are known:

```python
>>> erfc(0)
1
>>> erfc(oo)
0
>>> erfc(-oo)
2
```

(continues on next page)
The error function obeys the mirror symmetry:

```python
from sympy import conjugate
conjugate(erfc(z))
```

Differentiation with respect to \( z \) is supported:

```python
from sympy import diff
diff(erfc(z), z)
```

It also follows

```python
erfc(-z)
2 - erfc(z)
```

We can numerically evaluate the complementary error function to arbitrary precision on the whole complex plane:

```python
erfc(4).evalf(30)
0.0000000154172579002800188521596734869
```

```python
erfc(4*I).evalf(30)
1.0 - 1296959.73071763923152794095062*I
```

inverse(argindex=1)

Returns the inverse of this function.

class sympy.functions.special.error_functions.erfi(z)

Imaginary error function.

Explanation

The function erfi is defined as:

\[ \text{erfi}(x) = \frac{2}{\sqrt{\pi}} \int_{0}^{x} e^{t^2} dt \]

Examples

```python
>>> from sympy import I, oo, erfi
>>> from sympy.abc import z

Several special values are known:

>>> erfi(0)
0
>>> erfi(oo)
oo
>>> erfi(-oo)
-oo
>>> erfi(I*oo)
I
>>> erfi(-I*oo)
-I

In general one can pull out factors of -1 and I from the argument:

>>> erfi(-z)
-erfi(z)

>>> from sympy import conjugate
>>> conjugate(erfi(z))
erfi(conjugate(z))

Differentiation with respect to z is supported:

>>> from sympy import diff
>>> diff(erfi(z), z)
2*exp(z**2)/sqrt(pi)

We can numerically evaluate the imaginary error function to arbitrary precision on the whole complex plane:
>>> erfi(2).evalf(30)
18.5648024145755525987042919132

>>> erfi(-2*I).evalf(30)

class sympy.functions.special.error_functions.erf2(x, y)
Two-argument error function.

Explanation

This function is defined as:

\[
\text{erf}(x, y) = \frac{2}{\sqrt{\pi}} \int_x^y e^{-t^2} dt
\]

Examples

>>> from sympy import oo, erf2
>>> from sympy.abc import x, y

Several special values are known:

>>> erf2(0, 0)
\(0\)

>>> erf2(x, x)
\(0\)

>>> erf2(x, oo)
(continues on next page)
In general one can pull out factors of -1:

```python
>>> erf2(-x, -y)
-erf2(x, y)
```

The error function obeys the mirror symmetry:

```python
>>> from sympy import conjugate
>>> conjugate(erf2(x, y))
erf2(conjugate(x), conjugate(y))
```

Differentiation with respect to $x, y$ is supported:

```python
>>> from sympy import diff
>>> diff(erf2(x, y), x)
-2*exp(-x**2)/sqrt(pi)
>>> diff(erf2(x, y), y)
2*exp(-y**2)/sqrt(pi)
```

class sympy.functions.special.error_functions.FresnelIntegral(z)
Base class for the Fresnel integrals.

class sympy.functions.special.error_functions.fresnels(z)
Fresnel integral S.

**Explanation**

This function is defined by

\[ S(z) = \int_0^z \sin \frac{\pi t^2}{2} dt. \]

It is an entire function.

**Examples**

```python
>>> from sympy import I, oo, fresnels
>>> from sympy.abc import z
```

Several special values are known:

```python
>>> fresnels(0)
0
>>> fresnels(oo)
1/2
>>> fresnels(-oo)
-1/2
>>> fresnels(I*oo)
-I/2
>>> fresnels(-I*oo)
I/2
```

In general one can pull out factors of -1 and \( i \) from the argument:

```python
>>> fresnels(-z)
-fresnels(z)
>>> fresnels(I*z)
-I*fresnels(z)
```

The Fresnel S integral obeys the mirror symmetry \( S(z) = S(\bar{z}) \):

```python
>>> from sympy import conjugate
>>> conjugate(fresnels(z))
fresnels(conjugate(z))
```

Differentiation with respect to \( z \) is supported:
```python
>>> from sympy import diff
diff(fresnels(z), z)
sin(pi*z**2/2)
```

Defining the Fresnel functions via an integral:

```python
>>> from sympy import integrate, pi, sin, expand_func

>>> integrate(sin(pi*z*z/2), z)
3*fresnels(z)*gamma(3/4)/(4*gamma(7/4))

>>> expand_func(integrate(sin(pi*z*z/2), z))
fresnels(z)
```

We can numerically evaluate the Fresnel integral to arbitrary precision on the whole complex plane:

```python
>>> fresnels(2).evalf(30)
0.343415678363698242195300815958

>>> fresnels(-2*I).evalf(30)
0.343415678363698242195300815958*I
```

**Exponential, Logarithmic and Trigonometric Integrals**

```python
class sympy.functions.special.error_functions.Ei(z)
The classical exponential integral.
```

**Explanation**

For use in SymPy, this function is defined as

\[
Ei(x) = \sum_{n=1}^{\infty} \frac{x^n}{n n!} + \log(x) + \gamma,
\]

where \( \gamma \) is the Euler-Mascheroni constant.

If \( x \) is a polar number, this defines an analytic function on the Riemann surface of the logarithm. Otherwise this defines an analytic function in the cut plane \( \mathbb{C} \setminus (-\infty, 0] \).

**Background**

The name exponential integral comes from the following statement:

\[
Ei(x) = \int_{-\infty}^{x} \frac{e^t}{t} \, dt
\]

If the integral is interpreted as a Cauchy principal value, this statement holds for \( x > 0 \) and \( Ei(x) \) as defined above.

**Examples**

```python
>>> from sympy import Ei, polar_lift, exp_polar, I, pi
>>> from sympy.abc import x

>>> Ei(-1)
Ei(-1)

This yields a real value:

```python
>>> Ei(-1).n(chop=True)
-0.219383934395520
```

On the other hand the analytic continuation is not real:

```python
>>> Ei(polar_lift(-1)).n(chop=True)
-0.21938393439552 + 3.14159265358979*I
```

The exponential integral has a logarithmic branch point at the origin:
`>>> Ei(x*exp_polar(2*I*pi))
Ei(x) + 2*I*pi`

Differentiation is supported:

`>>> Ei(x).diff(x)
exp(x)/x`

The exponential integral is related to many other special functions. For example:

```python
>>> from sympy import expint, Shi

>>> Ei(x).rewrite(expint)
-expint(1, x*exp_polar(I*pi)) - I*pi

>>> Ei(x).rewrite(Shi)
Chi(x) + Shi(x)
```

  Upper incomplete gamma function.

References

[R379], [R380], [R381]

class sympy.functions.special.error_functions.expint(nu, z)
Generalized exponential integral.
**Explanation**

This function is defined as

\[ E_\nu(z) = z^{\nu-1} \Gamma(1 - \nu, z), \]

where \( \Gamma(1 - \nu, z) \) is the upper incomplete gamma function (uppergamma).

Hence for \( z \) with positive real part we have

\[ E_\nu(z) = \int_1^{\infty} e^{-zt} t^{\nu} \, dt, \]

which explains the name.

The representation as an incomplete gamma function provides an analytic continuation for \( E_\nu(z) \). If \( \nu \) is a non-positive integer, the exponential integral is thus an unbranched function of \( z \), otherwise there is a branch point at the origin. Refer to the incomplete gamma function documentation for details of the branching behavior.

**Examples**

```python
>>> from sympy import expint, S
>>> from sympy.abc import nu, z
```

Differentiation is supported. Differentiation with respect to \( z \) further explains the name: for integral orders, the exponential integral is an iterated integral of the exponential function.

```python
>>> expint(nu, z).diff(z)
-expint(nu - 1, z)
```

Differentiation with respect to \( \nu \) has no classical expression:

```python
>>> expint(nu, z).diff(nu)
-z**(nu - 1)*meijerg(((), (1, 1)), ((0, 0, 1 - nu), ()), z)
```

At non-postive integer orders, the exponential integral reduces to the exponential function:

```python
>>> expint(0, z)
exp(-z)/z
>>> expint(-1, z)
exp(-z)/z + exp(-z)/z**2
```

At half-integers it reduces to error functions:

```python
>>> expint(S(1)/2, z)
sqrt(pi)*erfc(sqrt(z))/sqrt(z)
```

At positive integer orders it can be rewritten in terms of exponentials and \( \text{expint}(1, z) \). Use \texttt{expand_func()} to do this:

```python
>>> from sympy import expand_func
>>> expand_func(expint(5, z))
z**4*expint(1, z)/24 + (-z**3 + z**2 - 2*z + 6)*exp(-z)/24
```
The generalised exponential integral is essentially equivalent to the incomplete gamma function:

```python
>>> from sympy import uppergamma
>>> expint(nu, z).rewrite(uppergamma)
z**(nu - 1)*uppergamma(1 - nu, z)
```

As such it is branched at the origin:

```python
>>> from sympy import exp_polar, pi, I
>>> expint(4, z*exp_polar(2*pi*I))
I*pi*z**3/3 + expint(4, z)
>>> expint(nu, z*exp_polar(2*pi*I))
z**(nu - 1)*(exp(2*I*pi*nu) - 1)*gamma(1 - nu) + expint(nu, z)
```

```python
class sympy.functions.special.error_functions.li(z)
```

The classical logarithmic integral.

Explanation

For use in SymPy, this function is defined as

\[ \text{li}(x) = \int_{0}^{x} \frac{1}{\log(t)} \, dt. \]
Examples

```python
>>> from sympy import I, oo, li
>>> from sympy.abc import z
```

Several special values are known:

```python
>>> li(0)
0
>>> li(1)
-oo
>>> li(oo)
oo
```

Differentiation with respect to $z$ is supported:

```python
>>> from sympy import diff
>>> diff(li(z), z)
1/log(z)
```

Defining the $li$ function via an integral:

```python
>>> from sympy import integrate
>>> integrate(li(z))
z*li(z) - Ei(2*log(z))
```

The logarithmic integral can also be defined in terms of $Ei$:

```python
>>> from sympy import Ei
>>> li(z).rewrite(Ei)
Ei(log(z))
```

We can numerically evaluate the logarithmic integral to arbitrary precision on the whole complex plane (except the singular points):

```python
>>> li(2).evalf(30)
1.0451637801174927848445888919
```

```python
>>> li(2*I).evalf(30)
1.065279578435749824701125598 + 3.08346052231061726610939702133*I
```

We can even compute Soldner's constant by the help of mpmath:

```python
>>> from mpmath import findroot
>>> findroot(li, 2)
1.45136923488338
```

Further transformations include rewriting $li$ in terms of the trigonometric integrals $Si$, $Ci$, $Shi$ and $Chi$:

```python
>>> from sympy import Si, Ci, Shi, Chi
>>> li(z).rewrite(Si)
```

(continues on next page)
-log(I*log(z)) - log(1/log(z))/2 + log(log(z))/2 + Ci(I*log(z)) + \rightarrow Shi(log(z))

>>> li(z).rewrite(Ci)
  -log(I*log(z)) - log(1/log(z))/2 + log(log(z))/2 + Ci(I*log(z)) + \rightarrow Shi(log(z))

>>> li(z).rewrite(Shi)
  -log(1/log(z))/2 + log(log(z))/2 + Chi(log(z)) - Shi(log(z))

>>> li(z).rewrite(Chi)
  -log(1/log(z))/2 + log(log(z))/2 + Chi(log(z)) - Shi(log(z))

[R385], [R386], [R387], [R388]

class sympy.functions.special.error_functions.Li(z)
  The offset logarithmic integral.

Explanation

For use in SymPy, this function is defined as

\[ Li(x) = li(x) - li(2) \]
Examples

```python
>>> from sympy import Li
>>> from sympy.abc import z
```

The following special value is known:

```python
>>> Li(2)
0
```

Differentiation with respect to \( z \) is supported:

```python
>>> from sympy import diff
globally
>>> diff(Li(z), z)
1/log(z)
```

The shifted logarithmic integral can be written in terms of \( li(z) \):

```python
>>> from sympy import li
globally
>>> Li(z).rewrite(li)
li(z) - li(2)
```

We can numerically evaluate the logarithmic integral to arbitrary precision on the whole complex plane (except the singular points):

```python
>>> Li(2).evalf(30)
0
```

```python
>>> Li(4).evalf(30)
1.92242131492155809316615998938
```

class sympy.functions.special.error_functions.Si(z)
Sine integral.

Explanation
This function is defined by
\[ \text{Si}(z) = \int_0^z \frac{\sin t}{t} \, dt. \]
It is an entire function.

Examples
```python
>>> from sympy import Si
>>> from sympy.abc import z

The sine integral is an antiderivative of \( \sin(z)/z \):
```n
```python
>>> Si(z).diff(z)
sin(z)/z
```
```python
It is unbranched:
```n
```python
>>> from sympy import exp_polar, I, pi
>>> Si(z*exp_polar(2*I*pi))
Si(z)
```
```python
Sine integral behaves much like ordinary sine under multiplication by \( I \):
```n
```python
>>> Si(I*z)
I*Shi(z)
>>> Si(-z)
-Si(z)
```
```python
It can also be expressed in terms of exponential integrals, but beware that the latter is branched:
```n
```python
>>> from sympy import expint
>>> Si(z).rewrite(expint)
-I*(-expint(1, z*exp_polar(-I*pi/2))/2 + 
    expint(1, z*exp_polar(I*pi/2))/2) + pi/2
```
```python
It can be rewritten in the form of sinc function (by definition):
```n
```python
>>> from sympy import sinc
>>> Si(z).rewrite(sinc)
Integral(sinc(t), (t, 0, z))
```

**Li** *(page 546)*
Offset logarithmic integral.

References

[R392]

```python
class sympy.functions.special.error_functions.Ci(z)

Cosine integral.
```

**Explanation**

This function is defined for positive $x$ by

$$
\text{Ci}(x) = \gamma + \log x + \int_0^x \frac{\cos t - 1}{t} \, dt = -\int_x^\infty \frac{\cos t}{t} \, dt,
$$

where $\gamma$ is the Euler-Mascheroni constant.

We have

$$
\text{Ci}(z) = -\frac{\text{E}_1(e^{i\pi/2}z) + \text{E}_1(e^{-i\pi/2}z)}{2}
$$

which holds for all polar $z$ and thus provides an analytic continuation to the Riemann surface of the logarithm.

The formula also holds as stated for $z \in \mathbb{C}$ with $\Re(z) > 0$. By lifting to the principal branch, we obtain an analytic function on the cut complex plane.
Examples

```python
>>> from sympy import Ci
>>> from sympy.abc import z
```

The cosine integral is a primitive of \( \cos(z)/z \):

```python
>>> Ci(z).diff(z)
cos(z)/z
```

It has a logarithmic branch point at the origin:

```python
>>> from sympy import exp_polar, I, pi
>>> Ci(z*exp_polar(2*I*pi))
Ci(z) + 2*I*pi
```

The cosine integral behaves somewhat like ordinary \( \cos \) under multiplication by \( i \):

```python
>>> from sympy import polar_lift
>>> Ci(polar_lift(I)*z)
Chi(z) + I*pi/2
>>> Ci(polar_lift(-1)*z)
Ci(z) + I*pi
```

It can also be expressed in terms of exponential integrals:

```python
>>> from sympy import expint
>>> Ci(z).rewrite(expint)
-expint(1, z*exp_polar(-I*pi/2))/2 - expint(1, z*exp_polar(I*pi/2))/2
```

class sympy.functions.special.error_functions.Shir(z)
Sinh integral.

Explanation
This function is defined by

\[ \text{Shi}(z) = \int_0^z \frac{\sinh t}{t} dt. \]

It is an entire function.

Examples
>>> from sympy import Shi
>>> from sympy.abc import z

The Sinh integral is a primitive of \( \sinh(z)/z \):

>>> Shi(z).diff(z)
\sinh(z)/z

It is unbranched:

>>> from sympy import exp_polar, I, pi
>>> Shi(z*exp_polar(2*I*pi))
Shi(z)

The sinh integral behaves much like ordinary sinh under multiplication by \( i \):

>>> Shi(I*z)
I*Si(z)

>>> Shi(-z)
-Shi(z)

It can also be expressed in terms of exponential integrals, but beware that the latter is branched:

>>> from sympy import expint
>>> Shi(z).rewrite(expint)
expint(1, z)/2 - expint(1, z*exp_polar(I*pi))/2 - I*pi/2

Logarithmic integral.

**Li (page 546)**
Offset logarithmic integral.

**References**

[R394]

class sympy.functions.special.error_functions.Chi(z)
Cosh integral.

**Explanation**

This function is defined for positive $x$ by

$$
\text{Chi}(x) = \gamma + \log x + \int_0^x \frac{\cosh t - 1}{t} \, dt,$$

where $\gamma$ is the Euler-Mascheroni constant.

We have

$$
\text{Chi}(z) = \text{Ci} \left( e^{i\pi/2} z \right) - \frac{i\pi}{2},
$$

which holds for all polar $z$ and thus provides an analytic continuation to the Riemann surface of the logarithm. By lifting to the principal branch we obtain an analytic function on the cut complex plane.

**Examples**

```python
>>> from sympy import Chi
>>> from sympy.abc import z
```

The cosh integral is a primitive of $\cosh(z)/z$:

```python
>>> Chi(z).diff(z)
cosh(z)/z
```

It has a logarithmic branch point at the origin:
>>> from sympy import exp_polar, I, pi
>>> Chi(z*exp_polar(2*I*pi))
Chi(z) + 2*I*pi

The cosh integral behaves somewhat like ordinary cosh under multiplication by $i$:

>>> from sympy import polar_lift

>>> Chi(polar_lift(I)*z)
Ci(z) + I*pi/2
>>> Chi(polar_lift(-1)*z)
Chi(z) + I*pi

It can also be expressed in terms of exponential integrals:

>>> from sympy import expint

>>> Chi(z).rewrite(expint)
-expint(1, z)/2 - expint(1, z*exp_polar(I*pi))/2 - I*pi/2

**Bessel Type Functions**

```python
class sympy.functions.special.bessel.BesselBase(nu, z)

Abstract base class for Bessel-type functions.

This class is meant to reduce code duplication. All Bessel-type functions can 1) be differentiated, with the derivatives expressed in terms of similar functions, and 2) be rewritten in terms of other Bessel-type functions.

Here, Bessel-type functions are assumed to have one complex parameter.

To use this base class, define class attributes _a and _b such that \(2F_n' = -aF_{n+1} + bF_{n-1}\).
```

**property argument**

The argument of the Bessel-type function.

**property order**

The order of the Bessel-type function.

```python
class sympy.functions.special.bessel.besselj(nu, z)

Bessel function of the first kind.
```

**Explanation**

The Bessel \(J\) function of order \(\nu\) is defined to be the function satisfying Bessel’s differential equation

\[
z^2 \frac{d^2 w}{dz^2} + z \frac{dw}{dz} + (z^2 - \nu^2)w = 0,
\]

with Laurent expansion

\[
J_\nu(z) = z^\nu \left( \frac{1}{\Gamma(\nu + 1)2^\nu} + O(z^2) \right),
\]

if \(\nu\) is not a negative integer. If \(\nu = -n \in \mathbb{Z}_{<0}\) is a negative integer, then the definition is

\[
J_{-n}(z) = (-1)^n J_n(z).
\]

**Examples**

Create a Bessel function object:

```python
>>> from sympy import besselj, jn
>>> from sympy.abc import z, n
>>> b = besselj(n, z)
```

Differentiate it:

```python
>>> b.diff(z)
besselj(n - 1, z)/2 - besselj(n + 1, z)/2
```

Rewrite in terms of spherical Bessel functions:
```python
>>> b.rewrite(jn)
sqrt(2)*sqrt(z)*jn(n - 1/2, z)/sqrt(pi)
```

Access the parameter and argument:

```python
>>> b.order
n
>>> b.argument
z
```

**References**

[R396], [R397], [R398], [R399]

```python
class sympy.functions.special.bessel.bessely(nu, z)
```

Bessel function of the second kind.

**Explanation**

The Bessel $Y$ function of order $\nu$ is defined as

$$Y_\nu(z) = \lim_{\mu \to \nu} \frac{J_\mu(z) \cos(\pi \mu) - J_{-\mu}(z)}{\sin(\pi \mu)},$$

where $J_\mu(z)$ is the Bessel function of the first kind.

It is a solution to Bessel’s equation, and linearly independent from $J_\nu$.

**Examples**

```python
>>> from sympy import bessely, yn
>>> from sympy.abc import z, n
>>> b = bessely(n, z)
>>> b.diff(z)
bessely(n - 1, z)/2 - bessely(n + 1, z)/2
>>> b.rewrite(yn)
sqrt(2)*sqrt(z)*yn(n - 1/2, z)/sqrt(pi)
```

References

[R400]
class sympy.functions.special.bessel.besseli(nu, z)
Modified Bessel function of the first kind.

Explanation

The Bessel $I$ function is a solution to the modified Bessel equation

$$
z^2 \frac{d^2 w}{dz^2} + z \frac{dw}{dz} + (z^2 + \nu^2)w = 0.
$$

It can be defined as

$$I_\nu(z) = i^{-\nu} J_\nu(iz),$$

where $J_\nu(z)$ is the Bessel function of the first kind.

Examples

```python
>>> from sympy import besseli
>>> from sympy.abc import z, n
>>> besseli(n, z).diff(z)
besseli(n - 1, z)/2 + besseli(n + 1, z)/2
```

References

[R401]
class sympy.functions.special.bessel.besselk(nu, z)
Modified Bessel function of the second kind.

Explanation

The Bessel $K$ function of order $\nu$ is defined as

$$
K_\nu(z) = \lim_{\mu \to \nu} \frac{\pi}{2} \frac{I_{-\mu}(z) - I_{\mu}(z)}{\sin(\pi \mu)},
$$

where $I_{\mu}(z)$ is the modified Bessel function of the first kind.

It is a solution of the modified Bessel equation, and linearly independent from $Y_{\nu}$.
Examples

```python
>>> from sympy import besselk
>>> from sympy.abc import z, n
>>> besselk(n, z).diff(z)
-besselk(n - 1, z)/2 - besselk(n + 1, z)/2
```

[R402]

class sympy.functions.special.bessel.hankel1(nu, z)
Hankel function of the first kind.

Explanation

This function is defined as

\[ H^{(1)}_\nu(z) = J_\nu(z) + iY_\nu(z), \]

where \( J_\nu(z) \) is the Bessel function of the first kind, and \( Y_\nu(z) \) is the Bessel function of the second kind.

It is a solution to Bessel’s equation.

Examples

```python
>>> from sympy import hankel1
>>> from sympy.abc import z, n
>>> hankel1(n, z).diff(z)
hankel1(n - 1, z)/2 - hankel1(n + 1, z)/2
```

[R404]

class sympy.functions.special.bessel.jn(nu, z)

Spherical Bessel function of the first kind.

Explanation

This function is a solution to the spherical Bessel equation

\[ z^2 \frac{d^2 w}{dz^2} + 2z \frac{dw}{dz} + (z^2 - \nu(\nu + 1))w = 0. \]

It can be defined as

\[ j_{\nu}(z) = \sqrt{\frac{\pi}{2z}} J_{\nu + \frac{1}{2}}(z), \]

where \( J_{\nu}(z) \) is the Bessel function of the first kind.

The spherical Bessel functions of integral order are calculated using the formula:

\[ j_n(z) = f_n(z) \sin z + (-1)^{n+1} f_{-n-1}(z) \cos z, \]

where the coefficients \( f_n(z) \) are available as `sympy.polys.orthopolys.spherical_bessel_fn()` (page 2517).
Examples

```python
>>> from sympy import Symbol, jn, sin, cos, expand_func, besselj, bessely
>>> z = Symbol("z")
>>> nu = Symbol("nu", integer=True)
>>> print(expand_func(jn(0, z)))
\sin(z)/z
>>> expand_func(jn(1, z)) == sin(z)/z**2 - cos(z)/z
True
>>> expand_func(jn(3, z))
(-6/z**2 + 15/z**4)*sin(z) + (1/z - 15/z**3)*cos(z)
>>> jn(nu, z).rewrite(besselj)
sqrt(2)*sqrt(pi)*sqrt(1/z)*besselj(nu + 1/2, z)/2
>>> jn(nu, z).rewrite(bessely)
(-1)**nu*sqrt(2)*sqrt(pi)*sqrt(1/z)*bessely(-nu - 1/2, z)/2
>>> jn(2, 5.2+0.3j).evalf(20)
0.099419756723640344491 - 0.054525080242173562897*I
```

References

[R405]

class sympy.functions.special.bessel.yn(nu, z)
Spherical Bessel function of the second kind.

Explanation

This function is another solution to the spherical Bessel equation, and linearly independent from $j_n$. It can be defined as

$$y_\nu(z) = \sqrt{\frac{\pi}{2z}} Y_{\nu+\frac{1}{2}}(z),$$

where $Y_\nu(z)$ is the Bessel function of the second kind.

For integral orders $n$, $y_n$ is calculated using the formula:

$$y_n(z) = (-1)^{n+1} j_{-n-1}(z)$$

Examples

```python
>>> from sympy import Symbol, yn, sin, cos, expand_func, besselj, bessely
>>> z = Symbol("z")
>>> nu = Symbol("nu", integer=True)
>>> print(expand_func(yn(0, z)))
-cos(z)/z
>>> expand_func(yn(1, z)) == -cos(z)/z**2 - sin(z)/z
(continues on next page)
```
True

```python
>>> yn(nu, z).rewrite(besselj)
(-1)**(nu + 1)*sqrt(2)*sqrt(pi)*sqrt(1/z)*besselj(-nu - 1/2, z)/2
```

```python
>>> yn(nu, z).rewrite(bessely)
sqrt(2)*sqrt(pi)*sqrt(1/z)*bessely(nu + 1/2, z)/2
```

```python
>>> yn(2, 5.2+0.3j).evalf(20)
0.18525034196069722536 + 0.014895573969924817587*I
```

## References

[R406]

sympy.functions.special.bessel.jn_zeros(n, k, method='sympy', dps=15)

Zeros of the spherical Bessel function of the first kind.

**Parameters**

- `n`: integer
  
  order of Bessel function

- `k`: integer
  
  number of zeros to return

**Explanation**

This returns an array of zeros of \( j_n \) up to the \( k \)-th zero.

- **method = "sympy"**: uses mpmath.besseljzero

- **method = "scipy"**: uses the SciPy's sph_jn and newton to find all roots, which is faster than computing the zeros using a general numerical solver, but it requires SciPy and only works with low precision floating point numbers. (The function used with method="sympy" is a recent addition to mpmath; before that a general solver was used.)

**Examples**

```python
>>> from sympy import jn_zeros

>>> jn_zeros(2, 4, dps=5)
[5.7635, 9.095, 12.323, 15.515]
```

See also:

- `jn` (page 558), `yn` (page 559), `besselj` (page 554), `besselk` (page 556), `bessely` (page 555)

**class** sympy.functions.special.bessel.marcumq(m, a, b)

The Marcum Q-function.
Explanation

The Marcum Q-function is defined by the meromorphic continuation of

\[ Q_m(a, b) = a^{-m+1} \int_b^\infty x^m e^{-\frac{x^2}{2} - \frac{a^2}{2}} I_{m-1}(ax) \, dx \]

Examples

```python
from sympy import marcumq
from sympy.abc import m, a, b
marcumq(m, a, b)
```

Special values:

```python
marcumq(m, 0, b)
uppergamma(m, b**2/2)/gamma(m)
marcumq(0, 0, 0)
0
marcumq(0, a, 0)
1 - exp(-a**2/2)
marcumq(1, a, a)
1/2 + exp(-a**2)*besseli(0, a**2)/2
marcumq(2, a, a)
1/2 + exp(-a**2)*besseli(0, a**2)/2 + exp(-a**2)*besseli(1, a**2)
```

Differentiation with respect to \(a\) and \(b\) is supported:

```python
from sympy import diff
diff(marcumq(m, a, b), a)
a*(-marcumq(m, a, b) + marcumq(m + 1, a, b))
diff(marcumq(m, a, b), b)
-a**2*(1 - m)*b**m*exp(-a**2/2 - b**2/2)*besseli(m - 1, a*b)
```

References

Airy Functions

```python
class sympy.functions.special.bessel.AiryBase(*args)
    Abstract base class for Airy functions.
    This class is meant to reduce code duplication.
class sympy.functions.special.bessel.airyai(arg)
    The Airy function Ai of the first kind.
```
Explanation

The Airy function $\text{Ai}(z)$ is defined to be the function satisfying Airy’s differential equation

$$\frac{d^2w(z)}{dz^2} - zw(z) = 0.$$ 

Equivalently, for real $z$

$$\text{Ai}(z) := \frac{1}{\pi} \int_0^\infty \cos \left( \frac{t^3}{3} + zt \right) dt.$$ 

Examples

Create an Airy function object:

```python
>>> from sympy import airyai
>>> from sympy.abc import z

>>> airyai(z)
airyai(z)
```

Several special values are known:

```python
>>> airyai(0)
3**(1/3)/(3*gamma(2/3))
>>> from sympy import oo
>>> airyai(oo)
0
>>> airyai(-oo)
0
```

The Airy function obeys the mirror symmetry:

```python
>>> from sympy import conjugate
>>> conjugate(airyai(z))
airyai(conjugate(z))
```

Differentiation with respect to $z$ is supported:

```python
>>> from sympy import diff
>>> diff(airyai(z), z)
airyaiprime(z)
>>> diff(airyai(z), z, 2)
z*airyai(z)
```

Series expansion is also supported:

```python
>>> from sympy import series
>>> series(airyai(z), z, 0, 3)
3**(5/6)*gamma(1/3)/(6*pi) - 3**(1/6)*z*gamma(2/3)/(2*pi) + O(z**3)
```

We can numerically evaluate the Airy function to arbitrary precision on the whole complex plane:
Rewrite \( \text{Ai}(z) \) in terms of hypergeometric functions:

```python
>>> from sympy import hyper
>>> airyai(z).rewrite(hyper)
-3**(2/3)*z*hyper((,), (4/3,), z**3/9)/(3*gamma(1/3)) + 3**(1/3)*hyper((,), (2/3,), z**3/9)/(3*gamma(2/3))
```

References

[R409], [R410], [R411], [R412]

**class sympy.functions.special.bessel.airybi(arg)**
The Airy function Bi of the second kind.

**Explanation**

The Airy function \( \text{Bi}(z) \) is defined to be the function satisfying Airy’s differential equation

\[
\frac{d^2w(z)}{dz^2} - zw(z) = 0.
\]

Equivalently, for real \( z \)

\[
\text{Bi}(z) := \frac{1}{\pi} \int_0^{\infty} \exp \left( -\frac{t^3}{3} + zt \right) + \sin \left( \frac{t^3}{3} + zt \right) dt.
\]

**Examples**

Create an Airy function object:

```python
>>> from sympy import airybi
>>> from sympy.abc import z

>>> airybi(z)
airybi(z)
```

Several special values are known:
The Airy function obeys the mirror symmetry:

```python
>>> from sympy import conjugate
>>> conjugate(airybi(z))
airybi(conjugate(z))
```

Differentiation with respect to \( z \) is supported:

```python
>>> from sympy import diff
>>> diff(airybi(z), z)
airybiprime(z)
>>> diff(airybi(z), z, 2)
z*airybi(z)
```

Series expansion is also supported:

```python
>>> from sympy import series
>>> series(airybi(z), z, 0, 3)
3**(1/3)*gamma(1/3)/(2*pi) + 3**(2/3)*z*gamma(2/3)/(2*pi) + O(z**3)
```

We can numerically evaluate the Airy function to arbitrary precision on the whole complex plane:

```python
>>> airybi(-2).evalf(50)
-0.41230258795639848808323405461146104203453483447240
```

Rewrite Bi(\( z \)) in terms of hypergeometric functions:

```python
>>> from sympy import hyper
>>> airybi(z).rewrite(hyper)
3**(1/6)*z*hyper((,), (4/3,), z**3/9)/gamma(1/3) + 3**(5/6)*hyper((,), (2/3,), z**3/9)/(3*gamma(2/3))
```

class sympy.functions.special.bessel.airyaiprime(arg)
The derivative \( \text{Ai}' \) of the Airy function of the first kind.

**Explanation**

The Airy function \( \text{Ai}'(z) \) is defined to be the function

\[
\text{Ai}'(z) := \frac{d\text{Ai}(z)}{dz}.
\]

**Examples**

Create an Airy function object:

```python
>>> from sympy import airyaiprime
>>> from sympy.abc import z

>>> airyaiprime(z)
airyaiprime(z)
```

Several special values are known:

```python
>>> airyaiprime(0)
-3**(2/3)/(3*gamma(1/3))
>>> from sympy import oo
>>> airyaiprime(oo)
0
```

The Airy function obeys the mirror symmetry:

```python
>>> from sympy import conjugate
>>> conjugate(airyaiprime(z))
airyaiprime(conjugate(z))
```

Differentiation with respect to \( z \) is supported:

```python
>>> from sympy import diff
>>> diff(airyaiprime(z), z)
z*airyai(z)
>>> diff(airyaiprime(z), z, 2)
z*airyaiprime(z) + airyai(z)
```

Series expansion is also supported:

```python
>>> from sympy import series
>>> series(airyaiprime(z), z, 0, 3)
-3**(2/3)/(3*gamma(1/3)) + 3**(1/3)*z**2/(6*gamma(2/3)) + 0(z**3)
```

5.8. Topics
We can numerically evaluate the Airy function to arbitrary precision on the whole complex plane:

```python
>>> airyaprimel(-2).evalf(50)
0.61825902074169104140626429133247528291577794512415
```

Rewrite Ai′(z) in terms of hypergeometric functions:

```python
>>> from sympy import hyper
>>> airyaprimel(z).rewrite(hyper)
3**(1/3)*z**2*hyper((,), (5/3,), z**3/9)/(6*gamma(2/3)) - 3**(2/3)*z**2*hyper((,), (1/3,), z**3/9)/(3*gamma(1/3))
```

### References

[R417], [R418], [R419], [R420]

#### class sympy.functions.special.bessel.airybiprime(arg)

The derivative Bi′ of the Airy function of the first kind.

### Explanation

The Airy function Bi′(z) is defined to be the function

\[
\text{Bi}'(z) := \frac{d\text{Bi}(z)}{dz}.
\]

### Examples

Create an Airy function object:

```python
>>> from sympy import airybiprime
>>> from sympy.abc import z

>>> airybiprime(z)
```

Several special values are known:
The Airy function obeys the mirror symmetry:

```python
>>> from sympy import conjugate
>>> conjugate(airybiprime(z))
airybiprime(conjugate(z))
```

Differentiation with respect to $z$ is supported:

```python
>>> from sympy import diff
>>> diff(airybiprime(z), z)
z*airybi(z)
>>> diff(airybiprime(z), z, 2)
z*airybiprime(z) + airybi(z)
```

Series expansion is also supported:

```python
>>> from sympy import series
>>> series(airybiprime(z), z, 0, 3)
3**(1/6)/gamma(1/3) + 3**(5/6)*z**2/(6*gamma(2/3)) + O(z**3)
```

We can numerically evaluate the Airy function to arbitrary precision on the whole complex plane:

```python
>>> airybiprime(-2).evalf(50)
0.27879516692116952268509756941098324140300059345163
```

Rewrite $\text{Bi}'(z)$ in terms of hypergeometric functions:

```python
>>> from sympy import hyper
>>> airybiprime(z).rewrite(hyper)
3**(5/6)*z**2*hyper((), (5/3,), z**3/9)/(6*gamma(2/3)) + 3**(1/6)*hyper((), (1/3,), z**3/9)/gamma(1/3)
```

**B-Splines**

`sympy.functions.special.bsplines.bspline_basis(d, knots, n, x)`

The \( n \)-th B-spline at \( x \) of degree \( d \) with knots.

**Parameters**

- **\( d \)**: integer  
  degree of bspline

- **knots**: list of integer values  
  list of knots points of bspline

- **\( n \)**: integer  
  \( n \)-th B-spline

- **\( x \)**: symbol

**Explanation**

B-Splines are piecewise polynomials of degree \( d \). They are defined on a set of knots, which is a sequence of integers or floats.

**Examples**

The 0th degree splines have a value of 1 on a single interval:

```
>>> from sympy import bspline_basis
>>> from sympy.abc import x
>>> d = 0
>>> knots = tuple(range(5))
>>> bspline_basis(d, knots, 0, x)
Piecewise((1, (x >= 0) & (x <= 1)), (0, True))
```

For a given \((d, \text{knots})\) there are \( \text{len(knots)} - d - 1 \) B-splines defined, that are indexed by \( n \) (starting at 0).

Here is an example of a cubic B-spline:

```
>>> bspline_basis(3, tuple(range(5)), 0, x)
Piecewise((-x**3/6 + 2*x**2 - 2*x + 2/3, (x >= 3) & (x <= 4)),
(-x**3/2 + 2*x**2 - 2*x + 2/3, (x >= 2) & (x <= 3)),
(x**3/2 - 4*x**2 + 10*x - 22/3, (x >= 1) & (x <= 2)),
(-x**3/2 + 2*x**2 - 2*x + 2/3, (x >= 0) & (x <= 1)),
(0, True))
```
By repeating knot points, you can introduce discontinuities in the B-splines and their derivatives:

```python
>>> d = 1
>>> knots = (0, 0, 2, 3, 4)
>>> bspline_basis(d, knots, 0, x)
Piecewise((1 - x/2, (x >= 0) & (x <= 2)), (0, True))
```

It is quite time consuming to construct and evaluate B-splines. If you need to evaluate a B-spline many times, it is best to lambdify them first:

```python
>>> from sympy import lambdify
>>> d = 3
>>> knots = tuple(range(10))
>>> b0 = bspline_basis(d, knots, 0, x)
>>> f = lambdify(x, b0)
>>> y = f(0.5)
```

**See also:**

*bspline_basis_set* (page 569)

**References**

[R425]

`sympy.functions.special.bsplines.bspline_basis_set(d, knots, x)`

Return the \( \text{len}(\text{knots}) - d - 1 \) B-splines at \( x \) of degree \( d \) with \( \text{knots} \).

**Parameters**

- **d**: integer
  
degree of bspline

- **knots**: list of integers
  
list of knot points of bspline

- **x**: symbol

**Explanation**

This function returns a list of piecewise polynomials that are the \( \text{len}(\text{knots}) - d - 1 \) B-splines of degree \( d \) for the given knots. This function calls `bspline_basis(d, knots, n, x)` for different values of \( n \).
Examples

```python
>>> from sympy import bspline_basis_set
>>> from sympy.abc import x
>>> d = 2
>>> knots = range(5)
>>> splines = bspline_basis_set(d, knots, x)
>>> splines
[Piecewise((x**2/2, (x >= 0) & (x <= 1)),
           (-x**2 + 3*x - 3/2, (x >= 1) & (x <= 2)),
           (x**2/2 - 3*x + 9/2, (x >= 2) & (x <= 3)),
           (0, True)),
Piecewise((x**2/2 - x + 1/2, (x >= 1) & (x <= 2)),
           (-x**2 + 5*x - 11/2, (x >= 2) & (x <= 3)),
           (x**2/2 - 4*x + 8, (x >= 3) & (x <= 4)),
           (0, True))]
```

See also:

- `bspline_basis` (page 568)
- `interpolating_spline` in `sympy.functions.special.bsplines`

Return spline of degree \( d \), passing through the given \( X \) and \( Y \) values.

**Parameters**

- \( d \) : integer
  - Degree of Bspline strictly greater than equal to one
- \( x \) : symbol
- \( X \) : list of strictly increasing real values
  - list of \( X \) coordinates through which the spline passes
- \( Y \) : list of real values
  - list of corresponding \( Y \) coordinates through which the spline passes

**Explanation**

This function returns a piecewise function such that each part is a polynomial of degree not greater than \( d \). The value of \( d \) must be 1 or greater and the values of \( X \) must be strictly increasing.

**Examples**

```python
>>> from sympy import interpolating_spline
>>> from sympy.abc import x
>>> interpolating_spline(1, x, [1, 2, 4, 7], [3, 6, 5, 7])
Piecewise((3*x, (x >= 1) & (x <= 2)),
           (7 - x/2, (x >= 2) & (x <= 4)),
           (2*x/3 + 7/3, (x >= 4) & (x <= 7)))
>>> interpolating_spline(3, x, [-2, 0, 1, 3, 4], [4, 2, 1, 1, 3])
Piecewise((7*x**3/117 + 7*x**2/117 - 131*x/117 + 2, (x >= -2) & (x <= 0)),
           (7*x**3/117 + x**2/117 - 7*x/117 + 1, (x > 0) & (x <= 1)),
           (x**3/117 - x/117 + 2, (x > 1) & (x <= 3)),
           (7*x**3/117 + 7*x**2/117 - 131*x/117 + 2, (x > 3) & (x <= 4)))
(continues on next page)

bspline_basis_set (page 569), interpolating_poly (page 2514)

Riemann Zeta and Related Functions

class sympy.functions.special.zeta_functions.zeta(s, a=None)
Hurwitz zeta function (or Riemann zeta function).

Explanation

For Re(a) > 0 and Re(s) > 1, this function is defined as
\[
\zeta(s, a) = \sum_{n=0}^{\infty} \frac{1}{(n + a)^s},
\]
where the standard choice of argument for \( n + a \) is used. For fixed \( a \) not a nonpositive integer the Hurwitz zeta function admits a meromorphic continuation to all of \( \mathbb{C} \); it is an unbranched function with a simple pole at \( s = 1 \).

The Hurwitz zeta function is a special case of the Lerch transcendent:
\[
\zeta(s, a) = \Phi(1, s, a).
\]
This formula defines an analytic continuation for all possible values of \( s \) and \( a \) (also Re(\( a \)) < 0), see the documentation of lerchphi (page 575) for a description of the branching behavior.

If no value is passed for \( a \) a default value of \( a = 1 \) is assumed, yielding the Riemann zeta function.

Examples

For \( a = 1 \) the Hurwitz zeta function reduces to the famous Riemann zeta function:
\[
\zeta(s, 1) = \zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s}.
\]

```python
>>> from sympy import zeta
>>> from sympy.abc import s
>>> zeta(s, 1)
zeta(s)
```

The Riemann zeta function can also be expressed using the Dirichlet eta function:
The Riemann zeta function at nonnegative even and negative integer values is related to the Bernoulli numbers and polynomials:

\[
\zeta(2) = \frac{\pi^2}{6}
\]
\[
\zeta(4) = \frac{\pi^4}{90}
\]
\[
\zeta(0) = -\frac{1}{2}
\]
\[
\zeta(-1) = -\frac{1}{12}
\]
\[
\zeta(-4) = 0
\]

The specific formulae are:

\[
\zeta(2n) = -\frac{(2\pi i)^{2n} B_{2n}}{2(2n)!}
\]
\[
\zeta(-n, a) = -\frac{B_{n+1}(a)}{n+1}
\]

No closed-form expressions are known at positive odd integers, but numerical evaluation is possible:

\[
\zeta(3).n()
\]
1.20205690315959

The derivative of \(\zeta(s, a)\) with respect to \(a\) can be computed:

\[
\text{from sympy import a}
\]
\[
\zeta(s, a).diff(a) = -s \zeta(s + 1, a)
\]

However the derivative with respect to \(s\) has no useful closed form expression:

\[
\text{from sympy import s}
\]
\[
\zeta(s, a).diff(s) = \text{Derivative}(\zeta(s, a), s)
\]

The Hurwitz zeta function can be expressed in terms of the Lerch transcendent, \(\text{lerchphi}\) (page 575):

\[
\text{from sympy import lerchphi}
\]
\[
\zeta(s, a).rewrite(lerchphi) = \text{lerchphi}(1, s, a)
\]

See also:

\(\text{dirichlet_eta}\) (page 573), \(\text{lerchphi}\) (page 575), \(\text{polylog}\) (page 573)
**class** sympy.functions.special.zeta_functions.dirichlet_eta(s, a=None)

Dirichlet eta function.

**Explanation**

For \( \text{Re}(s) > 0 \) and \( 0 < x \leq 1 \), this function is defined as

\[
\eta(s, a) = \sum_{n=0}^{\infty} \frac{(-1)^n}{(n + a)^s}.
\]

It admits a unique analytic continuation to all of \( \mathbb{C} \) for any fixed \( a \) not a nonpositive integer. It is an entire, unbranched function.

It can be expressed using the Hurwitz zeta function as

\[
\eta(s, a) = \zeta(s, a) - 2^{1-s} \zeta\left(s, \frac{a+1}{2}\right)
\]

and using the generalized Genocchi function as

\[
\eta(s, a) = \frac{G(1-s, a)}{2(s-1)}.
\]

In both cases the limiting value of \( \log 2 - \psi(a) + \psi\left(\frac{a+1}{2}\right) \) is used when \( s = 1 \).

**Examples**

```python
>>> from sympy import dirichlet_eta, zeta
>>> from sympy.abc import s
>>> dirichlet_eta(s).rewrite(zeta)
Piecewise((log(2), Eq(s, 1)), ((1 - 2**(1 - s))*zeta(s), True))
```

**See also:**

*zeta* (page 571)

**References**

[R428], [R429]
Explanation

For \( |z| < 1 \) and \( s \in \mathbb{C} \), the polylogarithm is defined by

\[
\text{Li}_s(z) = \sum_{n=1}^{\infty} \frac{z^n}{n^s},
\]

where the standard branch of the argument is used for \( n \). It admits an analytic continuation which is branched at \( z = 1 \) (notably not on the sheet of initial definition), \( z = 0 \) and \( z = \infty \).

The name polylogarithm comes from the fact that for \( s = 1 \), the polylogarithm is related to the ordinary logarithm (see examples), and that

\[
\text{Li}_{s+1}(z) = \int_0^z \frac{\text{Li}_s(t)}{t} \, dt.
\]

The polylogarithm is a special case of the Lerch transcendent:

\[
\text{Li}_s(z) = z \Phi(z, s, 1).
\]

Examples

For \( z \in \{0,1,-1\} \), the polylogarithm is automatically expressed using other functions:

```python
>>> from sympy import polylog
>>> from sympy.abc import s
>>> polylog(s, 0)
0
>>> polylog(s, 1)
zeta(s)
>>> polylog(s, -1)
dirichlet_eta(s)
```

If \( s \) is a negative integer, 0 or 1, the polylogarithm can be expressed using elementary functions. This can be done using `expand_func()`:

```python
>>> from sympy import expand_func
>>> from sympy.abc import z
>>> expand_func(polylog(1, z))
-log(1 - z)
>>> expand_func(polylog(0, z))
z/(1 - z)
```

The derivative with respect to \( z \) can be computed in closed form:

```python
>>> polylog(s, z).diff(z)
polylog(s - 1, z)/z
```

The polylogarithm can be expressed in terms of the lerch transcendent:

```python
>>> from sympy import lerchphi
>>> polylog(s, z).rewrite(lerchphi)
z*lerchphi(z, s, 1)
```
See also:

- `zeta` (page 571), `lerchphi` (page 575)

```python
class sympy.functions.special.zeta_functions.lerchphi(*args)
Lerch transcendent (Lerch phi function).
```

**Explanation**

For $\text{Re}(a) > 0$, $|z| < 1$ and $s \in \mathbb{C}$, the Lerch transcendent is defined as

$$
\Phi(z, s, a) = \sum_{n=0}^{\infty} \frac{z^n}{(n+a)^s},
$$

where the standard branch of the argument is used for $n+a$, and by analytic continuation for other values of the parameters.

A commonly used related function is the Lerch zeta function, defined by

$$
L(q, s, a) = \Phi(e^{2\pi i q}, s, a).
$$

**Analytic Continuation and Branching Behavior**

It can be shown that

$$
\Phi(z, s, a) = z\Phi(z, s, a + 1) + a^{-s}.
$$

This provides the analytic continuation to $\text{Re}(a) \leq 0$.

Assume now $\text{Re}(a) > 0$. The integral representation

$$
\Phi_0(z, s, a) = \int_{0}^{\infty} \frac{t^{s-1}e^{-a t}}{1 - z e^{-t}} \frac{dt}{\Gamma(s)}
$$

provides an analytic continuation to $\mathbb{C} - [1, \infty)$. Finally, for $x \in (1, \infty)$ we find

$$
\lim_{\epsilon \to 0^+} \Phi_0(x + i\epsilon, s, a) - \lim_{\epsilon \to 0^+} \Phi_0(x - i\epsilon, s, a) = \frac{2\pi i \log^{s-1} x}{x^s \Gamma(s)},
$$

using the standard branch for both $\log x$ and $\log \log x$ (a branch of $\log \log x$ is needed to evaluate $\log x^{s-1}$). This concludes the analytic continuation. The Lerch transcendent is thus branched at $z \in \{0, 1, \infty\}$ and $a \in \mathbb{Z}_{\leq 0}$. For fixed $z, a$ outside these branch points, it is an entire function of $s$.

**Examples**

The Lerch transcendent is a fairly general function, for this reason it does not automatically evaluate to simpler functions. Use `expand_func()` to achieve this.

If $z = 1$, the Lerch transcendent reduces to the Hurwitz zeta function:

```python
>>> from sympy import lerchphi, expand_func
>>> from sympy.abc import z, s, a
>>> expand_func(lerchphi(1, s, a))
zeta(s, a)
```
More generally, if \( z \) is a root of unity, the Lerch transcendent reduces to a sum of Hurwitz zeta functions:

```python
>>> expand_func(lerchphi(-1, s, a))
zeta(s, a/2)/2**s - zeta(s, a/2 + 1/2)/2**s
```

If \( a = 1 \), the Lerch transcendent reduces to the polylogarithm:

```python
>>> expand_func(lerchphi(z, s, 1))
polylog(s, z)/z
```

More generally, if \( a \) is rational, the Lerch transcendent reduces to a sum of polylogarithms:

```python
>>> from sympy import S
>>> expand_func(lerchphi(z, s, S(1)/2))
2**(s - 1)*(polylog(s, sqrt(z))/sqrt(z) - polylog(s, sqrt(z)*exp_polar(I*pi))/sqrt(z))
>>> expand_func(lerchphi(z, s, S(3)/2))
-2**s/z + 2**(s - 1)*(polylog(s, sqrt(z))/sqrt(z) - polylog(s, sqrt(z)*exp_polar(I*pi))/sqrt(z))/z
```

The derivatives with respect to \( z \) and \( a \) can be computed in closed form:

```python
>>> lerchphi(z, s, a).diff(z)
(-a*lerchphi(z, s, a) + lerchphi(z, s - 1, a))/z
>>> lerchphi(z, s, a).diff(a)
-s*lerchphi(z, s + 1, a)
```

polylog (page 573), zeta (page 571)

References

[R430], [R431], [R432]

class sympy.functions.special.zeta_functions.stieltjes(n, a=None)

Represents Stieltjes constants, \( \gamma_n \) that occur in Laurent Series expansion of the Riemann zeta function.

Examples

```python
>>> from sympy import stieltjes
>>> from sympy.abc import n, m
>>> stieltjes(n, m)
stieltjes(n)
```

The zero'th stieltjes constant:

```python
>>> stieltjes(0)
EulerGamma
```
For generalized stieltjes constants:

```python
>>> stieltjes(n, m)
Calculated value
```

Constants are only defined for integers \(\geq 0\):

```python
>>> stieltjes(-1)
zoo
```

**References**

[R433]

### Hypergeometric Functions

**class** `sympy.functions.special.hyper.hyper(ap, bq, z)`

The generalized hypergeometric function is defined by a series where the ratios of successive terms are a rational function of the summation index. When convergent, it is continued analytically to the largest possible domain.

**Explanation**

The hypergeometric function depends on two vectors of parameters, called the numerator parameters \(a_p\), and the denominator parameters \(b_q\). It also has an argument \(z\). The series definition is

\[
\begin{align*}
pFq\left( \begin{array}{c} a_1, \cdots, a_p \\ b_1, \cdots, b_q \end{array} \right| z \right) &= \sum_{n=0}^{\infty} \frac{(a_1)_n \cdots (a_p)_n}{(b_1)_n \cdots (b_q)_n} \frac{z^n}{n!},
\end{align*}
\]

where \((a)_n = (a)(a + 1)\cdots(a + n - 1)\) denotes the rising factorial.

If one of the \(b_q\) is a non-positive integer then the series is undefined unless one of the \(a_p\) is a larger (i.e., smaller in magnitude) non-positive integer. If none of the \(b_q\) is a non-positive integer and one of the \(a_p\) is a non-negative integer, then the series reduces to a polynomial. To simplify the following discussion, we assume that none of the \(a_p\) or \(b_q\) is a non-positive integer. For more details, see the references.

The series converges for all \(z\) if \(p \leq q\), and thus defines an entire single-valued function in this case. If \(p = q + 1\) the series converges for \(|z| < 1\), and can be continued analytically into a half-plane. If \(p > q + 1\) the series is divergent for all \(z\).

Please note the hypergeometric function constructor currently does *not* check if the parameters actually yield a well-defined function.
Examples

The parameters $a_p$ and $b_q$ can be passed as arbitrary iterables, for example:

```python
>>> from sympy import hyper
>>> from sympy import x, n, a
>>> hyper((1, 2, 3), [3, 4], x)
hyper((1, 2), (3, 4), x)
```

There is also pretty printing (it looks better using Unicode):

```python
>>> from sympy import pprint
>>> pprint(hyper((1, 2, 3), [3, 4], x), use_unicode=False)
   /
| /1, 2, 3 |
| 1 | x |
| 2 \ 3, 4 |
```

The parameters must always be iterables, even if they are vectors of length one or zero:

```python
>>> hyper((1,), [], x)
hyper((1,), (), x)
```

But of course they may be variables (but if they depend on $x$ then you should not expect much implemented functionality):

```python
>>> hyper((n, a), (n**2,), x)
hyper((n, a), (n**2,), x)
```

The hypergeometric function generalizes many named special functions. The function `hyperexpand()` tries to express a hypergeometric function using named special functions. For example:

```python
>>> from sympy import hyperexpand
>>> hyperexpand(hyper([], [], x))
exp(x)
```

You can also use `expand_func()`:

```python
>>> from sympy import expand_func
>>> expand_func(x*hyper([1], [1], -x))
log(x + 1)
```

More examples:

```python
>>> from sympy import S
>>> hyperexpand(hyper([1], [S(1)/2], -x**2/4))
cos(x)
>>> hyperexpand(x*hyper([S(1)/2, S(1)/2], [S(3)/2], x**2))
asin(x)
```

We can also sometimes `hyperexpand()` parametric functions:
```python
>>> from sympy import a
>>> hyperexpand(hyper([-a], [], x))
(1 - x)**a
```

References

[R434], [R435]

**property ap**

Numerator parameters of the hypergeometric function.

**property argument**

Argument of the hypergeometric function.

**property bq**

Denominator parameters of the hypergeometric function.

**property convergence_statement**

Return a condition on z under which the series converges.

**property eta**

A quantity related to the convergence of the series.

**property radius_of_convergence**

Compute the radius of convergence of the defining series.

**Explanation**

Note that even if this is not oo, the function may still be evaluated outside of the radius of convergence by analytic continuation. But if this is zero, then the function is not actually defined anywhere else.

**Examples**

```python
>>> from sympy import hyper
>>> from sympy.abc import z
>>> hyper((1, 2), [3], z).radius_of_convergence
1
>>> hyper((1, 2, 3), [4], z).radius_of_convergence
0
>>> hyper((1, 2), (3, 4), z).radius_of_convergence
oo
```

class sympy.functions.special.hyper.meijerg(*args)

The Meijer G-function is defined by a Mellin-Barnes type integral that resembles an inverse Mellin transform. It generalizes the hypergeometric functions.
**Explanation**

The Meijer G-function depends on four sets of parameters. There are “numerator parameters” $a_1, \ldots, a_n$ and $a_{n+1}, \ldots, a_p$, and there are “denominator parameters” $b_1, \ldots, b_m$ and $b_{m+1}, \ldots, b_q$. Confusingly, it is traditionally denoted as follows (note the position of $m$, $n$, $p$, $q$, and how they relate to the lengths of the four parameter vectors):

$$G_{m,n}^{p,q}(a_1, \ldots, a_n; a_{n+1}, \ldots, a_p; b_1, \ldots, b_m; b_{m+1}, \ldots, b_q; z).$$

However, in SymPy the four parameter vectors are always available separately (see examples), so that there is no need to keep track of the decorating sub- and super-scripts on the G symbol.

The G function is defined as the following integral:

$$\frac{1}{2\pi i} \int \frac{\prod_{j=1}^{m} \Gamma(b_j - s)}{\prod_{j=m+1}^{p} \Gamma(b_j + s)} \frac{\prod_{j=1}^{n} \Gamma(1 - a_j - s)}{\prod_{j=n+1}^{p} \Gamma(1 - a_j + s)} z^s ds,$$

where $\Gamma(z)$ is the gamma function. There are three possible contours which we will not describe in detail here (see the references). If the integral converges along more than one of them, the definitions agree. The contours all separate the poles of $\Gamma(1 - a_j + s)$ from the poles of $\Gamma(b_k - s)$, so in particular the G function is undefined if $a_j - b_k \in \mathbb{Z}_{>0}$ for some $j \leq n$ and $k \leq m$.

The conditions under which one of the contours yields a convergent integral are complicated and we do not state them here, see the references.

Please note currently the Meijer G-function constructor does not check any convergence conditions.

**Examples**

You can pass the parameters either as four separate vectors:

```python
>>> from sympy import meijerg, Tuple, pprint
>>> from sympy.abc import x, a
>>> pprint(meijerg((1, 2), (a, 4), (5,), [], x), use_unicode=False)
\_1, 2 \_1, 2 a, 4 | \ 
\_| \_4, 1 \_5 | /
```

Or as two nested vectors:

```python
>>> pprint(meijerg([(1, 2), (3, 4)], ([5], Tuple()), x), use_unicode=False)
\_1, 2 \_1, 2 3, 4 | \ 
\_| \_4, 1 \_5 | /
```

As with the hypergeometric function, the parameters may be passed as arbitrary iterables. Vectors of length zero and one also have to be passed as iterables. The parameters need not be constants, but if they depend on the argument then not much implemented functionality should be expected.

All the subvectors of parameters are available:
The Meijer G-function generalizes the hypergeometric functions. In some cases it can be expressed in terms of hypergeometric functions, using Slater’s theorem. For example:

```python
>>> from sympy import hyperexpand
>>> from sympy.abc import a, b, c
>>> hyperexpand(meijerg([a], [], [c], [b], x), allow_hyper=True)
x**c*gamma(-a + c + 1)*hyper((-a + c + 1,)
    (-b + c + 1,), -x)/gamma(-b + c + 1)
```

Thus the Meijer G-function also subsumes many named functions as special cases. You can use expand_func() or hyperexpand() to (try to) rewrite a Meijer G-function in terms of named special functions. For example:

```python
>>> from sympy import expand_func, S
>>> expand_func(meijerg([[]], [[0]], [[S(1)/2], [0]], x/2**2))
exp(x)
>>> hyperexpand(meijerg([[]], [[0]], [[S(1)/2], [0]], (x/2)**2))
sin(x)/sqrt(pi)
```

**property an**

First set of numerator parameters.

**property aother**

Second set of numerator parameters.

**property ap**

Combined numerator parameters.

5.8. Topics
**property argument**
Argument of the Meijer G-function.

**property bm**
First set of denominator parameters.

**property bother**
Second set of denominator parameters.

**property bq**
Combined denominator parameters.

**property delta**
A quantity related to the convergence region of the integral, c.f. references.

**get_period()**
Return a number $P$ such that $G(x * \exp(I * P)) = G(x)$.

**Examples**

```python
>>> from sympy import meijerg, pi, S
>>> from sympy.abc import z
```

```python
>>> meijerg([1], [], [], [], z).get_period()
2*pi
>>> meijerg([pi], [], [], [], z).get_period()
oo
>>> meijerg([1, 2], [], [], [], z).get_period()
oo
>>> meijerg([1, 1], [2], [1, S(1)/2, S(1)/3], [1], z).get_period()
12*pi
```

**integrand(s)**
Get the defining integrand $D(s)$.

**property is_number**
Returns true if expression has numeric data only.

**property nu**
A quantity related to the convergence region of the integral, c.f. references.

**class** sympy.functions.special.hyper.appellf1($a, b1, b2, c, x, y$)
This is the Appell hypergeometric function of two variables as:

$$F_1(a, b_1, b_2, c, x, y) = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(a)_{m+n}(b_1)_m(b_2)_n x^m y^n}{(c)_{m+n} m! n!}.$$
Examples

```python
>>> from sympy import appellf1, symbols
>>> x, y, a, b1, b2, c = symbols('x y a b1 b2 c')
>>> appellf1(2., 1., 6., 4., 5., 6.)
0.006339426292673
>>> appellf1(12., 12., 6., 4., 0.5, 0.12)
172870711.659936
>>> appellf1(40, 2, 6, 4, 15, 60)
appellf1(40, 2, 6, 4, 15, 60)
>>> appellf1(20., 12., 10., 3., 0.5, 0.12)
15605338197184.4
>>> appellf1(40, 2, 6, 4, x, y)
appellf1(40, 2, 6, 4, x, y)
>>> appellf1(a, b1, b2, c, x, y)
appellf1(a, b1, b2, c, x, y)
```

Elliptic integrals

```python
class sympy.functions.special.elliptic_integrals.elliptic_k(m)
The complete elliptic integral of the first kind, defined by

\[ K(m) = F \left( \frac{\pi}{2} | m \right) \]

where \( F(z|m) \) is the Legendre incomplete elliptic integral of the first kind.
```

Explanation

The function \( K(m) \) is a single-valued function on the complex plane with branch cut along the interval \((1, \infty)\).

Note that our notation defines the incomplete elliptic integral in terms of the parameter \( m \) instead of the elliptic modulus (eccentricity) \( k \). In this case, the parameter \( m \) is defined as \( m = k^2 \).

Examples

```python
>>> from sympy import elliptic_k, I
>>> from sympy import elliptic_k
>>> elliptic_k(0)
pi/2
>>> elliptic_k(1.0 + I)
1.50923695405127 + 0.625146415202697*I
>>> elliptic_k(m).series(n=3)
pi/2 + pi*m/8 + 9*pi*m**2/128 + 0(m**3)
```
**See also:**

`elliptic_f` (page 584)

**References**

[R440], [R441]

```python
class sympy.functions.special.elliptic_integrals.elliptic_f(z, m)
```

The Legendre incomplete elliptic integral of the first kind, defined by

\[
F(z|m) = \int_0^z \frac{dt}{\sqrt{1 - m \sin^2 t}}
\]

**Explanation**

This function reduces to a complete elliptic integral of the first kind, \(K(m)\), when \(z = \pi/2\). Note that our notation defines the incomplete elliptic integral in terms of the parameter \(m\) instead of the elliptic modulus (eccentricity) \(k\). In this case, the parameter \(m\) is defined as \(m = k^2\).

**Examples**

```python
>>> from sympy import elliptic_f, I
>>> from sympy.abc import z, m
>>> elliptic_f(z, m).series(z)
z + z**5*(3*m**2/40 - m/30) + m*z**3/6 + O(z**6)
>>> elliptic_f(3.0 + I/2, 1.0 + I)
2.909449841483 + 1.74720545502474*I
```

**See also:**

`elliptic_k` (page 583)

**References**

[R442], [R443]

```python
class sympy.functions.special.elliptic_integrals.elliptic_e(m, z=None)
```

Called with two arguments \(z\) and \(m\), evaluates the incomplete elliptic integral of the second kind, defined by

\[
E(z|m) = \int_0^z \sqrt{1 - m \sin^2 t}\, dt
\]

Called with a single argument \(m\), evaluates the Legendre complete elliptic integral of the second kind

\[
E(m) = E\left(\frac{\pi}{2} \middle| m\right)
\]
Explanation

The function \( E(m) \) is a single-valued function on the complex plane with branch cut along the interval \((1, \infty)\).

Note that our notation defines the incomplete elliptic integral in terms of the parameter \( m \) instead of the elliptic modulus (eccentricity) \( k \). In this case, the parameter \( m \) is defined as \( m = k^2 \).

Examples

```python
>>> from sympy import elliptic_e, I
>>> from sympy.abc import z, m
>>> elliptic_e(z, m).series(z)
z + z**5*(-m**2/40 + m/30) - m*z**3/6 + O(z**6)
>>> elliptic_e(m).series(n=4)
pi/2 - pi*m/8 - 3*pi*m**2/128 - 5*pi*m**3/512 + O(m**4)
>>> elliptic_e(1 + I, 2 - I/2).n()
1.55203744279187 + 0.290764986058437*I
>>> elliptic_e(0)
pi/2
>>> elliptic_e(2.0 - I)
0.991052601328069 + 0.81879421395609*I
```

Mathieu Functions

class sympy.functions.special.mathieu_functions.MathieuBase(*args)
Abstract base class for Mathieu functions.
This class is meant to reduce code duplication.
class sympy.functions.special.mathieu_functions.mathieus(a, q, z)
The Mathieu Sine function \( S(a,q,z) \).

Explanation

This function is one solution of the Mathieu differential equation:
\[
y(x)'' + (a - 2q \cos(2x))y(x) = 0
\]
The other solution is the Mathieu Cosine function.

Examples

```python
>>> from sympy import diff, mathieus
>>> from sympy.abc import a, q, z
```

```python
>>> mathieus(a, q, z)
mathieus(a, q, z)
```

```python
>>> diff(mathieus(a, q, z), z)
diff(mathieus(a, q, z), z)
```

**Orthogonal Polynomials**

This module mainly implements special orthogonal polynomials.

See also `functions.combinatorial.numbers` which contains some combinatorial polynomials.
Jacobi Polynomials

```python
class sympy.functions.special.polynomials.jacobi(n, a, b, x)
    Jacobi polynomial \( P_n^{(\alpha,\beta)}(x) \).
```

**Explanation**

`jacobi(n, alpha, beta, x)` gives the \( n \)th Jacobi polynomial in \( x \), \( P_n^{(\alpha,\beta)}(x) \).

The Jacobi polynomials are orthogonal on \([-1, 1]\) with respect to the weight \((1-x)\alpha(1+x)^\beta\).

**Examples**

```python
>>> from sympy import jacobi, S, conjugate, diff
>>> from sympy.abc import a, b, n, x
>>> jacobi(0, a, b, x)
1
>>> jacobi(1, a, b, x)
a/2 - b/2 + x*(a/2 + b/2 + 1)
>>> jacobi(2, a, b, x)
a**2/8 - a*b/4 - a/8 + b**2/8 - b/8 + x**2*(a**2/8 + a*b/4 + 7*a/8 + b**2/8 + 7*b/8 + 3/2) + x*(a**2/4 + 3*a/4 - b**2/4 - 3*b/4) - 1/2
>>> jacobi(n, a, b, x)
jacobi(n, a, b, x)
>>> jacobi(n, a, a, x)
RisingFactorial(a + 1, n)*gegenbauer(n, a + 1/2, x)/RisingFactorial(2*a + 1, n)
>>> jacobi(n, S(1)/2, S(1)/2, x)
RisingFactorial(3/2, n)*chebyshevu(n, x)/factorial(n + 1)
>>> jacobi(n, -S(1)/2, -S(1)/2, x)
RisingFactorial(1/2, n)*chebyshevt(n, x)/factorial(n)
>>> jacobi(n, a, b, -x)
(-1)**n*jacobi(n, b, a, x)
>>> jacobi(n, a, b, 0)
gamma(a + n + 1)*hyper((-b - n, -n), (a + 1,), -1)/
    hyper((-b - n, -n), (a + 1,), 1)/
    gamma(a + n + 1)/factorial(n)
>>> jacobi(n, a, b, 1)
RisingFactorial(a + 1, n)/factorial(n)
```
conjugate(jacobi(n, a, b, x))
jacobi(n, conjugate(a), conjugate(b), conjugate(x))

diff(jacobi(n,a,b,x), x)
(a/2 + b/2 + n/2 + 1/2)*jacobi(n - 1, a + 1, b + 1, x)

jacobi_normalized(n, a, b, x)
Jacobi polynomial $P_{n}^{(\alpha,\beta)}(x)$.

Parameters

- n : integer degree of polynomial
- a : alpha value
- b : beta value
- x : symbol

Explanation

jacobi_normalized(n, alpha, beta, x) gives the $n$th Jacobi polynomial in $x$, $P_{n}^{(\alpha,\beta)}(x)$.

The Jacobi polynomials are orthogonal on $[-1,1]$ with respect to the weight $(1-x)^{\alpha}(1+x)^{\beta}$.

This function returns the polynomials normalized:

$$\int_{-1}^{1} P_{m}^{(\alpha,\beta)}(x)P_{n}^{(\alpha,\beta)}(x)(1-x)^{\alpha}(1+x)^{\beta}dx = \delta_{m,n}$$
Examples

```python
>>> from sympy import jacobi_normalized
>>> from sympy.abc import n, a, b, x

>>> jacobi_normalized(n, a, b, x)
jacobi(n, a, b, x)/sqrt(2**(a + b + 1)*gamma(a + n + 1)*gamma(b + n + 1)/
→((a + b + 2*n + 1)*factorial(n)*gamma(a + b + n + 1)))
```

Gegenbauer Polynomials

class sympy.functions.special.polynomials.gegenbauer(n, a, x)

Gegenbauer polynomial \( C_n^{(\alpha)}(x) \).

Explanation

gegenbauer(n, alpha, x) gives the \( n \)th Gegenbauer polynomial in \( x \), \( C_n^{(\alpha)}(x) \).
The Gegenbauer polynomials are orthogonal on \([-1,1]\) with respect to the weight
\((1-x^2)^{\alpha-\frac{1}{2}}\).

Examples

```python
>>> from sympy import gegenbauer, conjugate, diff
>>> from sympy.abc import n, a, x

>>> gegenbauer(0, a, x)
1
>>> gegenbauer(1, a, x)
2*a*x
>>> gegenbauer(2, a, x)
-a + x**2*(2*a**2 + 2*a)
```
\[
\text{gegenbauer}(3, a, x) = x^3 \left( \frac{4a^3}{3} + 4a^2 + \frac{8a}{3} \right) + x(-2a^2 - 2a)
\]

\[
\text{gegenbauer}(n, a, x) = \text{gegenbauer}(n, a, x)
\]

\[
\text{gegenbauer}(n, a, -x) = (-1)^n \text{gegenbauer}(n, a, x)
\]

\[
\text{gegenbauer}(n, a, 0) = 2^n \sqrt{\pi} \frac{\Gamma(a + n/2)}{\Gamma(a) \Gamma(1/2 - n/2) \Gamma(n + 1)}
\]

\[
\text{gegenbauer}(n, a, 1) = \frac{\Gamma(2a + n)}{\Gamma(2a) \Gamma(n + 1)}
\]

\[
\text{conjugate(gegenbauer}(n, a, x)) = \text{gegenbauer}(n, \text{conjugate}(a), \text{conjugate}(x))
\]

\[
\text{diff(gegenbauer}(n, a, x), x) = 2a \text{gegenbauer}(n - 1, a + 1, x)
\]

Chebyshev Polynomials

**class** sympy.functions.special.polynomials.chebyshevt(n, x)

Chebyshev polynomial of the first kind, $T_n(x)$.

**Explanation**

`chebyshevt(n, x)` gives the $n$th Chebyshev polynomial (of the first kind) in $x$, $T_n(x)$. The Chebyshev polynomials of the first kind are orthogonal on $[-1, 1]$ with respect to the weight $\frac{1}{\sqrt{1-x^2}}$.

**Examples**

```python
>>> from sympy import chebyshevt, diff
>>> from sympy.abc import n, x
>>> chebyshevt(0, x)
1
>>> chebyshevt(1, x)
x
>>> chebyshevt(2, x)
2*x**2 - 1
```

```python
>>> chebyshevt(n, x)
chebyshevt(n, x)
>>> chebyshevt(n, -x)
(-1)**n*chebyshevt(n, x)
>>> chebyshevt(-n, x)
chebyshevt(n, x)
```

```python
>>> chebyshevt(n, 0)
\cos(\pi*n/2)
>>> chebyshevt(n, -1)
(-1)**n
```

```python
>>> diff(chebyshevt(n, x), x)
n*chebyshevu(n - 1, x)
```

class sympy.functions.special.polynomials.chebyshevu(n, x)

Chebyshev polynomial of the second kind, \( U_n(x) \).

Explanation

chebyshevu(n, x) gives the \( n \)th Chebyshev polynomial of the second kind in \( x \), \( U_n(x) \).
The Chebyshev polynomials of the second kind are orthogonal on \([-1,1]\) with respect to the weight \( \sqrt{1-x^2} \).

Examples

```python
>>> from sympy import chebyshevu, diff
>>> from sympy.abc import n, x
>>> chebyshevu(0, x)
1
>>> chebyshevu(1, x)
2*x
>>> chebyshevu(2, x)
4*x**2 - 1
```

```python
>>> chebyshevu(n, x)
chebyshevu(n, x)
>>> chebyshevu(n, -x)
(-1)**n*chebyshevu(n, x)
>>> chebyshevu(-n, x)
-chebyshevu(n - 2, x)
```

```python
>>> chebyshevu(n, 0)
cos(pi*n/2)
>>> chebyshevu(n, 1)
n + 1
```

```python
>>> diff(chebyshevu(n, x), x)
(-x*chebyshevu(n, x) + (n + 1)*chebyshevt(n + 1, x))/(x**2 - 1)
```

class sympy.functions.special.polynomials.chebyshev_root(n, k)
chebyshev_root(n, k) returns the $k$th root (indexed from zero) of the $n$th Chebyshev polynomial of the first kind; that is, if $0 \leq k < n$, chebyshev(n, chebyshev_root(n, k)) == 0.

Examples

```python
>>> from sympy import chebyshev, chebyshev_root
>>> chebyshev_root(3, 2)
-sqrt(3)/2
>>> chebyshev(3, chebyshev_root(3, 2))
0
```

class sympy.functions.special.polynomials.chebyshevu_root(n, k)
chebyshevu_root(n, k) returns the $k$th root (indexed from zero) of the $n$th Chebyshev polynomial of the second kind; that is, if $0 \leq k < n$, chebyshevu(n, chebyshevu_root(n, k)) == 0.

Examples

```python
>>> from sympy import chebyshevu, chebyshevu_root
>>> chebyshevu_root(3, 2)
-sqrt(2)/2
>>> chebyshevu(3, chebyshevu_root(3, 2))
0
```

chebyshevt (page 594), chebyshevt_root (page 596), chebyshev (page 595), legendre (page 597), assoc_legendre (page 597), hermite (page 598), hermite_prob (page 599), laguerre (page 600), assoc_laguerre (page 601), sympy.polys.orthopolys.jacobi_poly (page 2516), sympy.polys.orthopolys.gegenbauer_poly (page 2516), sympy.polys.orthopolys.chebyshevt_poly (page 2515), sympy.polys.orthopolys.chebyshevu_poly (page 2515), sympy.polys.orthopolys.hermite_poly (page 2516), sympy.polys.orthopolys.hermite_prob_poly (page 2516), sympy.polys.orthopolys.legendre_poly (page 2517), sympy.polys.orthopolys.laguerre_poly (page 2517)
**Legendre Polynomials**

```python
class sympy.functions.special.polynomials.legendre(n, x)
legendre(n, x) gives the nth Legendre polynomial of x, \( P_n(x) \)
```

**Explanation**

The Legendre polynomials are orthogonal on \([-1, 1]\) with respect to the constant weight 1. They satisfy \( P_n(1) = 1 \) for all \( n \); further, \( P_n \) is odd for odd \( n \) and even for even \( n \).

**Examples**

```python
>>> from sympy import legendre, diff
>>> from sympy.abc import x, n
>>> legendre(0, x)
1
>>> legendre(1, x)
x
>>> legendre(2, x)
3*x**2/2 - 1/2
>>> legendre(n, x)
legendre(n, x)
>>> diff(legendre(n,x), x)
n*(x*legendre(n, x) - legendre(n - 1, x))/(x**2 - 1)
```

**See also:**

**References**

[R485], [R486], [R487], [R488]

```python
class sympy.functions.special.polynomials.assoc_legendre(n, m, x)
assoc_legendre(n, m, x) gives \( P_n^m(x) \), where \( n \) and \( m \) are the degree and order or an expression which is related to the nth order Legendre polynomial, \( P_n(x) \) in the following manner:

\[
P_n^m(x) = (-1)^m(1 - x^2)^{\frac{m}{2}} \frac{d^m P_n(x)}{dx^m}
\]
```
Explanation

Associated Legendre polynomials are orthogonal on $[-1,1]$ with:

- weight $= 1$ for the same $m$ and different $n$.
- weight $= \frac{1}{1-x^2}$ for the same $n$ and different $m$.

Examples

```python
>>> from sympy import assoc_legendre
>>> from sympy.abc import x, m, n
>>> assoc_legendre(0, 0, x)
1
>>> assoc_legendre(1, 0, x)
x
>>> assoc_legendre(1, 1, x)
-sqrt(1 - x**2)
>>> assoc_legendre(n, m, x)
assoc_legendre(n, m, x)
```

Hermite Polynomials

class sympy.functions.special.polynomials.hermite(n, x)

hermite(n, x) gives the $n$th Hermite polynomial in $x$, $H_n(x)$. 
**Explanation**

The Hermite polynomials are orthogonal on \((-\infty, \infty)\) with respect to the weight \(\exp(-x^2)\).

**Examples**

```python
>>> from sympy import hermite, diff
>>> from sympy.abc import x, n
>>> hermite(0, x)
1
>>> hermite(1, x)
2*x
>>> hermite(2, x)
4*x**2 - 2
>>> hermite(n, x)
hermite(n, x)
>>> diff(hermite(n, x), x)
2*n*hermite(n - 1, x)
>>> hermite(n, -x)
(-1)**n*hermite(n, x)
```

**References**

[R493], [R494], [R495]

class sympy.functions.special.polynomials.hermite_prob(n, x)

hermite_prob(n, x) gives the \(n\)th probabilist’s Hermite polynomial in \(x\), \(He_n(x)\).

**Explanation**

The probabilist’s Hermite polynomials are orthogonal on \((-\infty, \infty)\) with respect to the weight \(\exp(-x^2/2)\). They are monic polynomials, related to the plain Hermite polynomials (`hermite`
(page 598)) by

\[
He_n(x) = 2^{-n/2} H_n(x/\sqrt{2})
\]
Examples

```python
>>> from sympy import hermite_prob, diff, I
>>> from sympy.abc import x, n
>>> hermite_prob(1, x)
0
>>> hermite_prob(5, x)
x**5 - 10*x**3 + 15*x
>>> diff(hermite_prob(n, x), x)
n*hermite_prob(n - 1, x)
>>> hermite_prob(n, -x)
(-1)**n*hermite_prob(n, x)
```

The sum of absolute values of coefficients of $He_n(x)$ is the number of matchings in the complete graph $K_n$ or telephone number, A000085 in the OEIS:

```python
>>> [hermite_prob(n, I) / I**n for n in range(11)]
[1, 1, 2, 4, 10, 26, 76, 232, 764, 2620, 9496]
```

Laguerre Polynomials

class sympy.functions.special.polynomials.laguerre(n, x)

Returns the $n$th Laguerre polynomial in $x$, $L_n(x)$.

Parameters

n : int

Degree of Laguerre polynomial. Must be $n \geq 0$. 
Examples

```python
>>> from sympy import laguerre, diff
>>> from sympy.abc import x, n
>>> laguerre(0, x)
1
>>> laguerre(1, x)
1 - x
>>> laguerre(2, x)
x**2/2 - 2*x + 1
>>> laguerre(3, x)
-x**3/6 + 3*x**2/2 - 3*x + 1

>>> laguerre(n, x)
laguerre(n, x)
```

```python
>>> diff(laguerre(n, x), x)
-assoc_laguerre(n - 1, 1, x)
```

class sympy.functions.special.polynomials.assoc_laguerre(n, alpha, x)
Returns the n-th generalized Laguerre polynomial in x, \( L_n(x) \).

Parameters

- **n**: int
  Degree of Laguerre polynomial. Must be \( n \geq 0 \).

- **alpha**: Expr
  Arbitrary expression. For \( \alpha=0 \) regular Laguerre polynomials will be generated.

5.8. Topics
Examples

```python
>>> from sympy import assoc_laguerre, diff
>>> from sympy.abc import x, n, a
>>> assoc_laguerre(0, a, x)
1
>>> assoc_laguerre(1, a, x)
a - x + 1
>>> assoc_laguerre(2, a, x)
a**2/2 + 3*a/2 + x**2/2 + x*(-a - 2) + 1
>>> assoc_laguerre(3, a, x)
a**3/6 + a**2 + 11*a/6 - x**3/6 + x**2*(a/2 + 3/2) +
x*(-a**2/2 - 5*a/2 - 3) + 1
>>> assoc_laguerre(n, a, 0)
binomial(a + n, a)
>>> assoc_laguerre(n, a, x)
assoc_laguerre(n, a, x)
>>> assoc_laguerre(n, 0, x)
laguerre(n, x)
>>> diff(assoc_laguerre(n, a, x), x)
-assoc_laguerre(n - 1, a + 1, x)
>>> diff(assoc_laguerre(n, a, x), a)
Sum(assoc_laguerre(_k, a, x)/(-a + n), (_k, 0, n - 1))
```

**Spherical Harmonics**

```python
class sympy.functions.special.spherical_harmonics.Ynm(n, m, theta, phi)
```

Spherical harmonics defined as

\[
Y_n^m(\theta, \phi) := \sqrt{\frac{(2n+1)(n-m)!}{4\pi(n+m)!}} \exp(im\phi)P_n^m(\cos(\theta))
\]

**Explanation**

`Ynm()` gives the spherical harmonic function of order \(n\) and \(m\) in \(\theta\) and \(\varphi\), \(Y_n^m(\theta, \varphi)\). The four parameters are as follows: \(n \geq 0\) an integer and \(m\) an integer such that \(-n \leq m \leq n\) holds. The two angles are real-valued with \(\theta \in [0, \pi]\) and \(\varphi \in [0, 2\pi]\).

**Examples**

```python
>>> from sympy import Ynm, Symbol, simplify
>>> from sympy.abc import n, m
>>> theta = Symbol("theta")
>>> phi = Symbol("phi")

>>> Ynm(n, m, theta, phi)
Ynm(n, m, theta, phi)

Several symmetries are known, for the order:

```python
>>> Ynm(n, -m, theta, phi)
(-1)**m*exp(-2*I*m*phi)*Ynm(n, m, theta, phi)
```

As well as for the angles:

```python
>>> Ynm(n, m, -theta, phi)
Ynm(n, m, theta, phi)
```

```python
>>> Ynm(n, m, theta, -phi)
exp(-2*I*m*phi)*Ynm(n, m, theta, phi)
```

For specific integers \(n\) and \(m\) we can evaluate the harmonics to more useful expressions:

```python
>>> simplify(Ynm(0, 0, theta, phi).expand(func=True))
1/(2*sqrt(pi))
```

```python
>>> simplify(Ynm(1, -1, theta, phi).expand(func=True))
sqrt(6)*exp(-I*phi)*sin(theta)/(4*sqrt(pi))
```

```python
>>> simplify(Ynm(1, 0, theta, phi).expand(func=True))
sqrt(3)*cos(theta)/(2*sqrt(pi))
```
>>> simplify(Ynm(1, 1, theta, phi).expand(func=True))
-sqrt(6)*exp(I*phi)*sin(theta)/(4*sqrt(pi))

>>> simplify(Ynm(2, -2, theta, phi).expand(func=True))
sqrt(30)*exp(-2*I*phi)*sin(theta)**2/(8*sqrt(pi))

>>> simplify(Ynm(2, -1, theta, phi).expand(func=True))
sqrt(30)*exp(-I*phi)*sin(2*theta)/(8*sqrt(pi))

>>> simplify(Ynm(2, 0, theta, phi).expand(func=True))
sqrt(5)*(3*cos(theta)**2 - 1)/(4*sqrt(pi))

>>> simplify(Ynm(2, 1, theta, phi).expand(func=True))
-sqrt(30)*exp(I*phi)*sin(2*theta)/(8*sqrt(pi))

We can differentiate the functions with respect to both angles:

>>> from sympy import Ynm, Symbol, diff
>>> from sympy.abc import n, m
>>> theta = Symbol("theta")
>>> phi = Symbol("phi")

>>> diff(Ynm(n, m, theta, phi), theta)
m*cot(theta)*Ynm(n, m, theta, phi) + sqrt((-m + n)*(m + n + 1))*exp(-I*phi)*Ynm(n, m + 1, theta, phi)

>>> diff(Ynm(n, m, theta, phi), phi)
I*m*Ynm(n, m, theta, phi)

Further we can compute the complex conjugation:

>>> from sympy import Ynm, Symbol, conjugate
>>> from sympy.abc import n, m
>>> theta = Symbol("theta")
>>> phi = Symbol("phi")

>>> conjugate(Ynm(n, m, theta, phi))
(-1)**(2*m)*exp(-2*I*m*phi)*Ynm(n, m, theta, phi)

To get back the well known expressions in spherical coordinates, we use full expansion:

>>> from sympy import Ynm, Symbol, expand_func
>>> from sympy.abc import n, m
>>> theta = Symbol("theta")
>>> phi = Symbol("phi")
```python
>>> expand_func(Ynm(n, m, theta, phi))
sqrt((2*n + 1)*factorial(-m + n)/factorial(m + n))*exp(I*m*phi)*assoc_legendre(n, m, cos(theta))/(2*sqrt(pi))
```

**See also:**

Ynm_c (page 605), Znm (page 605)

**References**

[R506], [R507], [R508], [R509]

```python
sympy.functions.special.spherical_harmonics.Ynm_c(n, m, theta, phi)
Conjugate spherical harmonics defined as

\[ Y_{n}^{m}(\theta, \varphi) := (-1)^{m}Y_{n}^{-m}(\theta, \varphi). \]
```

**Examples**

```python
>>> from sympy import Ynm_c, Symbol, simplify
>>> from sympy.abc import n,m
>>> theta = Symbol("theta")
>>> phi = Symbol("phi")
>>> Ynm_c(n, m, theta, phi)
(-1)**(2*m)*exp(-2*I*m*phi)*Ynm(n, m, theta, phi)
>>> Ynm_c(n, m, -theta, phi)
(-1)**(2*m)*exp(-2*I*m*phi)*Ynm(n, m, theta, phi)
```

For specific integers \( n \) and \( m \) we can evaluate the harmonics to more useful expressions:

```python
>>> simplify(Ynm_c(0, 0, theta, phi).expand(func=True))
1/(2*sqrt(pi))
>>> simplify(Ynm_c(1, -1, theta, phi).expand(func=True))
sqrt(6)*exp(I*(-phi + 2*conjugate(phi)))*sin(theta)/(4*sqrt(pi))
```

**See also:**

Ynm (page 603), Znm (page 605)

**References**

[R510], [R511], [R512]

```python
class sympy.functions.special.spherical_harmonics.Znm(n, m, theta, phi)
Real spherical harmonics defined as

\[
Z_{n}^{m}(\theta, \varphi) := \begin{cases} 
\frac{Y_{n}^{m}(\theta, \varphi)+Y_{n}^{-m}(\theta, \varphi)}{\sqrt{2}} & m > 0 \\
Y_{n}^{m}(\theta, \varphi) & m = 0 \\
\frac{Y_{n}^{m}(\theta, \varphi)-Y_{n}^{-m}(\theta, \varphi)}{i\sqrt{2}} & m < 0 
\end{cases}
\]
```

5.8. Topics 605
which gives in simplified form

\[ Z^m_n(\theta, \varphi) = \begin{cases} 
Y^m_n(\theta, \varphi) + (-1)^m Y^{-m}_n(\theta, \varphi) & m > 0 \\
Y^m_n(\theta, \varphi) & m = 0 \\
\frac{Y^m_n(\theta, \varphi) - (-1)^m Y^{-m}_n(\theta, \varphi)}{\sqrt{2}} & m < 0 
\end{cases} \]

**Examples**

```python
>>> from sympy import Znm, Symbol, simplify
>>> from sympy.abc import n, m
>>> theta = Symbol("theta")
>>> phi = Symbol("phi")
>>> Znm(n, m, theta, phi)
Znm(n, m, theta, phi)
```

For specific integers \( n \) and \( m \) we can evaluate the harmonics to more useful expressions:

```python
>>> simplify(Znm(0, 0, theta, phi).expand(func=True))
1/(2*sqrt(pi))
>>> simplify(Znm(1, 1, theta, phi).expand(func=True))
-sqrt(3)*sin(theta)*cos(phi)/(2*sqrt(pi))
>>> simplify(Znm(2, 1, theta, phi).expand(func=True))
-sqrt(15)*sin(2*theta)*cos(phi)/(4*sqrt(pi))
```

**Tensor Functions**

```python
sympy.functions.special.tensor_functions.Eijk(*args, **kwargs)
```

Represent the Levi-Civita symbol.

This is a compatibility wrapper to LeviCivita().

**See also:**

LeviCivita (page 606)

```python
sympy.functions.special.tensor_functions.eval_levicivita(*args)
```

Evaluate Levi-Civita symbol.

```python
class sympy.functions.special.tensor_functions.LeviCivita(*args)
```

Represent the Levi-Civita symbol.
Explanation

For even permutations of indices it returns 1, for odd permutations -1, and for everything else (a repeated index) it returns 0.

Thus it represents an alternating pseudotensor.

Examples

```python
>>> from sympy import LeviCivita
>>> from sympy.abc import i, j, k
>>> LeviCivita(1, 2, 3)
1
>>> LeviCivita(1, 3, 2)
-1
>>> LeviCivita(1, 2, 2)
0
>>> LeviCivita(i, j, k)
LeviCivita(i, j, k)
>>> LeviCivita(i, j, i)
0
```

See also:

\( E_{i j k} \) (page 606)

class sympy.functions.special.tensor_functions.KroneckerDelta(i, j, delta_range=None)

The discrete, or Kronecker, delta function.

Parameters

i : Number, Symbol

The first index of the delta function.

j : Number, Symbol

The second index of the delta function.

Explanation

A function that takes in two integers \( i \) and \( j \). It returns 0 if \( i \) and \( j \) are not equal, or it returns 1 if \( i \) and \( j \) are equal.
Examples

An example with integer indices:

```python
>>> from sympy import KroneckerDelta
>>> KroneckerDelta(1, 2)
0
>>> KroneckerDelta(3, 3)
1
```

Symbolic indices:

```python
>>> from sympy import KroneckerDelta
>>> KroneckerDelta(i, j)
KroneckerDelta(i, j)
>>> KroneckerDelta(i, i)
1
>>> KroneckerDelta(i, i + 1)
0
>>> KroneckerDelta(i, i + 1 + k)
KroneckerDelta(i, i + k + 1)

See also:

`eval` (page 608), `DiracDelta` (page 506)

References

[R516]

classmethod eval(i, j, delta_range=None)

  Evaluates the discrete delta function.

Examples

```python
>>> from sympy import KroneckerDelta
>>> from sympy import KroneckerDelta
>>> KroneckerDelta(i, j)
KroneckerDelta(i, j)
>>> KroneckerDelta(i, i)
1
>>> KroneckerDelta(i, i + 1)
0
>>> KroneckerDelta(i, i + 1 + k)
KroneckerDelta(i, i + k + 1)

# indirect doctest

property indices_contain_equal_information

  Returns True if indices are either both above or below fermi.
Examples

```python
from sympy import KroneckerDelta, Symbol

a = Symbol('a', above_fermi=True)
i = Symbol('i', below_fermi=True)
p = Symbol('p')
q = Symbol('q')

KroneckerDelta(p, q).indices_contain_equal_information
True
KroneckerDelta(p, q+1).indices_contain_equal_information
True
KroneckerDelta(i, p).indices_contain_equal_information
False
```

**property is_above_fermi**

True if Delta can be non-zero above fermi.

Examples

```python
from sympy import KroneckerDelta, Symbol

a = Symbol('a', above_fermi=True)
i = Symbol('i', below_fermi=True)
p = Symbol('p')
q = Symbol('q')

KroneckerDelta(p, a).is_above_fermi
True
KroneckerDelta(p, i).is_above_fermi
False
KroneckerDelta(p, q).is_above_fermi
True
```

See also:

* is_below_fermi (page 609),  
* is_only_below_fermi (page 610),  
* is_only_above_fermi (page 610)

**property is_below_fermi**

True if Delta can be non-zero below fermi.

Examples

```python
from sympy import KroneckerDelta, Symbol

a = Symbol('a', above_fermi=True)
i = Symbol('i', below_fermi=True)
p = Symbol('p')
q = Symbol('q')

KroneckerDelta(p, a).is_below_fermi
False
KroneckerDelta(p, i).is_below_fermi
True
```

(continues on next page)
KroneckerDelta(p, q).is_below_fermi
True

See also:
is_above_fermi (page 609), is_only_above_fermi (page 610),
is_only_below_fermi (page 610)

property is_only_above_fermi
True if Delta is restricted to above fermi.

Examples

>>> from sympy import KroneckerDelta, Symbol
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')
>>> q = Symbol('q')
>>> KroneckerDelta(p, a).is_only_above_fermi
True
>>> KroneckerDelta(p, q).is_only_above_fermi
False
>>> KroneckerDelta(p, i).is_only_above_fermi
False

See also:
is_above_fermi (page 609), is_below_fermi (page 609), is_only_below_fermi
(property 610)

property is_only_below_fermi
True if Delta is restricted to below fermi.

Examples

>>> from sympy import KroneckerDelta, Symbol
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')
>>> q = Symbol('q')
>>> KroneckerDelta(p, i).is_only_below_fermi
True
>>> KroneckerDelta(p, q).is_only_below_fermi
False
>>> KroneckerDelta(p, a).is_only_below_fermi
False

See also:
is_above_fermi (page 609), is_below_fermi (page 609), is_only_above_fermi
(property 610)
property killable_index
Returns the index which is preferred to substitute in the final expression.

Explanation
The index to substitute is the index with less information regarding fermi level. If indices contain the same information, 'a' is preferred before 'b'.

Examples

```python
>>> from sympy import KroneckerDelta, Symbol
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> j = Symbol('j', below_fermi=True)
>>> p = Symbol('p')
>>> KroneckerDelta(p, i).killable_index
p
>>> KroneckerDelta(p, a).killable_index
p
>>> KroneckerDelta(i, j).killable_index
j
```

See also:
preferred_index (page 611)

property preferred_index
Returns the index which is preferred to keep in the final expression.

Explanation
The preferred index is the index with more information regarding fermi level. If indices contain the same information, ‘a’ is preferred before ‘b’.

Examples

```python
>>> from sympy import KroneckerDelta, Symbol
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> j = Symbol('j', below_fermi=True)
>>> p = Symbol('p')
>>> KroneckerDelta(p, i).preferred_index
i
>>> KroneckerDelta(p, a).preferred_index
a
>>> KroneckerDelta(i, j).preferred_index
i
```

killable_index (page 610)
Integrals

This module documentation contains details about Meijer G-functions and SymPy integrals.

Contents

Computing Integrals using Meijer G-Functions

This text aims to describe in some detail the steps (and subtleties) involved in using Meijer G-functions for computing definite and indefinite integrals. We shall ignore proofs completely.

Overview

The algorithm to compute \( \int f(x) \, dx \) or \( \int_0^\infty f(x) \, dx \) generally consists of three steps:

1. Rewrite the integrand using Meijer G-functions (one or sometimes two).
2. Apply an integration theorem, to get the answer (usually expressed as another G-function).
3. Expand the result in named special functions.

Step (3) is implemented in the function hyperexpand (q.v.). Steps (1) and (2) are described below. Moreover, G-functions are usually branched. Thus our treatment of branched functions is described first.

Some other integrals (e.g. \( \int_{-\infty}^{\infty} \)) can also be computed by first recasting them into one of the above forms. There is a lot of choice involved here, and the algorithm is heuristic at best.

Polar Numbers and Branched Functions

Both Meijer G-Functions and Hypergeometric functions are typically branched (possible branchpoints being 0, \( \pm 1 \), \( \infty \)). This is not very important when e.g. expanding a single hypergeometric function into named special functions, since sorting out the branches can be left to the human user. However this algorithm manipulates and transforms G-functions, and to do this correctly it needs at least some crude understanding of the branchings involved.

To begin, we consider the set \( S = \{(r, \theta) : r > 0, \theta \in \mathbb{R}\} \). We have a map \( p : S \to \mathbb{C} - \{0\}, (r, \theta) \mapsto re^{i\theta} \). Decreeing this to be a local biholomorphism gives \( S \) both a topology and a complex structure. This Riemann Surface is usually referred to as the Riemann Surface of the logarithm, for the following reason: We can define maps \( \text{Exp} : \mathbb{C} \to S, (x + iy) \mapsto (\exp(x), y) \) and \( \text{Log} : S \to \mathbb{C}, (e^x, y) \mapsto x + iy \). These can both be shown to be holomorphic, and are indeed mutual inverses.

We also sometimes formally attach a point “zero” (0) to \( S \) and denote the resulting object \( S_0 \). Notably there is no complex structure defined near 0. A fundamental system of neighbourhoods is given by \{\text{Exp}(z) : \Re(z) < k\}, which at least defines a topology. Elements of \( S_0 \) shall be called polar numbers. We further define functions \( \text{Arg} : S \to \mathbb{R}, (r, \theta) \mapsto \theta \) and \( |\,| : S_0 \to \mathbb{R}_{>0}, (r, \theta) \mapsto r \). These have evident meaning and are both continuous everywhere.

Using these maps many operations can be extended from \( \mathbb{C} \) to \( S \). We define \( \text{Exp}(a) \text{Exp}(b) = \text{Exp}(a + b) \) for \( a, b \in \mathbb{C} \), also for \( a \in \mathbb{S} \) and \( b \in \mathbb{C} \) we define \( a^b = \text{Exp}(b \text{Log}(a)) \). It can be checked easily that using these definitions, many algebraic properties holding for positive reals (e.g.
\((ab)^c = a^c b^c\) which hold in \(\mathbb{C}\) only for some numbers (because of branch cuts) hold indeed for all polar numbers.

As one peculiarity it should be mentioned that addition of polar numbers is not usually defined. However, formal sums of polar numbers can be used to express branching behaviour. For example, consider the functions \(F(z) = \sqrt{1 + z}\) and \(G(a, b) = \sqrt{a + b}\), where \(a, b, z\) are polar numbers. The general rule is that functions of a single polar variable are defined in such a way that they are continuous on circles, and agree with the usual definition for positive reals. Thus if \(S(z)\) denotes the standard branch of the square root function on \(\mathbb{C}\), we are forced to define

\[
F(z) = \begin{cases} 
S(p(z)) & : |z| < 1 \\
S(p(z)) & : -\pi < \text{Arg}(z) + 4\pi n \leq \pi \text{ for some } n \in \mathbb{Z} \\
-S(p(z)) & : \text{else}
\end{cases}
\]

(We are omitting \(|z| = 1\) here, this does not matter for integration.) Finally we define \(G(a, b) = \sqrt{a} F(b/a)\).

### Representing Branched Functions on the Argand Plane

Suppose \(f : S \to \mathbb{C}\) is a holomorphic function. We wish to define a function \(F\) on (part of) the complex numbers \(\mathbb{C}\) that represents \(f\) as closely as possible. This process is known as "introducing branch cuts". In our situation, there is actually a canonical way of doing this (which is adhered to in all of SymPy), as follows: Introduce the "cut complex plane" \(\mathbb{C} = \mathbb{C} \setminus \mathbb{R}_{\leq 0}\). Define a function \(l : \mathbb{C} \to S\) via \(re^{\theta} \mapsto r \exp(i\theta)\). Here \(r > 0\) and \(-\pi < \theta \leq \pi\). Then \(l\) is holomorphic, and we define \(G = f \circ l\). This called “lifting to the principal branch” throughout the SymPy documentation.

### Table Lookups and Inverse Mellin Transforms

Suppose we are given an integrand \(f(x)\) and are trying to rewrite it as a single G-function. To do this, we first split \(f(x)\) into the form \(x^s g(x)\) (where \(g(x)\) is supposed to be simpler than \(f(x)\)). This is because multiplicative powers can be absorbed into the G-function later. This splitting is done by \(\_\text{split}_\text{mul}(f, x)\). Then we assemble a tuple of functions that occur in \(f\) (e.g. \(f(x) = e^{x} \cos x\), we would assemble the tuple \((\cos, \exp)\)). This is done by the function \(\_\text{mytype}(f, x)\). Next we index a lookup table (created using \(\_\text{create}_\text{lookup}_\text{table()}) with this tuple. This (hopefully) yields a list of Meijer G-function formulae involving these functions, we then pattern-match all of them. If one fits, we were successful, otherwise not and we have to try something else.

Suppose now we want to rewrite as a product of two G-functions. To do this, we (try to) find all inequivalent ways of splitting \(f(x)\) into a product \(f_1(x)f_2(x)\). We could try these splittings in any order, but it is often a good idea to minimize (a) the number of powers occurring in \(f_1(x)\) and (b) the number of different functions occurring in \(f_1(x)\). Thus given e.g. \(f(x) = \sin x e^{x} \sin 2x\) we should try \(f_1(x) = \sin x \sin 2x\) first. All of this is done by the function \(\_\text{mul}_\text{as}_\text{two}_\text{parts}(f)\).

Finally, we can try a recursive Mellin transform technique. Since the Meijer G-function is defined essentially as a certain inverse mellin transform, if we want to write a function \(f(x)\) as a G-function, we can compute its mellin transform \(F(s)\). If \(F(s)\) is in the right form, the G-function expression can be read off. This technique generalises many standard rewrites, e.g. \(e^{ax} e^{bx} = e^{(a+b)x}\).
One twist is that some functions don’t have mellin transforms, even though they can be written as G-functions. This is true for example for \( f(x) = e^x \sin x \) (the function grows too rapidly to have a mellin transform). However if the function is recognised to be analytic, then we can try to compute the mellin-transform of \( f(ax) \) for a parameter \( a \), and deduce the G-function expression by analytic continuation. (Checking for analyticity is easy. Since we can only deal with a certain subset of functions anyway, we only have to filter out those which are not analytic.)

The function \(_\text{rewrite}_\text{single}\) does the table lookup and recursive mellin transform. The functions \(_\text{rewrite}_\text{1}\) and \(_\text{rewrite}_\text{2}\) respectively use above-mentioned helpers and \(_\text{rewrite}_\text{single}\) to rewrite their argument as respectively one or two G-functions.

### Applying the Integral Theorems

If the integrand has been recast into G-functions, evaluating the integral is relatively easy. We first do some substitutions to reduce e.g. the exponent of the argument of the G-function to unity (see \(_\text{rewrite}_\text{saxena}_\text{1}\) and \(_\text{rewrite}_\text{saxena}\), respectively, for one or two G-functions). Next we go through a list of conditions under which the integral theorem applies. It can fail for basically two reasons: either the integral does not exist, or the manipulations in deriving the theorem may not be allowed (for more details, see this \([\text{BlogPost}]\)).

Sometimes this can be remedied by reducing the argument of the G-functions involved. For example it is clear that the G-function representing \( e^z \) is satisfies \( G(\text{Exp}(2\pi i)z) = G(z) \) for all \( z \in S \). The function \( \text{meijerg.get\_period()} \) can be used to discover this, and the function \( \text{principal\_branch}(z, \text{period}) \) in \texttt{functions/elementary/complexes.py} can be used to exploit the information. This is done transparently by the integration code.

### The G-Function Integration Theorems

This section intends to display in detail the definite integration theorems used in the code. The following two formulae go back to Meijer (In fact he proved more general formulae; indeed in the literature formulae are usually staded in more general form. However it is very easy to deduce the general formulae from the ones we give here. It seemed best to keep the theorems as simple as possible, since they are very complicated anyway.):

1. 
   \[
   \int_0^\infty G_{p,q}^{m,n} (a_1, \ldots, a_p; b_1, \ldots, b_q | x) \eta dx = \frac{\prod_{j=1}^p \Gamma(b_j + 1) \prod_{j=1}^n \Gamma(-a_j)}{\eta \prod_{j=m+1}^q \Gamma(-b_j) \prod_{j=n+1}^p \Gamma(a_j + 1)}
   \]

2. 
   \[
   \int_0^\infty G_{u,v}^{s,t} (c_1, \ldots, c_u; d_1, \ldots, d_v | x) G_{p,q}^{m,n} (a_1, \ldots, a_p; b_1, \ldots, b_q | x) dx = G_{v+p,u+q}^{m+t,n+s} (a_1, \ldots, a_n, -d_1, \ldots, -d_v, a_{n+1}, \ldots, a_p; b_1, \ldots, b_m, -c_1, \ldots, -c_u, b_{m+1}, \ldots, b_q | x)
   \]

The more interesting question is under what conditions these formulae are valid. Below we detail the conditions implemented in SymPy. They are an amalgamation of conditions found in \([\text{Prudnikov1990}]\) and \([\text{Luke1969}]\); please let us know if you find any errors.
Conditions of Convergence for Integral (1)

We can without loss of generality assume \( p \leq q \), since the G-functions of indices \( m, n, p, q \) and of indices \( n, m, q, p \) can be related easily (see e.g. [Luke1969], section 5.3). We introduce the following notation:

\[
\begin{align*}
\xi &= m + n - p \\
\delta &= m + n - \frac{p + q}{2}
\end{align*}
\]

\[
C_3 : -\Re(b_j) < 1 \text{ for } j = 1, \ldots, m \\
0 < -\Re(a_j) \text{ for } j = 1, \ldots, n
\]

\[
C_3^* : -\Re(b_j) < 1 \text{ for } j = 1, \ldots, q \\
0 < -\Re(a_j) \text{ for } j = 1, \ldots, p
\]

\[
C_4 : -\Re(\delta) + \frac{q + 1 - p}{2} > q - p
\]

The convergence conditions will be detailed in several “cases”, numbered one to five. For later use it will be helpful to separate conditions “at infinity” from conditions “at zero”. By conditions “at infinity” we mean conditions that only depend on the behaviour of the integrand for large, positive values of \( x \), whereas by conditions “at zero” we mean conditions that only depend on the behaviour of the integrand on \((0, \epsilon)\) for any \( \epsilon > 0 \). Since all our conditions are specified in terms of parameters of the G-functions, this distinction is not immediately visible. They are, however, of very distinct character mathematically; the conditions at infinity being in particular much harder to control.

In order for the integral theorem to be valid, conditions \( n \) “at zero” and “at infinity” both have to be fulfilled, for some \( n \).

These are the conditions “at infinity”:

1. \[
\delta > 0 \land |\arg(\eta)| < \delta \pi \land (A \lor B \lor C),
\]

where

\[
A = 1 \leq n \land p < q \land 1 \leq m
\]

\[
B = 1 \leq p \land 1 \leq m \land q = p + 1 \land \neg(n = 0 \land m = p + 1)
\]

\[
C = 1 \leq n \land q = p \land |\arg(\eta)| \neq (\delta - 2k)\pi \text{ for } k = 0, 1, \ldots \left\lfloor \frac{\delta}{2} \right\rfloor.
\]

2. \[
n = 0 \land p + 1 \leq m \land |\arg(\eta)| < \delta \pi
\]

3. \[
(p < q \land 1 \leq m \land \delta > 0 \land |\arg(\eta)| = \delta \pi) \lor (p \leq q - 2 \land \delta = 0 \land \arg(\eta) = 0)
\]

4. \[
p = q \land \delta = 0 \land \arg(\eta) = 0 \land \eta \neq 0 \land \Re\left(\sum_{j=1}^{p} b_j - a_j\right) < 0
\]
And these are the conditions “at zero”:

1. \( \eta \neq 0 \land C_3 \)

2. \( C_3 \)

3. \( C_3 \land C_4 \)

4. \( C_3 \)

5. \( C_3 \)

**Conditions of Convergence for Integral (2)**

We introduce the following notation:

\[
\begin{align*}
b^* &= s + t - \frac{u + v}{2} \\
c^* &= m + n - \frac{p + q}{2} \\
\rho &= \sum_{j=1}^{v} d_j - \sum_{j=1}^{u} c_j + \frac{u - v}{2} + 1 \\
\mu &= \sum_{j=1}^{q} b_j - \sum_{j=1}^{p} a_j + \frac{p - q}{2} + 1 \\
\phi &= q - p - \frac{u - v}{2} + 1 \\
\eta &= 1 - (v - u) - \mu - \rho \\
\psi &= \frac{\pi (q - m - n) + |\arg(\omega)|}{q - p} \\
\theta &= \frac{\pi (v - s - t) + |\arg(\sigma)|}{v - u} \\
\lambda_c &= (q - p)|\omega|^{1/(q - p)} \cos \psi + (v - u)|\sigma|^{1/(v - u)} \cos \theta \\
\lambda_{0}(c_1, c_2) &= c_1 (q - p)|\omega|^{1/(q - p)} \sin \psi + c_2 (v - u)|\sigma|^{1/(v - u)} \sin \theta
\end{align*}
\]
\[
\lambda_s = \begin{cases} 
\lambda_{s0} (-1, -1) \lambda_{s0} (1, 1) & \text{for } \arg(\omega) = 0 \land \arg(\sigma) = 0 \\
\lambda_{s0} (\text{sign} (\arg(\omega)), -1) \lambda_{s0} (\text{sign} (\arg(\omega)), 1) & \text{for } \arg(\omega) \neq 0 \land \arg(\sigma) = 0 \\
\lambda_{s0} (-1, \text{sign} (\arg(\omega))) \lambda_{s0} (1, \text{sign} (\arg(\omega))) & \text{for } \arg(\omega) = 0 \land \arg(\sigma) \neq 0 \\
\lambda_{s0} (\text{sign} (\arg(\omega)), \text{sign} (\arg(\sigma))) & \text{otherwise}
\end{cases}
\]

The following conditions will be helpful:

\[C_1 : (a_i - b_j \notin \mathbb{Z}_{\geq 0} \text{ for } i = 1, \ldots, n, j = 1, \ldots, m) \land (c_i - d_j \notin \mathbb{Z}_{\geq 0} \text{ for } i = 1, \ldots, t, j = 1, \ldots, s)\]

\[C_2 : \Re(1 + b_i + d_j) > 0 \text{ for } i = 1, \ldots, m, j = 1, \ldots, s\]

\[C_3 : \Re(a_i + c_j) < 1 \text{ for } i = 1, \ldots, n, j = 1, \ldots, t\]

\[C_4 : (p - q) \Re(c_i) - \Re(\mu) > -\frac{3}{2} \text{ for } i = 1, \ldots, t\]

\[C_5 : (p - q) \Re(1 + d_i) - \Re(\mu) > -\frac{3}{2} \text{ for } i = 1, \ldots, s\]

\[C_6 : (u - v) \Re(a_i) - \Re(\rho) > -\frac{3}{2} \text{ for } i = 1, \ldots, n\]

\[C_7 : (u - v) \Re(1 + b_i) - \Re(\rho) > -\frac{3}{2} \text{ for } i = 1, \ldots, m\]

\[C_8 : 0 < |\phi| + 2 \Re((\mu - 1)(-u + v) + (-p + q)(\rho - 1) + (-p + q)(-u + v))\]

\[C_9 : 0 < |\phi| - 2 \Re((\mu - 1)(-u + v) + (-p + q)(\rho - 1) + (-p + q)(-u + v))\]

\[C_{10} : |\arg(\sigma)| < \pi b^*\]

\[C_{11} : |\arg(\sigma)| = \pi b^*\]

\[C_{12} : |\arg(\omega)| < c^* \pi\]

\[C_{13} : |\arg(\omega)| = c^* \pi\]

\[C_{14}^1 : (z_0 \neq 1 \land |\arg(1 - z_0)| < \pi) \lor (z_0 = 1 \land \Re(\mu + \rho - u + v) < 1)\]

\[C_{14}^2 : (z_1 \neq 1 \land |\arg(1 - z_1)| < \pi) \lor (z_1 = 1 \land \Re(\mu + \rho - p + q) < 1)\]

\[C_{14} : \phi = 0 \land b^* + c^* \leq 1 \lor (C_{14}^1 \lor C_{14}^2)\]

\[C_{15} : \lambda_c > 0 \lor (\lambda_c = 0 \land \lambda_s \neq 0 \land \Re(\eta) > -1) \lor (\lambda_c = 0 \land \lambda_s = 0 \land \Re(\eta) > 0)\]

\[C_{16} : \int_0^\infty G_{u,v}^{m,n}(\sigma x) \, dx \text{ converges at infinity}\]

\[C_{17} : \int_0^\infty G_{p,q}^{m,n}(\omega x) \, dx \text{ converges at infinity}\]

Note that \(C_{16}\) and \(C_{17}\) are the reason we split the convergence conditions for integral (1).

With this notation established, the implemented convergence conditions can be enumerated as follows:

1. \(mnst \neq 0 \land 0 < b^* \land 0 < c^* \land C_1 \land C_2 \land C_3 \land C_{10} \land C_{12}\)

The Inverse Laplace Transform of a G-function

The inverse laplace transform of a Meijer G-function can be expressed as another G-function. This is a fairly versatile method for computing this transform. However, I could not find the details in the literature, so I work them out here. In [Luke1969], section 5.6.3, there is a formula for the inverse Laplace transform of a G-function of argument $b z^a$, and convergence conditions are also given. However, we need a formula for argument $b z^a$ for rational $a$.

We are asked to compute

$$f(t) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} e^{zt} G(bz^a) dz,$$

for positive real $t$. Three questions arise:

1. When does this integral converge?
2. How can we compute the integral?
3. When is our computation valid?

How to compute the integral

We shall work formally for now. Denote by $\Delta(s)$ the product of gamma functions appearing in the definition of $G$, so that

$$G(z) = \frac{1}{2\pi i} \int_L \Delta(s) z^s ds.$$

Thus

$$f(t) = \frac{1}{(2\pi i)^2} \int_{c-i\infty}^{c+i\infty} \int_L e^{zt} \Delta(s) b^s z^{as} ds dz.$$

We interchange the order of integration to get

$$f(t) = \frac{1}{2\pi i} \int_L b^s \Delta(s) \int_{c-i\infty}^{c+i\infty} e^{zt} z^{as} \frac{dz}{2\pi i} ds.$$

The inner integral is easily seen to be $\frac{1}{\Gamma(-as) \Gamma(1+as)}$. (Using Cauchy’s theorem and Jordan’s lemma deform the contour to run from $-\infty$ to $-\infty$, encircling 0 once in the negative sense. For $as$ real and greater than one, this contour can be pushed onto the negative real axis and the integral is recognised as a product of a sine and a gamma function. The formula is then proved using the functional equation of the gamma function, and extended to the entire domain of convergence of the original integral by appealing to analytic continuation.) Hence we find

$$f(t) = \frac{1}{(2\pi i)^2} \int_L \Delta(s) \frac{1}{\Gamma(-as)} \left( \frac{b}{t} \right)^s ds,$$

which is a so-called Fox H function (of argument $\frac{b}{t^a}$). For rational $a$, this can be expressed as a Meijer G-function using the gamma function multiplication theorem.
When this computation is valid

There are a number of obstacles in this computation. Interchange of integrals is only valid if all integrals involved are absolutely convergent. In particular the inner integral has to converge. Also, for our identification of the final integral as a Fox H / Meijer G-function to be correct, the poles of the newly obtained gamma function must be separated properly.

It is easy to check that the inner integral converges absolutely for \( \Re(as) < -1 \). Thus the contour \( L \) has to run left of the line \( \Re(as) = -1 \). Under this condition, the poles of the newly-introduced gamma function are separated properly.

It remains to observe that the Meijer G-function is an analytic, unbranched function of its parameters, and of the coefficient \( b \). Hence so is \( f(t) \). Thus the final computation remains valid as long as the initial integral converges, and if there exists a changed set of parameters where the computation is valid. If we assume w.l.o.g. that \( a > 0 \), then the latter condition is fulfilled if \( G \) converges along contours (2) or (3) of [Luke1969], section 5.2, i.e. either \( \delta \geq \frac{1}{2} \) or \( p \geq 1, p \geq q \).

When the integral exists

Using [Luke1969], section 5.10, for any given meijer G-function we can find a dominant term of the form \( z^a e^{b \tau} \) (although this expression might not be the best possible, because of cancellation).

We must thus investigate

\[
\lim_{T \to \infty} \int_{c-iT}^{c+iT} e^{zt} z^a e^{b \tau} \mathrm{d}z.
\]

(This principal value integral is the exact statement used in the Laplace inversion theorem.) We write \( z = c + i \tau \). Then \( \arg(z) \to \pm \frac{\pi}{2} \), and so \( e^{zt} \sim e^{it \tau} \) (where \( \sim \) shall always mean “asymptotically equivalent up to a positive real multiplicative constant”). Also \( z^{x+iy} \sim |r| \tau e^{iy \log |r|} e^{\pm xi \pi} \).

Set \( \omega_{\pm} = be^{\pm i \arg(c) \frac{\pi}{2}} \). We have three cases:

1. \( b = 0 \) or \( \Re(c) \leq 0 \). In this case the integral converges if \( \Re(a) \leq -1 \).
2. \( b \neq 0, \Re(c) = 0, \Re(c) > 0 \). In this case the integral converges if \( \Re(\omega_{\pm}) < 0 \).
3. \( b \neq 0, \Re(c) = 0, \Re(c) > 0, \Re(\omega_{\pm}) \leq 0 \), and at least one of \( \Re(\omega_{\pm}) = 0 \). Here the same condition as in (1) applies.

Implemented G-Function Formulae

An important part of the algorithm is a table expressing various functions as Meijer G-functions. This is essentially a table of Mellin Transforms in disguise. The following automatically generated table shows the formulae currently implemented in SymPy. An entry “generated” means that the corresponding G-function has a variable number of parameters. This table is intended to shrink in future, when the algorithm’s capabilities of deriving new formulae improve. Of course it has to grow whenever a new class of special functions is to be dealt with. Elementary functions:

\[
a = a G^{1,0}_{1,1} \left( \begin{array}{c} 0 \\ 1 \end{array} \right) z + a G^{0,1}_{1,1} \left( \begin{array}{c} 1 \\ 0 \end{array} \right) z
\]
\[(z^q p + b)^{-a} = \frac{b^{-a} G^{1,1}_{1,1} \left( \begin{array}{c} 1 - a \\ 0 \\ \frac{z^q p}{b} \end{array} \right)}{\Gamma (a)}\]

\[-b^a + (z^q p)^a = \frac{b^{a-1} G_{2,2}^{2,2} \left( \begin{array}{c} 0, a \\ 0, a \end{array} \right) \left( \frac{z^q p}{b} \right) \sin (\pi a)}{\pi}\]

\[(a + \sqrt{z^q p + a^2})^b = \frac{a^b G_{2,2}^{1,2} \left( \frac{b}{2} + \frac{1}{2}, \frac{b}{2} + 1 \right) \left( \frac{z^q p}{a^2} \right)}{2\sqrt{\pi}}\]

\[(-a + \sqrt{z^q p + a^2})^b = \frac{a^b G_{2,2}^{1,2} \left( \frac{b}{2} + \frac{1}{2}, \frac{b}{2} ight) \left( \frac{z^q p}{a^2} \right)}{2\sqrt{\pi}}\]

\[(a + \sqrt{z^q p + a^2})^b = \frac{a^b G_{2,2}^{1,2} \left( \frac{b}{2} + \frac{1}{2}, \frac{b}{2} \right) \left( \frac{z^q p}{a^2} \right)}{\sqrt{\pi}}\]

\[(-a + \sqrt{z^q p + a^2})^b = \frac{a^b G_{2,2}^{1,2} \left( \frac{b}{2} + \frac{1}{2}, \frac{b}{2} \right) \left( \frac{z^q p}{a^2} \right)}{\sqrt{\pi}}\]

\[\left( z^\frac{b}{2} \sqrt{p} + \sqrt{z^q p + a} \right)^b = \frac{a^b G_{2,2}^{1,2} \left( \frac{b}{2} + 1, \frac{1}{2} \right) \left( \frac{z^q p}{a} \right)}{2\sqrt{\pi}}\]

\[\left( -z^\frac{b}{2} \sqrt{p} + \sqrt{z^q p + a} \right)^b = \frac{a^b G_{2,2}^{1,2} \left( \frac{b}{2} + 1, \frac{1}{2} \right) \left( \frac{z^q p}{a} \right)}{2\sqrt{\pi}}\]

\[\left( z^\frac{b}{2} \sqrt{p} + \sqrt{z^q p + a} \right)^b = \frac{a^b G_{2,2}^{1,2} \left( \frac{b}{2} + 1, \frac{1}{2} \right) \left( \frac{z^q p}{a} \right)}{\sqrt{\pi}}\]

\[\left( -z^\frac{b}{2} \sqrt{p} + \sqrt{z^q p + a} \right)^b = \frac{a^b G_{2,2}^{1,2} \left( \frac{b}{2} + 1, \frac{1}{2} \right) \left( \frac{z^q p}{a} \right)}{\sqrt{\pi}}\]

Functions involving \(\theta (z^q p - b)\):

\[(z^q p - b)^{a-1} \theta (z^q p - b) = b^{a-1} G_{1,1}^{0,1} \left( \begin{array}{c} a \\ 0 \\ \frac{z^q p}{b} \end{array} \right) \Gamma (a), \text{ if } b > 0\]

\[(-z^q p + b)^{a-1} \theta (-z^q p + b) = b^{a-1} G_{1,1}^{1,0} \left( \begin{array}{c} a \\ 0 \\ \frac{z^q p}{b} \end{array} \right) \Gamma (a), \text{ if } b > 0\]

\[(z^q p - b)^{a-1} \theta \left( z - \left( \frac{b}{p} \right)^\frac{1}{2} \right) = b^{a-1} G_{1,1}^{0,1} \left( \begin{array}{c} a \\ 0 \\ \frac{z^q p}{b} \end{array} \right) \Gamma (a), \text{ if } b > 0\]

\[(-z^q p + b)^{a-1} \theta \left( -z + \left( \frac{b}{p} \right)^\frac{1}{2} \right) = b^{a-1} G_{1,1}^{1,0} \left( \begin{array}{c} a \\ 0 \\ \frac{z^q p}{b} \end{array} \right) \Gamma (a), \text{ if } b > 0\]

Functions involving \(|z^q p - b|^a\):

\[|z^q p - b|^{-a} = 2 G_{2,2}^{1,2} \left( \begin{array}{c} 1 - a \\ 0 \\ \frac{1}{2} - \frac{a}{2} \frac{z^q p}{b} \end{array} \right) \sin \left( \frac{\pi a}{2} \right) \left| \frac{b}{2} \right|^{-a} \Gamma (1 - a), \text{ if } \text{Re} (a) < 1\]
Functions involving \( e^{z^q p e^{i\pi}} \):

\[
e^{z^q p e^{i\pi}} = G^{1,0}_{0,1} \left( 0 \left| \frac{z^q p}{4} \right. \right)
\]

Functions involving \( \sinh(z^q p) \):

\[
\sinh(z^q p) = \frac{3}{2} G^{1,0}_{1,3} \left( 0 \left| \frac{z^{2q} p^2}{4} \right. \right)
\]

Functions involving \( \cosh(z^q p) \):

\[
\cosh(z^q p) = \frac{3}{2} G^{1,0}_{1,3} \left( 0 \left| \frac{z^{2q} p^2}{4} \right. \right) \]

Functions involving \( \sin(z^q p) \):

\[
\sin(z^q p) = \sqrt{\pi} G^{1,0}_{0,2} \left( 0 \left| \frac{z^{2q} p^2}{4} \right. \right) \]

Functions involving \( \cos(z^q p) \):

\[
\cos(z^q p) = \sqrt{\pi} G^{1,0}_{0,2} \left( 0 \left| \frac{z^{2q} p^2}{4} \right. \right) \]

Functions involving \( \sinc(z^q p) \):

\[
sinc(z^q p) = \frac{\sqrt{\pi} G^{1,0}_{0,2} \left( 0 \left| \frac{z^{2q} p^2}{4} \right. \right)}{2} \]

Functions involving \( \log(z^q p), \theta (-z^q p + 1) \):

\[
\log(z^q p)^n \theta (-z^q p + 1) = \text{generated}
\]

\[
\log(z^q p)^n \theta (z^q p - 1) = \text{generated}
\]

Functions involving \( \log(z^q p) \):

\[
\log(z^q p)^n = \text{generated}
\]

\[
\log(z^q p + a) = G^{1,0}_{1,1} \left( 0 \left| \frac{1}{z} \right. \right) \log(a) + G^{0,1}_{1,1} \left( 1 \left| \frac{1}{z} \right. \right) \log(a) + G^{1,2}_{2,2} \left( 1,1 \left| 0 \left| \frac{z^q p}{a} \right. \right. \right) \]

\[
\log(|z^q p - a|) = G^{1,0}_{1,1} \left( 0 \left| \frac{1}{z} \right. \right) \log(|a|) + G^{0,1}_{1,1} \left( 1 \left| \frac{1}{z} \right. \right) \log(|a|) + \pi G^{1,2}_{3,3} \left( 1,1 \left| 0 \left| \frac{z^q p}{a} \right. \right. \right) \]

Functions involving \( \text{Ei}(z^q p) \):

\[
\text{Ei}(z^q p) = -i\pi G^{1,0}_{1,1} \left( 0 \left| \frac{1}{z} \right. \right) - G^{2,0}_{1,2} \left( 0,0 \left| \frac{1}{z} \right. \right) - i\pi G^{0,1}_{1,1} \left( 1 \left| \frac{1}{z} \right. \right) \]

Functions involving \( \text{Si}(z^q p) \):

\[
\text{Si}(z^q p) = \frac{\sqrt{\pi} G^{1,1}_{1,3} \left( 1 \left| 0 \left| \frac{z^q p^2}{4} \right. \right. \right)}{2}
\]
Functions involving \(\text{Ci}(z^q p)\):

\[
\text{Ci}(z^q p) = -\frac{\sqrt{\pi} G_{1.3}^{2.0}(0, 0 \left| \frac{1}{2} \frac{z^{2q} p^2}{4} \right. )}{2}
\]

Functions involving \(\text{Shi}(z^q p)\):

\[
\text{Shi}(z^q p) = \frac{z^q \sqrt{\pi} p G_{1.3}^{1.1}(\frac{1}{2} \left| -\frac{1}{2} \frac{z^{2q} p^2 e^{i\pi}}{4} \right. )}{4}
\]

Functions involving \(\text{Chi}(z^q p)\):

\[
\text{Chi}(z^q p) = -\frac{\pi^{\frac{3}{2}} G_{2.4}^{2.0}(0, 0 \left| \frac{1}{2} \frac{z^{2q} p^2}{4} \right. )}{2}
\]

Functions involving \(\text{E}_a(z^q p)\):

\[
\text{E}_a(z^q p) = G_{1.2}^{2.0}(a-1, 0 \left| z^q p \right. )
\]

Functions involving \(\text{erf}(z^q p)\):

\[
\text{erf}(z^q p) = G_{1.2}^{1.1}(\frac{1}{2} \left| 0 \frac{z^{2q} p^2}{2} \right. )
\]

Functions involving \(\text{erfc}(z^q p)\):

\[
\text{erfc}(z^q p) = G_{1.2}^{2.0}(0, \frac{1}{2} \left| 1 \frac{z^{2q} p^2}{2} \right. )
\]

Functions involving \(\text{erfi}(z^q p)\):

\[
\text{erfi}(z^q p) = G_{1.2}^{1.1}(\frac{1}{2} \left| 0 \frac{-z^{2q} p^2}{2} \right. )
\]

Functions involving \(S(z^q p)\):

\[
S(z^q p) = G_{1.3}^{1.1}(\frac{1}{4} \left| 0 \frac{\frac{4\pi z^{4q} p^4}{16}}{2} \right. )
\]

Functions involving \(C(z^q p)\):

\[
C(z^q p) = G_{1.3}^{1.1}(\frac{1}{4} \left| 0 \frac{3}{4} \frac{\frac{4\pi z^{4q} p^4}{16}}{2} \right. )
\]

Functions involving \(\text{J}_a(z^q p)\):

\[
\text{J}_a(z^q p) = G_{0.2}^{1.0}(\frac{a}{2} \left| -\frac{1}{2} \frac{z^{2q} p^2}{4} \right. )
\]
Functions involving $Y_a(z^q)$p):

$$Y_a(z^q) = G^{2,0}_{1,3} \left( \frac{a}{2}, -\frac{a}{2} - \frac{1}{2}, -\frac{1}{2}; \frac{3}{4} z^{2q}p^2 \right)$$

Functions involving $I_a(z^q)\):$

$$I_a(z^q) = \pi G^{1,0}_{1,3} \left( \frac{a}{2}, -\frac{a}{2} + \frac{1}{2}; -\frac{1}{2}; \frac{3}{4} z^{2q}p^2 \right)$$

Functions involving $K_a(z^q)$:\)

$$K_a(z^q) = G^{2,0}_{0,2} \left( \frac{a}{2}, -\frac{a}{2}; \frac{3}{4} z^{2q}p^2 \right)$$

Functions involving $K(z^q)$:

$$K(z^q) = G^{1,2}_{2,2} \left( \frac{1}{2}; 0, 0; \frac{3}{2}; 0; \frac{3}{4} z^q p \right)$$

Functions involving $E(z^q)$:

$$E(z^q) = -\frac{G^{1,2}_{2,2} \left( \frac{1}{2}; 0, 0; \frac{3}{2}; 0; \frac{3}{4} z^q p \right)}{4}$$

**Internal API Reference**

Integrate functions by rewriting them as Meijer G-functions.

There are three user-visible functions that can be used by other parts of the sympy library to solve various integration problems:

- `meijerint_indefinite`
- `meijerint_definite`
- `meijerint_inversion`

They can be used to compute, respectively, indefinite integrals, definite integrals over intervals of the real line, and inverse laplace-type integrals (from $c-\text{i}\cdot\infty$ to $c+\text{i}\cdot\infty$). See the respective docstrings for details.

The main references for this are:

Integrals and Series: More Special Functions, Vol. 3., Gordon and Breach Science Publisher

**exception** sympy.integrals.meijerint._CoeffExpValueError

Exception raised by _get_coeff_exp, for internal use only.
sympy.integrals.meijerint._check_antecedents(g1, g2, x)
Return a condition under which the integral theorem applies.
sympy.integrals.meijerint._check_antecedents_1(g, x, helper=False)
Return a condition under which the mellin transform of g exists. Any power of x has
already been absorbed into the G function, so this is just \( \int_0^\infty \! g \, dx. \)
See [L, section 5.6.1]. (Note that s=1.)
If helper is True, only check if the MT exists at infinity, i.e. if \( \int_1^\infty \! g \, dx \) exists.
sympy.integrals.meijerint._check_antecedents_inversion(g, x)
Check antecedents for the laplace inversion integral.
sympy.integrals.meijerint._condsimp(cond, first=True)
Do naive simplifications on cond.

**Explanation**

Note that this routine is completely ad-hoc, simplification rules being added as need
arises rather than following any logical pattern.

**Examples**

```python
>>> from sympy.integrals.meijerint import _condsimp as simp
>>> from sympy import Or, Eq
>>> from sympy.abc import x, y
>>> simp(Or(x < y, Eq(x, y)))
x <= y
```

sympy.integrals.meijerint._create_lookup_table(table)
Add formulae for the function -> meijerg lookup table.
sympy.integrals.meijerint._dummy(name, token, expr, **kwargs)
Return a dummy. This will return the same dummy if the same token+name is requested
more than once, and it is not already in expr. This is for being cache-friendly.
sympy.integrals.meijerint._dummy_(name, token, **kwargs)
Return a dummy associated to name and token. Same effect as declaring it globally.
sympy.integrals.meijerint._eval_cond(cond)
Re-evaluate the conditions.
sympy.integrals.meijerint._exponents(expr, x)
Find the exponents of x (not including zero) in expr.
Examples

```python
>>> from sympy.integrals.meijerint import _exponents
>>> from sympy import sin
>>> _exponents(x, x)
{1}
>>> _exponents(x**2, x)
{2}
>>> _exponents(x**2 + x, x)
{1, 2}
>>> _exponents(x**3*sin(x + x**y) + 1/x, x)
{-1, 1, 3, y}
```

sympy.integrals.meijerint._find_splitting_points(expr, x)
Find numbers a such that a linear substitution x -> x + a would (hopefully) simplify expr.

Examples

```python
>>> from sympy.integrals.meijerint import _find_splitting_points as fsp
>>> from sympy import sin
>>> fsp(x, x)
{0}
>>> fsp((x-1)**3, x)
{1}
>>> fsp(sin(x+3)*x, x)
{-3, 0}
```

sympy.integrals.meijerint._flip_g(g)
Turn the G function into one of inverse argument (i.e. G(1/x) -> G'(x))

sympy.integrals.meijerint._functions(expr, x)
Find the types of functions in expr, to estimate the complexity.

sympy.integrals.meijerint._get_coeff_exp(expr, x)
When expr is known to be of the form c*x**b, with c and/or b possibly 1, return c, b.

Examples

```python
>>> from sympy import x, a, b
>>> from sympy.integrals.meijerint import _get_coeff_exp
>>> _get_coeff_exp(a*x**b, x)
(a, b)
>>> _get_coeff_exp(x, x)
(1, 1)
>>> _get_coeff_exp(2*x, x)
(2, 1)
>>> _get_coeff_exp(x**3, x)
(1, 3)
```
Try to guess sensible re writings for integrand \( f(x) \).

Let \( a \) denote the integrand in the definition of the G function \( g \). Consider the function \( H \) which is defined in the same way, but with integrand \( d/\Gamma(a*s) \) (contour conventions as usual).

If \( a \) is rational, the function \( H \) can be written as \( C*G \), for a constant \( C \) and a G-function \( G \).

This function returns \( C, G \).

Return \( C, h \) such that \( h \) is a G function of argument \( z^n \) and \( g = C*h \).

Express integral from zero to infinity \( g1*g2 \) using a G function, assuming the necessary conditions are fulfilled.

Examples

```python
>>> from sympy.integrals.meijerint import _int0oo
>>> from sympy.abc import s, t, m
>>> g1 = meijerg([], [], [-s**2*t/4], t/4)
>>> int0oo(g1, g2, t)
4*meijerg(((1/2, 0), ()), ((m/2, ), (-m/2,)), s**(-2))/s**2
```

Evaluate \( \int_0^\infty g dx \) using G functions, assuming the necessary conditions are fulfilled.

Examples

```python
>>> from sympy.abc import a, b, c, d, x, y
>>> from sympy import meijerg
>>> from sympy.integrals.meijerint import _int0oo_1
>>> _int0oo_1(meijerg([a], [b], [c], [d], x*y), x)
gamma(-a)*gamma(c + 1)/(y*gamma(-d)*gamma(b + 1))
```

Compute the laplace inversion integral, assuming the formula applies.

Check if \( f(x) \), when expressed using G functions on the positive reals, will in fact agree with the G functions almost everywhere.

Try to integrate \( f dx \) from zero to infinity.

The body of this function computes various ‘simplifications’ \( f1, f2, \ldots \) of \( f \) (e.g. by calling expand_mul(), trigexpand() - see _guess_expansion) and calls _meijerint_definite_3 with
each of these in succession. If \texttt{meijerint\_definite\_3} succeeds with any of the simplified
functions, returns this result.

\texttt{sympy\_integrals\_meijerint\_meijerint\_definite\_3}(f, x)

Try to integrate $f \, dx$ from zero to infinity.

This function calls \texttt{meijerint\_definite\_4} to try to compute the integral. If this fails, it
tries using linearity.

\texttt{sympy\_integrals\_meijerint\_meijerint\_definite\_4}(f, x, only\_double=False)

Try to integrate $f \, dx$ from zero to infinity.

\textbf{Explanation}

This function tries to apply the integration theorems found in literature, i.e. it tries to
rewrite $f$ as either one or a product of two G-functions.

The parameter \texttt{only\_double} is used internally in the recursive algorithm to disable trying
to rewrite $f$ as a single G-function.

\texttt{sympy\_integrals\_meijerint\_meijerint\_indefinite\_1}(f, x)

Helper that does not attempt any substitution.

\texttt{sympy\_integrals\_meijerint\_mul\_args}(f)

Return a list $L$ such that $\text{Mul}(*L) == f$.

If $f$ is not a Mul or Pow, $L=[f]$. If $f=g**n$ for an integer $n$, $L=[g]*n$. If $f$ is a Mul, $L$ comes
from applying \texttt{mul\_args} to all factors of $f$.

\texttt{sympy\_integrals\_meijerint\_mul\_as\_two\_parts}(f)

Find all the ways to split $f$ into a product of two terms. Return None on failure.

\textbf{Explanation}

Although the order is canonical from multiset partitions, this is not necessarily the best order to process the terms. For example, if the case of \texttt{len(gs) == 2} is removed and multiset is allowed to sort the terms, some tests fail.

\textbf{Examples}

```python
>>> from sympy\_integrals\_meijerint import _mul\_as\_two\_parts
>>> from sympy import sin, exp, ordered
>>> from sympy\_abc import x
>>> list(ordered(_mul\_as\_two\_parts(x*\sin(x)*\exp(x))))
[(x, exp(x)*\sin(x)), (x*\exp(x), \sin(x)), (x*\sin(x), exp(x))]
```

\texttt{sympy\_integrals\_meijerint\_my\_principal\_branch}(\texttt{expr, period, full\_pb=False})

Bring expr nearer to its principal branch by removing superfluous factors. This function does \textit{not} guarantee to yield the principal branch, to avoid introducing opaque principal\_branch() objects, unless \texttt{full\_pb=True}.
sympy.integrals.meijerint._mytype(f: Basic (page 979), x: Symbol (page 1028)) \rightarrow
tuple[type[Basic (page 979)], ...]

Create a hashable entity describing the type of f.

sympy.integrals.meijerint._rewrite1(f, x, recursive=True)

Try to rewrite f using a (sum of) single G function with argument a*x**b. Return fac, po, g such that f = fac*po*g, fac is independent of x and po = x**s. Here g is a result from _rewrite_single. Return None on failure.

sympy.integrals.meijerint._rewrite2(f, x)

Try to rewrite f as a product of two G functions of arguments a*x**b. Return fac, po, g1, g2 such that f = fac*po*g1*g2, where fac is independent of x and po is x**s. Here g1 and g2 are results of _rewrite_single. Returns None on failure.

sympy.integrals.meijerint._rewrite_inversion(fac, po, g, x)

Absorb po == x**s into g.

sympy.integrals.meijerint._rewrite_saxena(fac, po, g1, g2, x, full_pb=False)

Rewrite the integral fac*po*g1*g2 from 0 to oo in terms of G functions with argument c*x.

**Explanation**

Return C, f1, f2 such that integral C f1 f2 from 0 to infinity equals integral fac po, g1, g2 from 0 to infinity.

**Examples**

```python
>>> from sympy.integrals.meijerint import _rewrite_saxena
>>> from sympy.abc import s, t, m
>>> from sympy import meijerg
>>> g1 = meijerg([], [], [0], [], s*t)
>>> g2 = meijerg([], [], [m/2], [], -m/2, t**2/4)
>>> r = _rewrite_saxena(1, t**0, g1, g2, t)
>>> r[0]
s/(4*sqrt(pi))
>>> r[1]
meijerg(((,), ()), ((-1/2, 0), ()), s**2*t/4)
>>> r[2]
meijerg(((,), ()), ((m/2,), (-m/2,)), t/4)
```

sympy.integrals.meijerint._rewrite_saxena_1(fac, po, g, x)

Rewrite the integral fac*po*g dx, from zero to infinity, as integral fac*G, where G has argument a*x. Note po=x**s. Return fac, G.

sympy.integrals.meijerint._rewrite_single(f, x, recursive=True)

Try to rewrite f as a sum of single G functions of the form C*x**s*G(a*x**b), where b is a rational number and C is independent of x. We guarantee that result.argument.as_coeff_mul(x) returns (a, (x**b,)) or (a, ()). Returns a list of tuples (C, s, G) and a condition cond. Returns None on failure.
sympy.integrals.meijerint._split_mul(f, x)
Split expression f into fac, po, g, where fac is a constant factor, po = x**s for some s independent of s, and g is “the rest”.

Examples

```python
>>> from sympy.integrals.meijerint import _split_mul
>>> from sympy import sin
>>> from sympy.abc import s, x
>>> _split_mul((3*x)*s*sin(x**2)*x, x)
(3**s, x*x**s, sin(x**2))
```

sympy.integrals.meijerint.meijerint_definite(f, x, a, b)
Integrate f over the interval [a, b], by rewriting it as a product of two G functions, or as a single G function.

Return res, cond, where cond are convergence conditions.

Examples

```python
>>> from sympy.integrals.meijerint import meijerint_definite
>>> from sympy import exp, oo
>>> from sympy.abc import x
>>> meijerint_definite(exp(-x**2), x, -oo, oo)
(sqrt(pi), True)
```

This function is implemented as a succession of functions meijerint_definite, _meijerint_definite_2, _meijerint_definite_3, _meijerint_definite_4. Each function in the list calls the next one (presumably) several times. This means that calling meijerint_definite can be very costly.

sympy.integrals.meijerint.meijerint_indefinite(f, x)
Compute an indefinite integral of f by rewriting it as a G function.

Examples

```python
>>> from sympy.integrals.meijerint import meijerint_indefinite
>>> from sympy import sin
>>> from sympy.abc import x
>>> meijerint_indefinite(sin(x), x)
-cos(x)
```

sympy.integrals.meijerint.meijerint_inversion(f, x, t)
Compute the inverse laplace transform \(\int_{c-i\infty}^{c+i\infty} f(x)e^{tx} dx\), for real c larger than the real part of all singularities of f.

Note that t is always assumed real and positive.

Return None if the integral does not exist or could not be evaluated.
Examples

```python
>>> from sympy.abc import x, t
>>> from sympy.integrals.meijerint import meijerint_inversion
>>> meijerint_inversion(1/x, x, t)
Heaviside(t)
```

Integrals

The integrals module in SymPy implements methods to calculate definite and indefinite integrals of expressions.

Principal method in this module is `integrate()` (page 657)

- `integrate(f, x)` returns the indefinite integral \( \int f \, dx \)
- `integrate(f, (x, a, b))` returns the definite integral \( \int_a^b f \, dx \)

Examples

SymPy can integrate a vast array of functions. It can integrate polynomial functions:

```python
>>> from sympy import *
>>> init_printing(use_unicode=False, wrap_line=False)
>>> x = Symbol('x')
>>> integrate(x**2 + x + 1, x)
3 2 3 2
x x + x
3 2
```

Rational functions:

```python
>>> integrate(x/(x**2+2*x+1), x)
1
log(x + 1) + -----
x + 1
```

Exponential-polynomial functions. These multiplicative combinations of polynomials and the functions \( \exp, \cos \) and \( \sin \) can be integrated by hand using repeated integration by parts, which is an extremely tedious process. Happily, SymPy will deal with these integrals.

```python
>>> integrate(x**2 * exp(x) * cos(x), x)
2 x 2 x 2 x 2 x 2 x 2 x
x *e *sin(x) x *e *cos(x) x e *sin(x) e *cos(x)
-------------------- + -------------------- - x*e *sin(x) + -------------------- - --------------------
2 2 2 2
```

even a few nonelementary integrals (in particular, some integrals involving the error function) can be evaluated:
Integral Transforms

SymPy has special support for definite integrals, and integral transforms.

sympy.integrals.transforms.mellin_transform(f, x, s, **hints)

Compute the Mellin transform $F(s)$ of $f(x)$,

$$F(s) = \int_{0}^{\infty} x^{s-1} f(x) \, dx.$$ 

For all “sensible” functions, this converges absolutely in a strip

$$a < \text{Re}(s) < b.$$ 

Explanation

The Mellin transform is related via change of variables to the Fourier transform, and also to the (bilateral) Laplace transform.

This function returns $(F, (a, b), \text{cond})$ where $F$ is the Mellin transform of $f$, $(a, b)$ is the fundamental strip (as above), and $\text{cond}$ are auxiliary convergence conditions.

If the integral cannot be computed in closed form, this function returns an unevaluated MellinTransform (page 634) object.

For a description of possible hints, refer to the docstring of sympy.integrals.transforms.IntegralTransform.doit() (page 645). If noconds=False, then only $F$ will be returned (i.e. not cond, and also not the strip $(a, b)$).

Examples

```python
>>> from sympy import mellin_transform, exp
>>> from sympy.abc import x, s
>>> mellin_transform(exp(-x), x, s)
(gamma(s), (0, oo), True)
```

See also:

inverse_mellin_transform (page 635), laplace_transform (page 635), fourier_transform (page 638), hankel_transform (page 643), inverse_hankel_transform (page 644)

class sympy.integrals.transforms.MellinTransform(*args)

Class representing unevaluated Mellin transforms.

For usage of this class, see the IntegralTransform (page 645) docstring.

For how to compute Mellin transforms, see the mellin_transform() (page 634) docstring.
sympy.integrals.transforms.inverse_mellin_transform(F, s, x, strip, **hints)

Compute the inverse Mellin transform of $F(s)$ over the fundamental strip given by $strip=(a, b)$.

**Explanation**

This can be defined as

$$f(x) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} x^{-s} F(s) \, ds,$$

for any $c$ in the fundamental strip. Under certain regularity conditions on $F$ and/or $f$, this recovers $f$ from its Mellin transform $F$ (and vice versa), for positive real $x$.

One of $a$ or $b$ may be passed as `None`; a suitable $c$ will be inferred.

If the integral cannot be computed in closed form, this function returns an unevaluated `InverseMellinTransform` object.

Note that this function will assume $x$ to be positive and real, regardless of the SymPy assumptions!

For a description of possible hints, refer to the docstring of `sympy.integrals.transforms.IntegralTransform.doit()` (page 645).

**Examples**

```python
>>> from sympy import inverse_mellin_transform, oo, gamma
>>> from sympy.abc import x, s
>>> inverse_mellin_transform(gamma(s), s, x, (0, oo))
exp(-x)
```

The fundamental strip matters:

```python
>>> f = 1/(s**2 - 1)
>>> inverse_mellin_transform(f, s, x, (-oo, -1))
x*(1 - 1/x**2)*Heaviside(x - 1)/2
>>> inverse_mellin_transform(f, s, x, (-1, 1))
-x*Heaviside(1 - x)/2 - Heaviside(x - 1)/(2*x)
>>> inverse_mellin_transform(f, s, x, (1, oo))
(1/2 - x**2/2)*Heaviside(1 - x)/x
```

**See also:**

- `mellin_transform` (page 634), `hankel_transform` (page 643), `inverse_hankel_transform` (page 644)

**class** sympy.integrals.transforms.InverseMellinTransform(*args)

Class representing unevaluated inverse Mellin transforms.

For usage of this class, see the `IntegralTransform` (page 645) docstring.

For how to compute inverse Mellin transforms, see the `inverse_mellin_transform()` (page 635) docstring.
sympy.integrals.transforms.laplace_transform(f, t, s, legacy_matrix=True, **hints)

Compute the Laplace Transform $F(s)$ of $f(t)$,

$$F(s) = \int_{0^-}^{\infty} e^{-st} f(t) dt.$$ 

**Explanation**

For all sensible functions, this converges absolutely in a half-plane

$$a < \text{Re}(s)$$

This function returns $(F, a, \text{cond})$ where $F$ is the Laplace transform of $f$, $a$ is the half-plane of convergence, and $\text{cond}$ are auxiliary convergence conditions.

The implementation is rule-based, and if you are interested in which rules are applied, and whether integration is attempted, you can switch debug information on by setting `sympy.SYMPY_DEBUG=True`. The numbers of the rules in the debug information (and the code) refer to Bateman’s Tables of Integral Transforms [1].

The lower bound is $0^-$, meaning that this bound should be approached from the lower side. This is only necessary if distributions are involved. At present, it is only done if $f(t)$ contains `DiracDelta`, in which case the Laplace transform is computed implicitly as

$$F(s) = \lim_{\tau \to 0^-} \int_{\tau}^{\infty} e^{-st} f(t) dt$$

by applying rules.

If the Laplace transform cannot be fully computed in closed form, this function returns expressions containing unevaluated `LaplaceTransform` objects.

For a description of possible hints, refer to the docstring of `sympy.integrals.transforms.IntegralTransform.doit()` (page 645). If `noconds=True`, only $F$ will be returned (i.e. not cond, and also not the plane a).

Deprecated since version 1.9: Legacy behavior for matrices where `laplace_transform` with `noconds=False` (the default) returns a Matrix whose elements are tuples. The behavior of `laplace_transform` for matrices will change in a future release of SymPy to return a tuple of the transformed Matrix and the convergence conditions for the matrix as a whole. Use `legacy_matrix=False` to enable the new behavior.

**Examples**

```python
>>> from sympy import DiracDelta, exp, laplace_transform
>>> from sympy.abc import t, s, a
>>> laplace_transform(t**4, t, s)
(24/s**5, 0, True)
>>> laplace_transform(t**a, t, s)
(gamma(a + 1)/(s**a), 0, re(a) > -1)
>>> laplace_transform(DiracDelta(t) - a*exp(-a*t), t, s, simplify=True)
(s/(a + s), -re(a), True)
```
See also:

- `inverse_laplace_transform` (page 637), `mellin_transform` (page 634),
- `fourier_transform` (page 638), `hankel_transform` (page 643),
- `inverse_hankel_transform` (page 644)

References

[R539]

class sympy.integrals.transforms.LaplaceTransform(*args)

Class representing unevaluated Laplace transforms.

For usage of this class, see the `IntegralTransform` (page 645) docstring.

For how to compute Laplace transforms, see the `laplace_transform()` (page 635) docstring.

If this is called with `.doit()`, it returns the Laplace transform as an expression. If it is called with `.doit(noconds=False)`, it returns a tuple containing the same expression, a convergence plane, and conditions.

```python
doit(**hints)
```

Try to evaluate the transform in closed form.

Explanation

Standard hints are the following: - `noconds`: if True, do not return convergence conditions. The default setting is `True`. - `simplify`: if True, it simplifies the final result. The default setting is `False`.

```python
sympy.integrals.transforms.inverse_laplace_transform(F, s, t, plane=None, **hints)
```

Compute the inverse Laplace transform of $F(s)$, defined as

$$f(t) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} e^{st}F(s)\,ds,$$

for $c$ so large that $F(s)$ has no singularities in the half-plane $\text{Re}(s) > c - \epsilon$.

Explanation

The plane can be specified by argument `plane`, but will be inferred if passed as `None`.

Under certain regularity conditions, this recovers $f(t)$ from its Laplace Transform $F(s)$, for non-negative $t$, and vice versa.

If the integral cannot be computed in closed form, this function returns an unevaluated `InverseLaplaceTransform` (page 638) object.

Note that this function will always assume $t$ to be real, regardless of the SymPy assumption on $t$.

For a description of possible hints, refer to the docstring of `sympy.integrals.transforms.IntegralTransform.doit()` (page 645).
Examples

```python
>>> from sympy import inverse_laplace_transform, exp, Symbol
>>> from sympy.abc import s, t
>>> a = Symbol('a', positive=True)
>>> inverse_laplace_transform(exp(-a*s)/s, s, t)
Heaviside(-a + t)
```

- `hankel_transform` (page 643)
- `inverse_hankel_transform` (page 644)

class sympy.integrals.transforms.InverseLaplaceTransform(*args)

Class representing unevaluated inverse Laplace transforms.

For usage of this class, see the `IntegralTransform` (page 645) docstring.

For how to compute inverse Laplace transforms, see the `inverse_laplace_transform()` (page 637) docstring.

doit(**hints)

Try to evaluate the transform in closed form.

Explanation

Standard hints are the following:
- noconds: if True, do not return convergence conditions. The default setting is `True`.
- simplify: if True, it simplifies the final result. The default setting is `False`.

```python
sympy.integrals.transforms.fourier_transform(f, x, k, **hints)
```

Compute the unitary, ordinary-frequency Fourier transform of \( f \), defined as

\[
F(k) = \int_{-\infty}^{\infty} f(x) e^{-2\pi i x k} \, dx.
\]

Explanation

If the transform cannot be computed in closed form, this function returns an unevaluated `FourierTransform` (page 639) object.

For other Fourier transform conventions, see the function `sympy.integrals.transforms._fourier_transform()` (page 639).

For a description of possible hints, refer to the docstring of `sympy.integrals.transforms.IntegralTransform.doit()` (page 645). Note that for this transform, by default noconds=True.
Examples

```python
>>> from sympy import fourier_transform, exp
>>> from sympy.abc import x, k
>>> fourier_transform(exp(-x**2), x, k)
sqrt(pi)*exp(-pi**2*k**2)
>>> fourier_transform(exp(-x**2), x, k, noconds=False)
(sqrt(pi)*exp(-pi**2*k**2), True)
```

See also:
- `inverse_fourier_transform`
- `sine_transform`
- `inverse_sine_transform`
- `cosine_transform`
- `inverse_cosine_transform`

- `inverse_hankel_transform`
- `mellin_transform`
- `laplace_transform`

`sympy.integrals.transforms._fourier_transform(f, x, k, a, b, name, simplify=True)`

Compute a general Fourier-type transform

\[ F(k) = a \int_{-\infty}^{\infty} e^{bixk} f(x) \, dx. \]

For suitable choice of \(a\) and \(b\), this reduces to the standard Fourier and inverse Fourier transforms.

```python
class sympy.integrals.transforms.FourierTransform(*args)
```

Class representing unevaluated Fourier transforms.

For usage of this class, see the `IntegralTransform` docstring.

For how to compute Fourier transforms, see the `fourier_transform()` docstring.

`sympy.integrals.transforms.inverse_fourier_transform(F, k, x, **hints)`

Compute the unitary, ordinary-frequency inverse Fourier transform of \(F\), defined as

\[ f(x) = \int_{-\infty}^{\infty} F(k)e^{2\pi ikx} \, dk. \]

Explanation

If the transform cannot be computed in closed form, this function returns an unevaluated `InverseFourierTransform` object.

For other Fourier transform conventions, see the function `sympy.integrals.transforms._fourier_transform()`.

For a description of possible hints, refer to the docstring of `sympy.integrals.transforms.IntegralTransform.doit()`.

5.8. Topics
Examples

```python
>>> from sympy import inverse_fourier_transform, exp, sqrt, pi
>>> from sympy.abc import x, k
>>> inverse_fourier_transform(sqrt(pi)*exp(-pi*k**2), k, x)
exp(-x**2)
>>> inverse_fourier_transform(sqrt(pi)*exp(-pi*k**2), k, x, noconds=False)
(exp(-x**2), True)
```

- `laplace_transform` (page 635)

class sympy.integrals.transforms.InverseFourierTransform(*args)

Class representing unevaluated inverse Fourier transforms.

For usage of this class, see the `IntegralTransform` (page 645) docstring.

For how to compute inverse Fourier transforms, see the `inverse_fourier_transform()` (page 639) docstring.

sympy.integrals.transforms.sine_transform(f, x, k, **hints)

Compute the unitary, ordinary-frequency sine transform of \( f \), defined as

\[
F(k) = \sqrt{\frac{2}{\pi}} \int_{0}^{\infty} f(x) \sin(2\pi x k) dx.
\]

Explanation

If the transform cannot be computed in closed form, this function returns an unevaluated `SineTransform` (page 641) object.

For a description of possible hints, refer to the docstring of `sympy.integrals.transforms.IntegralTransform.doit()` (page 645). Note that for this transform, by default noconds=True.

Examples

```python
>>> from sympy import sine_transform, exp
>>> from sympy.abc import x, k, a
>>> sine_transform(x*exp(-a*x**2), x, k)
sqrt(2)*k*exp(-k**2/(4*a))/(4*a**(3/2))
>>> sine_transform(x*(-a), x, k)
2**(1/2 - a)*k**(a - 1)*gamma(1 - a/2)/gamma(a/2 + 1/2)
```

class sympy.integrals.transforms.SineTransform(*args)

Class representing unevaluated sine transforms.

For usage of this class, see the IntegralTransform (page 645) docstring.

For how to compute sine transforms, see the sine_transform() (page 640) docstring.

sympy.integrals.transforms.inverse_sine_transform(F, k, x, **hints)

Compute the unitary, ordinary-frequency inverse sine transform of F, defined as

\[ f(x) = \sqrt{\frac{2}{\pi}} \int_0^{\infty} F(k) \sin(2\pi k x) \, dk. \]

Explanation

If the transform cannot be computed in closed form, this function returns an unevaluated InverseSineTransform (page 641) object.

For a description of possible hints, refer to the docstring of sympy.integrals.transforms.IntegralTransform.doit() (page 645). Note that for this transform, by default noconds=True.

Examples

```python
>>> from sympy import inverse_sine_transform, exp, sqrt, gamma
>>> from sympy.abc import x, k, a
>>> inverse_sine_transform(2**((1-2*a)/2)**(a - 1)*
                         x**(a) + 1)/gamma((a+1)/2), k, x)
>>> inverse_sine_transform(sqrt(2)*k*exp(-k**2/(4*a))/(4*sqrt(a)**3), k, u)
```

See also:

class sympy.integrals.transforms.InverseSineTransform(*args)

Class representing unevaluated inverse sine transforms.

For usage of this class, see the IntegralTransform (page 645) docstring.

For how to compute inverse sine transforms, see the inverse_sine_transform() (page 641) docstring.

sympy.integrals.transforms.cosine_transform(f, x, k, **hints)

Compute the unitary, ordinary-frequency cosine transform of f, defined as

\[ F(k) = \sqrt{\frac{2}{\pi}} \int_0^{\infty} f(x) \cos(2\pi k x) \, dx. \]
Explanation

If the transform cannot be computed in closed form, this function returns an unevaluated `CosineTransform` object.

For a description of possible hints, refer to the docstring of `sympy.integrals.transforms.IntegralTransform.doit()` (page 645). Note that for this transform, by default noconds=True.

Examples

```python
>>> from sympy import cosine_transform, exp, sqrt, cos
>>> from sympy.abc import x, k, a
>>> cosine_transform(exp(-a*x), x, k)
sqrt(2)*a/(sqrt(pi)*(a**2 + k**2))
```

```
>>> cosine_transform(exp(-a*sqrt(x))*cos(a*sqrt(x)), x, k)
a*exp(-a**2/(2*k))/(2*k**(3/2))
```

- `inverse_hankel_transform` (page 644)
- `mellin_transform` (page 634)
- `laplace_transform` (page 635)

```python
class sympy.integrals.transforms.CosineTransform(*args)
```

Class representing unevaluated cosine transforms.

For usage of this class, see the `IntegralTransform` (page 645) docstring.

For how to compute cosine transforms, see the `cosine_transform()` (page 641) docstring.

```python
sympy.integrals.transforms.inverse_cosine_transform(F, k, x, **hints)
```

Compute the unitary, ordinary-frequency inverse cosine transform of F, defined as

\[ f(x) = \sqrt{\frac{2}{\pi}} \int_{0}^{\infty} F(k) \cos(2\pi x k) dk. \]

Explanation

If the transform cannot be computed in closed form, this function returns an unevaluated `InverseCosineTransform` object.

For a description of possible hints, refer to the docstring of `sympy.integrals.transforms.IntegralTransform.doit()` (page 645). Note that for this transform, by default noconds=True.
Examples

```python
>>> from sympy import inverse_cosine_transform, sqrt, pi
>>> from sympy.abc import x, k, a
>>> inverse_cosine_transform(sqrt(2)*a/(sqrt(pi)*(a**2 + k**2)), k, x)
exp(-a*x)
>>> inverse_cosine_transform(1/sqrt(k), k, x)
1/sqrt(x)
```

- `inverse_hankel_transform` (page 644),
- `mellin_transform` (page 634), `laplace_transform` (page 635)

class sympy.integrals.transforms.InverseCosineTransform(*args)
Class representing unevaluated inverse cosine transforms.
For usage of this class, see the `IntegralTransform` (page 645) docstring.
For how to compute inverse cosine transforms, see the `inverse_cosine_transform()` (page 642) docstring.

sympy.integrals.transforms.hankel_transform(f, r, k, nu, **hints)
Compute the Hankel transform of f, defined as

\[ F_\nu(k) = \int_0^\infty f(r) J_\nu(kr) r \, dr. \]

Explanation

If the transform cannot be computed in closed form, this function returns an unevaluated HankelTransform (page 644) object.
For a description of possible hints, refer to the docstring of sympy.integrals.transforms.IntegralTransform.doit() (page 645). Note that for this transform, by default noconds=True.

Examples

```python
>>> from sympy import hankel_transform, inverse_hankel_transform
>>> from sympy import exp
>>> from sympy.abc import r, k, m, nu, a

>>> ht = hankel_transform(1/r**m, r, k, nu)
>>> ht
2*k**(m - 2)*gamma(-m/2 + nu/2 + 1)/(2**m*gamma(m/2 + nu/2))

>>> inverse_hankel_transform(ht, k, r, nu)
r**(-m)
```
```python
>>> ht = hankel_transform(exp(-a*r), r, k, 0)
>>> ht
a/(k**3*(a**2/k**2 + 1)**(3/2))

>>> inverse_hankel_transform(ht, k, r, 0)
exp(-a*r)
```

**See also:**

- `laplace_transform` (page 635)

**class** sympy.integrals.transforms.HankelTransform(*args)

Class representing unevaluated Hankel transforms.

For usage of this class, see the `IntegralTransform` (page 645) docstring.

For how to compute Hankel transforms, see the `hankel_transform()` (page 643) docstring.

**sympy.integrals.transforms.inverse_hankel_transform(F, k, r, nu, **hints)**

Compute the inverse Hankel transform of \( F \) defined as

\[
f(r) = \int_0^{\infty} F_\nu(k) J_\nu(kr) k dk.
\]

**Explanation**

If the transform cannot be computed in closed form, this function returns an unevaluated `InverseHankelTransform` (page 645) object.

For a description of possible hints, refer to the docstring of `sympy.integrals.transforms.IntegralTransform.doit()` (page 645). Note that for this transform, by default `noconds=True`.

**Examples**

```python
>>> from sympy import hankel_transform, inverse_hankel_transform
>>> from sympy import exp
>>> from sympy.abc import r, k, m, nu, a

>>> ht = hankel_transform(1/r**m, r, k, nu)
>>> ht
2*k**(m - 2)*gamma(-m/2 + nu/2 + 1)/(2**m*gamma(m/2 + nu/2))

>>> inverse_hankel_transform(ht, k, r, nu)
r**(-m)

>>> ht = hankel_transform(exp(-a*r), r, k, 0)
>>> ht
a/(k**3*(a**2/k**2 + 1)**(3/2))
```
```python
>>> inverse_hankel_transform(ht, k, r, 0)
exp(-a*r)
```

class `sympy.integrals.transforms.InverseHankelTransform(*args)`

Class representing unevaluated inverse Hankel transforms.

For usage of this class, see the `IntegralTransform` (page 645) docstring.

For how to compute inverse Hankel transforms, see the `inverse_hankel_transform()` (page 644) docstring.

class `sympy.integrals.transforms.IntegralTransform(*args)`

Base class for integral transforms.

**Explanation**

This class represents unevaluated transforms.

To implement a concrete transform, derive from this class and implement the
`_compute_transform(f, x, s, **hints)` and `as_integral(f, x, s)` functions. If
the transform cannot be computed, raise `IntegralTransformError` (page 646).

Also set cls._name. For instance,

```python
>>> from sympy import LaplaceTransform
>>> LaplaceTransform._name
'Laplace'
```

Implement self._collapse_extra if your function returns more than just a number and
possibly a convergence condition.

doit(**hints)

Try to evaluate the transform in closed form.

**Explanation**

This general function handles linearity, but apart from that leaves pretty much every-
ting to _compute_transform.

Standard hints are the following:

- **simplify**: whether or not to simplify the result
- **noconds**: if True, do not return convergence conditions
- **needeval**: if True, raise `IntegralTransformError` instead of returning `IntegralTransform` objects

The default values of these hints depend on the concrete transform, usually the
default is `(simplify, noconds, needeval) = (True, False, False)`.
property function
The function to be transformed.

property function_variable
The dependent variable of the function to be transformed.

property transform_variable
The independent transform variable.

exception sympy.integrals.transforms.IntegralTransformError(transform, function, msg)

Exception raised in relation to problems computing transforms.

Explanation
This class is mostly used internally; if integrals cannot be computed objects representing unevaluated transforms are usually returned.

The hint needeval=True can be used to disable returning transform objects, and instead raise this exception if an integral cannot be computed.

Internals
SymPy uses a number of algorithms to compute integrals. Algorithms are tried in order until one produces an answer. Most of these algorithms can be enabled or disabled manually using various flags to integrate() (page 657) or doit() (page 662).

SymPy first applies several heuristic algorithms, as these are the fastest:

1. If the function is a rational function, there is a complete algorithm for integrating rational functions called the Lazard-Rioboo-Trager and the Horowitz-Ostrogradsky algorithms. They are implemented in ratint() (page 646).

   sympy.integrals.rationaltools.ratint(f, x, **flags)
   Performs indefinite integration of rational functions.

Explanation
Given a field \( K \) and a rational function \( f = \frac{p}{q} \), where \( p \) and \( q \) are polynomials in \( K[x] \), returns a function \( g \) such that \( f = g' \).

Examples

```python
>>> from sympy.integrals.rationaltools import ratint
>>> from sympy.abc import x

>>> ratint((36/(x**5 - 2*x**4 - 2*x**3 + 4*x**2 + x - 2)), x)
(12*x + 6)/(x**2 - 1) + 4*log(x - 2) - 4*log(x + 1)
```
See also:

- `sympy.integrals.integrals.Integral.doit` (page 662)
- `sympy.integrals.rationaltools.ratint_logpart` (page 647)
- `sympy.integrals.rationaltools.ratint_ratpart` (page 647)

References

[R540]

**Explanation**

Given a field $K$ and polynomials $f$ and $g$ in $K[x]$, such that $f$ and $g$ are coprime and $\deg(f) < \deg(g)$, returns fractions $A$ and $B$ in $K(x)$, such that $f/g = A' + B$ and $B$ has square-free denominator.

**Examples**

```python
>>> from sympy.integrals.rationaltools import ratint_ratpart
>>> from sympy.abc import x, y
>>> ratint_ratpart(Poly(1, x, domain='ZZ'), ...
... Poly(x + 1, x, domain='ZZ'), x)
(0, 1/(x + 1))
>>> ratint_ratpart(Poly(1, x, domain='EX'), ...
... Poly(x**2 + y**2, x, domain='EX'), x)
(0, 1/(x**2 + y**2))
>>> ratint_ratpart(Poly(36, x, domain='ZZ'), ...
... Poly(x**5 - 2*x**4 - 2*x**3 + 4*x**2 + x - 2, x, domain='ZZ'), x)
(((12*x + 6)/(x**2 - 1), 12/(x**2 - x - 2))
```

See also:

- `ratint` (page 646), `ratint_logpart` (page 647)

**Explanation**

Given a field $K$ and polynomials $f$ and $g$ in $K[x]$, such that $f$ and $g$ are coprime, $\deg(f) < \deg(g)$ and $g$ is square-free, returns a list of tuples $(s_i, q_i)$ of polynomials, for $i = 1..n$, such that $s_i$ in $K[t, x]$ and $q_i$ in $K[t]$, and:

\[
d \frac{d}{d} \left( \log(s_i(a, x)) \right)
```

(continues on next page)
dx g dx /__, /__,
i=1..n a | q_i(a) = 0

Examples

```python
>>> from sympy.integrals.rationaltools import ratint_logpart
>>> from sympy import x
>>> from sympy import Poly
>>> ratint_logpart(Poly(1, x, domain='ZZ'),
... Poly(x**2 + x + 1, x, domain='ZZ'), x)
[(Poly(x + 3*_t/2 + 1/2, x, domain='QQ[_t]'),
  ...Poly(3*_t**2 + 1, _t, domain='ZZ'))]
>>> ratint_logpart(Poly(12, x, domain='ZZ'),
... Poly(x**2 - x - 2, x, domain='ZZ'), x)
[(Poly(x - 3*_t/8 - 1/2, x, domain='QQ[_t]'),
  ...Poly(-_t**2 + 16, _t, domain='ZZ'))]
```

See also:
- `ratint` (page 646), `ratint_ratpart` (page 647)

2. `trigintegrate()` (page 648) solves integrals of trigonometric functions using pattern matching

```python
>>> from sympy import sin, cos, tan, sec
>>> from sympy.integrals.trigonometry import trigintegrate
>>> from sympy.abc import x

>>> trigintegrate(sin(x)*cos(x), x)
sin(x)**2/2

>>> trigintegrate(sin(x)*sin(x)**2, x)
x/2 - sin(x)*cos(x)/2

>>> trigintegrate(tan(x)*sec(x), x)
1/cos(x)

>>> trigintegrate(sin(x)*tan(x), x)
-log(sin(x) - 1)/2 + log(sin(x) + 1)/2 - sin(x)
```

See also:
- `sympy.integrals.integrals.Integral.doit` (page 662), `sympy.integrals.integrals.Integral` (page 660)

**References**

[R541]

3. `deltaintegrate()` (page 649) solves integrals with `DiracDelta` (page 506) objects.

```
sympy.integrals.deltafunctions.deltaintegrate(f, x)
```

**Explanation**

The idea for integration is the following:

- If we are dealing with a `DiracDelta` expression, i.e. `DiracDelta(g(x))`, we try to simplify it.

  If we could simplify it, then we integrate the resulting expression. We already know we can integrate a simplified expression, because only simple `DiracDelta` expressions are involved.

  If we couldn't simplify it, there are two cases:

  1) The expression is a simple expression: we return the integral, taking care if we are dealing with a `Derivative` or with a proper `DiracDelta`.

  2) The expression is not simple (i.e. `DiracDelta(cos(x))`): we can do nothing at all.

- If the node is a multiplication node having a `DiracDelta` term:

  First we expand it.

  If the expansion did work, then we try to integrate the expansion.

  If not, we try to extract a simple `DiracDelta` term, then we have two cases:

  1) We have a simple `DiracDelta` term, so we return the integral.

  2) We didn't have a simple term, but we do have an expression with simplified `DiracDelta` terms, so we integrate this expression.

**Examples**

```
>>> from sympy.abc import x, y, z
>>> from sympy.integrals.deltafunctions import deltainegrate
>>> from sympy import sin, cos, DiracDelta

>>> deltainegrate(x*sin(x)*cos(x)*DiracDelta(x - 1), x)
sin(1)*cos(1)*Heaviside(x - 1)

>>> deltainegrate(y**2*DiracDelta(x - z)*DiracDelta(y - z), y)
z**2*DiracDelta(x - z)*Heaviside(y - z)
```

**See also:**

- `sympy.functions.special.delta_functions.DiracDelta` (page 506), `sympy.integrals.integrals.Integral` (page 660)

4. `singularityintegrate()` (page 649) is applied if the function contains a `SingularityFunction` (page 513)
This function handles the indefinite integrations of Singularity functions. The `integrate` function calls this function internally whenever an instance of SingularityFunction is passed as argument.

**Explanation**

The idea for integration is the following:

- If we are dealing with a SingularityFunction expression, i.e. `SingularityFunction(x, a, n)`, we just return `SingularityFunction(x, a, n + 1)/(n + 1)` if `n >= 0` and `SingularityFunction(x, a, n + 1)` if `n < 0`.

- If the node is a multiplication or power node having a SingularityFunction term we rewrite the whole expression in terms of Heaviside and DiracDelta and then integrate the output. Lastly, we rewrite the output of integration back in terms of SingularityFunction.

- If none of the above case arises, we return None.

**Examples**

```python
>>> from sympy.integrals.singularityfunctions import singularityintegrate
>>> from sympy import SingularityFunction, symbols, Function
>>> x, a, n, y = symbols('x a n y')
>>> f = Function('f')
>>> singularityintegrate(SingularityFunction(x, a, 3), x)
SingularityFunction(x, a, 4)/4
>>> singularityintegrate(5*SingularityFunction(x, 5, -2), x)
5*SingularityFunction(x, 5, -1)
>>> singularityintegrate(6*SingularityFunction(x, 5, -1), x)
6*SingularityFunction(x, 5, 0)
>>> singularityintegrate(x*SingularityFunction(x, 0, -1), x)
0
>>> singularityintegrate(SingularityFunction(x, 1, -1) * f(x), x)
f(1)*SingularityFunction(x, 1, 0)
```

5. If the heuristic algorithms cannot be applied, `risch_integrate()` (page 650) is tried next. The Risch algorithm is a general method for calculating antiderivatives of elementary functions. The Risch algorithm is a decision procedure that can determine whether an elementary solution exists, and in that case calculate it. It can be extended to handle many nonelementary functions in addition to the elementary ones. However, the version implemented in SymPy only supports a small subset of the full algorithm, particularly, on part of the transcendental algorithm for exponentials and logarithms is implemented. An advantage of `risch_integrate()` (page 650) over other methods is that if it returns an instance of NonElementaryIntegral (page 652), the integral is proven to be nonelementary by the algorithm, meaning the integral cannot be represented using a combination of exponentials, logarithms, trig functions, powers, rational functions, algebraic functions, and function composition.
The Risch Integration Algorithm.

**Explanation**

Only transcendental functions are supported. Currently, only exponentials and logarithms are supported, but support for trigonometric functions is forthcoming.

If this function returns an unevaluated Integral in the result, it means that it has proven that integral to be nonelementary. Any errors will result in raising NotImplementedError. The unevaluated Integral will be an instance of NonElementaryIntegral, a subclass of Integral.

`handle_first` may be either `'exp'` or `'log'`. This changes the order in which the extension is built, and may result in a different (but equivalent) solution (for an example of this, see issue 5109). It is also possible that the integral may be computed with one but not the other, because not all cases have been implemented yet. It defaults to `'log'` so that the outer extension is exponential when possible, because more of the exponential case has been implemented.

If `separate_integral` is `True`, the result is returned as a tuple `(ans, i)`, where the integral is `ans + i`, `ans` is elementary, and `i` is either a `NonElementaryIntegral` or `0`. This useful if you want to try further integrating the `NonElementaryIntegral` part using other algorithms to possibly get a solution in terms of special functions. It is `False` by default.

**Examples**

```python
>>> from sympy.integrals.risch import risch_integrate
>>> from sympy import exp, log, pprint
>>> from sympy.abc import x
```

First, we try integrating `exp(-x**2)`. Except for a constant factor of `2/sqrt(pi)`, this is the famous error function.

```python
>>> pprint(risch_integrate(exp(-x**2), x))
/  2
|   -x
|   e  dx
/ 
```

The unevaluated Integral in the result means that `risch_integrate()` has proven that `exp(-x**2)` does not have an elementary anti-derivative.

In many cases, `risch_integrate()` can split out the elementary anti-derivative part from the nonelementary anti-derivative part. For example,
>>> pprint(risch_integrate((2*log(x)**2 - log(x) - x**2)/(log(x)**3 - x**2*log(x)), x))

\[
\frac{\log(-x + \log(x))}{2} + \frac{\log(x + \log(x))}{2} + \frac{1}{\log(x)} \, \mathrm{dx}
\]

This means that it has proven that the integral of $1/\log(x)$ is nonelementary. This function is also known as the logarithmic integral, and is often denoted as $\text{Li}(x)$.

\text{risch\_integrate()} currently only accepts purely transcendental functions with exponentials and logarithms, though note that this can include nested exponentials and logarithms, as well as exponentials with bases other than $E$.

>>> pprint(risch_integrate(exp(x)*exp(exp(x)), x))

\[
\frac{1}{x} \, \mathrm{e} \, \mathrm{dx}
\]

>>> pprint(risch_integrate(exp(exp(x)), x))

\[
\frac{1}{x} \, \mathrm{e} \, \mathrm{dx}
\]

>>> pprint(risch_integrate(x**x**x*log(x) + x**x + x*x**x, x))

\[
x \, x^x \, \mathrm{dx}
\]

>>> pprint(risch_integrate(x**x, x))

\[
x \, x \, \mathrm{dx}
\]

>>> pprint(risch_integrate(-1/(x*log(x)*log(log(x))**2), x))

\[
\frac{1}{\log(\log(x))}
\]

class sympy.integrals.risch.NonElementaryIntegral(function, *symbols, **assumptions)

Represents a nonelementary Integral.
**Explanation**

If the result of `integrate()` is an instance of this class, it is guaranteed to be nonelementary. Note that `integrate()` by default will try to find any closed-form solution, even in terms of special functions which may themselves not be elementary. To make `integrate()` only give elementary solutions, or, in the cases where it can prove the integral to be nonelementary, instances of this class, use `integrate(risch=True)`. In this case, `integrate()` may raise `NotImplementedError` if it cannot make such a determination.

`integrate()` uses the deterministic Risch algorithm to integrate elementary functions or prove that they have no elementary integral. In some cases, this algorithm can split an integral into an elementary and nonelementary part, so that the result of `integrate` will be the sum of an elementary expression and a `NonElementaryIntegral`.

**Examples**

```python
>>> from sympy import integrate, exp, log, Integral

>>> a = integrate(exp(-x**2), x, risch=True)
>>> print(a)
Integral(exp(-x**2), x)

>>> type(a)
<class 'sympy.integrals.risch.NonElementaryIntegral'>

>>> expr = (2*log(x)**2 - log(x) - x**2)/(log(x)**3 - x**2*log(x))
>>> b = integrate(expr, x, risch=True)
```

6. For non-elementary definite integrals, SymPy uses so-called Meijer G-functions. Details are described in *Computing Integrals using Meijer G-Functions* (page 612).

7. All the algorithms mentioned thus far are either pattern-matching based heuristic, or solve integrals using algorithms that are much different from the way most people are taught in their calculus courses. SymPy also implements a method that can solve integrals in much the same way you would in calculus. The advantage of this method is that it is possible to extract the integration steps from, so that one can see how to compute the integral “by hand”. This is used by SymPy Gamma. This is implemented in the `manualintegrate()` (page 653) function. The steps for an integral can be seen with the `integral_steps()` (page 654) function.

```python
sympy.integrals.manualintegrate.manualintegrate(f, var)
```
**Explanation**

Compute indefinite integral of a single variable using an algorithm that resembles what a student would do by hand.

Unlike \texttt{integrate()} (page 657), \texttt{var} can only be a single symbol.

**Examples**

```python
>>> from sympy import sin, cos, tan, exp, log, integrate
>>> from sympy.integrals.manualintegrate import manualintegrate
>>> from sympy.abc import x

>>> manualintegrate(1 / x, x)
log(x)

>>> integrate(1/x)
log(x)

>>> manualintegrate(log(x), x)
x*log(x) - x

>>> integrate(log(x))
x*log(x) - x

>>> manualintegrate(exp(x) / (1 + exp(2 * x)), x)
atan(exp(x))

>>> integrate(exp(x) / (1 + exp(2 * x)))
RootSum(4*_z**2 + 1, Lambda(_i, _i*log(2*_i + exp(x))))

>>> manualintegrate(cos(x)**4 * sin(x), x)
-cos(x)**5/5

>>> integrate(cos(x)**4 * sin(x), x)
-cos(x)**5/5

>>> manualintegrate(cos(x)**4 * sin(x)**3, x)
cos(x)**7/7 - cos(x)**5/5

>>> integrate(cos(x)**4 * sin(x)**3, x)
cos(x)**7/7 - cos(x)**5/5

>>> manualintegrate(tan(x), x)
-log(cos(x))

>>> integrate(tan(x), x)
-log(cos(x))
```

**See also:**

\texttt{sympy.integrals.integrals.integrate} (page 657), \texttt{sympy.integrals.integrals.Integral.doit} (page 662), \texttt{sympy.integrals.integrals.Integral} (page 660)

\texttt{sympy.integrals.manualintegrate.\texttt{integral}_\texttt{steps} (integrand, symbol. **options)}

Returns the steps needed to compute an integral.

**Returns**

- **rule**: Rule

  The first step; most rules have substeps that must also be considered. These substeps can be evaluated using \texttt{manualintegrate} to obtain a result.
**Explanation**

This function attempts to mirror what a student would do by hand as closely as possible.

SymPy Gamma uses this to provide a step-by-step explanation of an integral. The code it uses to format the results of this function can be found at https://github.com/sympy/sympy_gamma/blob/master/app/logic/intsteps.py.

**Examples**

```python
>>> from sympy import exp, sin
>>> from sympy.integrals.manualintegrate import integral_steps
>>> from sympy.abc import x

>>> print(repr(integral_steps(exp(x) / (1 + exp(2 * x)), x)))
URule(integrand=exp(x)/(exp(2*x) + 1), variable=x, u_var=_u, u_func=exp(x),
substep=ArctanRule(integrand=1/(_u**2 + 1), variable=_u, a=1, b=1, c=1))

>>> print(repr(integral_steps(sin(x), x)))
SinRule(integrand=sin(x), variable=x)

>>> print(repr(integral_steps((x**2 + 3)**2, x)))
RewriteRule(integrand=(x**2 + 3)**2, variable=x, rewritten=x**4 + 6*x**2 + 9,
substep=AddRule(integrand=x**4 + 6*x**2 + 9, variable=x, substeps=[PowerRule(integrand=x**4, variable=x, base=x, exp=4),
ConstantTimesRule(integrand=6*x**2, variable=x, constant=6, other=x**2),
ConstantRule(integrand=9, variable=x)])
```

8. Finally, if all the above fail, SymPy also uses a simplified version of the Risch algorithm, called the Risch-Norman algorithm. This algorithm is tried last because it is often the slowest to compute. This is implemented in `heurisch()` (page 655):

```python
sympy.integrals.heurisch.heurisch(f, x, rewrite=False, hints=None, mappings=None, retries=3, degree_offset=0, unnecessary_permutations=None, _try_heurisch=None)
```

Compute indefinite integral using heuristic Risch algorithm.

**Explanation**

This is a heuristic approach to indefinite integration in finite terms using the extended heuristic (parallel) Risch algorithm, based on Manuel Bronstein’s “Poor Man’s Integrator”.

The algorithm supports various classes of functions including transcendental elementary or special functions like Airy, Bessel, Whittaker and Lambert.

Note that this algorithm is not a decision procedure. If it isn’t able to compute the antiderivative for a given function, then this is not a proof that such a functions
does not exist. One should use recursive Risch algorithm in such case. It’s an open question if this algorithm can be made a full decision procedure.

This is an internal integrator procedure. You should use top level ‘integrate’ function in most cases, as this procedure needs some preprocessing steps and otherwise may fail.

**Specification**

heurisch(f, x, rewrite=False, hints=None)

**where**

- `f`: expression
- `x`: symbol
- `rewrite` -> force rewrite ‘f’ in terms of ‘tan’ and ‘tanh’
- `hints` -> a list of functions that may appear in anti-derivate
  - `hints = None` -> no suggestions at all
  - `hints = []` -> try to figure out
  - `hints = [f1, ..., fn]` -> we know better

**Examples**

```python
>>> from sympy import tan
>>> from sympy.integrals.heurisch import heurisch
>>> from sympy.abc import x, y

>>> heurisch(y*tan(x), x)
y*log(tan(x)**2 + 1)/2
```

See Manuel Bronstein’s “Poor Man’s Integrator”:

**References**

For more information on the implemented algorithm refer to:

[R542], [R543], [R544], [R545], [R546]

`sympy.integrals.heurisch.components(f, x)`

Returns a set of all functional components of the given expression which includes symbols, function applications and compositions and non-integer powers. Fractional powers are collected with minimal, positive exponents.
Examples

```python
>>> from sympy import cos, sin
>>> from sympy.abc import x
>>> from sympy.integrals.heurisch import components

>>> components(sin(x)*cos(x)**2, x)
{x, sin(x), cos(x)}
```

heurisch (page 655)

API reference

```python
sympy.integrals.integrals.integrate(f, var, ...)
```

Deprecated since version 1.6: Using integrate() with Poly (page 2453) is deprecated. Use Poly.integrate() (page 2473) instead. See Using integrate with Poly (page 228).

Explanation

Compute definite or indefinite integral of one or more variables using Risch-Norman algorithm and table lookup. This procedure is able to handle elementary algebraic and transcendental functions and also a huge class of special functions, including Airy, Bessel, Whittaker and Lambert.

var can be:

- a symbol – indefinite integration
- a tuple (symbol, a) - indefinite integration with result given with a replacing symbol
- a tuple (symbol, a, b) - definite integration

Several variables can be specified, in which case the result is multiple integration. (If var is omitted and the integrand is univariate, the indefinite integral in that variable will be performed.)

Indefinite integrals are returned without terms that are independent of the integration variables. (see examples)

Definite improper integrals often entail delicate convergence conditions. Pass conds='piecewise', 'separate' or 'none' to have these returned, respectively, as a Piecewise function, as a separate result (i.e. result will be a tuple), or not at all (default is 'piecewise').

Strategy

SymPy uses various approaches to definite integration. One method is to find an antiderivative for the integrand, and then use the fundamental theorem of calculus. Various functions are implemented to integrate polynomial, rational and trigonometric functions, and integrands containing DiracDelta terms.

SymPy also implements the part of the Risch algorithm, which is a decision procedure for integrating elementary functions, i.e., the algorithm can either find an elementary
antiderivative, or prove that one does not exist. There is also a (very successful, albeit somewhat slow) general implementation of the heuristic Risch algorithm. This algorithm will eventually be phased out as more of the full Risch algorithm is implemented. See the docstring of \texttt{Integral.\_eval\_integral()} for more details on computing the antiderivative using algebraic methods.

The option \texttt{risch=True} can be used to use only the (full) Risch algorithm. This is useful if you want to know if an elementary function has an elementary antiderivative. If the indefinite Integral returned by this function is an instance of \texttt{NonElementaryIntegral}, that means that the Risch algorithm has proven that integral to be non-elementary. Note that by default, additional methods (such as the Meijer G method outlined below) are tried on these integrals, as they may be expressible in terms of special functions, so if you only care about elementary answers, use \texttt{risch=True}. Also note that an unevaluated Integral returned by this function is not necessarily a \texttt{NonElementaryIntegral}, even with \texttt{risch=True}, as it may just be an indication that the particular part of the Risch algorithm needed to integrate that function is not yet implemented.

Another family of strategies comes from re-writing the integrand in terms of so-called Meijer G-functions. Indefinite integrals of a single G-function can always be computed, and the definite integral of a product of two G-functions can be computed from zero to infinity. Various strategies are implemented to rewrite integrands as G-functions, and use this information to compute integrals (see the \texttt{meijerint} module).

The option \texttt{manual=True} can be used to use only an algorithm that tries to mimic integration by hand. This algorithm does not handle as many integrands as the other algorithms implemented but may return results in a more familiar form. The \texttt{manualintegrate} module has functions that return the steps used (see the module docstring for more information).

In general, the algebraic methods work best for computing antiderivatives of (possibly complicated) combinations of elementary functions. The G-function methods work best for computing definite integrals from zero to infinity of moderately complicated combinations of special functions, or indefinite integrals of very simple combinations of special functions.

The strategy employed by the integration code is as follows:

- If computing a definite integral, and both limits are real, and at least one limit is +/-oo, try the G-function method of definite integration first.
- Try to find an antiderivative, using all available methods, ordered by performance (that is try fastest method first, slowest last; in particular polynomial integration is tried first, Meijer G-functions second to last, and heuristic Risch last).
- If still not successful, try G-functions irrespective of the limits.

The option \texttt{meijerg=True, False, None} can be used to, respectively: always use G-function methods and no others, never use G-function methods, or use all available methods (in order as described above). It defaults to None.
Examples

```python
>>> from sympy import integrate, log, exp, oo
>>> from sympy.abc import a, x, y

>>> integrate(x*y, x)
x**2*y/2

>>> integrate(log(x), x)
x*log(x) - x

>>> integrate(log(x), (x, 1, a))
a*log(a) - a + 1

>>> integrate(x)
x**2/2

Terms that are independent of x are dropped by indefinite integration:

```python
>>> from sympy import sqrt

```python
>>> integrate(sqrt(1 + x), (x, 0, x))
2*(x + 1)**(3/2)/3 - 2/3

>>> integrate(sqrt(1 + x), x)
2*(x + 1)**(3/2)/3

>>> integrate(x*y)
Traceback (most recent call last):
... ValueError: specify integration variables to integrate x*y
```

Note that `integrate(x)` syntax is meant only for convenience in interactive sessions and should be avoided in library code.

```python
>>> integrate(x**a*exp(-x), (x, 0, oo)) # same as conds='piecewise'
Piecewise((gamma(a + 1), re(a) > -1),
(Integral(x**a*exp(-x), (x, 0, oo)), True))
```

```python
>>> integrate(x**a*exp(-x), (x, 0, oo), conds='none')
gamma(a + 1)
```

```python
>>> integrate(x**a*exp(-x), (x, 0, oo), conds='separate')
(gamma(a + 1), re(a) > -1)
```

See also:
```
Integral (page 660), Integral.doit (page 662)
sympy.integrals.integrals.line_integrate(field, Curve, variables)
```

Compute the line integral.
Examples

```python
>>> from sympy import Curve, line_integrate, E, ln
>>> from sympy.abc import x, y, t
>>> C = Curve([E**t + 1, E**t - 1], (t, 0, ln(2)))
>>> line_integrate(x + y, C, [x, y])
3*sqrt(2)
```

See also:

- `sympy.integrals.integrals.integrate` (page 657), `Integral` (page 660)

The class `Integral` (page 660) represents an unevaluated integral and has some methods that help in the integration of an expression.

```python
class sympy.integrals.integrals.Integral(function, *symbols, **assumptions)

Represents unevaluated integral.
```

- `is_commutative`
  Returns whether all the free symbols in the integral are commutative.

- `as_sum(n=None, method='midpoint', evaluate=True)`
  Approximates a definite integral by a sum.

  **Parameters**
  - `n`: The number of subintervals to use, optional.
  - `evaluate`: bool
    If False, returns an unevaluated Sum expression. The default is True, evaluate the sum.

**Notes**

These methods of approximate integration are described in [1].

Examples

```python
>>> from sympy import Integral, sin, sqrt
>>> from sympy.abc import x, n
>>> e = Integral(sin(x), (x, 3, 7))
>>> e
Integral(sin(x), (x, 3, 7))
```

For demonstration purposes, this interval will only be split into 2 regions, bounded by [3, 5] and [5, 7].

The left-hand rule uses function evaluations at the left of each interval:
The midpoint rule uses evaluations at the center of each interval:

```python
>>> e.as_sum(2, 'midpoint')
2*sin(4) + 2*sin(6)
```

The right-hand rule uses function evaluations at the right of each interval:

```python
>>> e.as_sum(2, 'right')
2*sin(5) + 2*sin(7)
```

The trapezoid rule uses function evaluations on both sides of the intervals. This is equivalent to taking the average of the left and right hand rule results:

```python
>>> e.as_sum(2, 'trapezoid')
2*sin(5) + sin(3) + sin(7)
```

```python
>>> (e.as_sum(2, 'left') + e.as_sum(2, 'right'))/2 == _
True
```

Here, the discontinuity at $x = 0$ can be avoided by using the midpoint or right-hand method:

```python
>>> e = Integral(1/sqrt(x), (x, 0, 1))
>>> e.as_sum(5, 'right').expand()
8/3 + 4/n + 4/(3*n**2)
```

This shows that the midpoint rule is more accurate, as its error term decays as the square of $n$:

```python
>>> e.as_sum(method='midpoint').expand()
8/3 - 2/(3*_n**2)
```

A symbolic sum is returned with `evaluate=False`:

```python
>>> e.as_sum(n, 'midpoint', evaluate=False)
2*Sum((2*_k/n - 1/n)**2, (_k, 1, n))/n
```
See also:

*Integral.doit* (page 662)

Perform the integration using any hints

**References**

[R547]

*doit(**hints**)*

Perform the integration using any hints given.

**Examples**

```python
>>> from sympy import Piecewise, S
>>> from sympy.abc import x, t
>>> p = x**2 + Piecewise((0, x/t < 0), (1, True))
>>> p.integrate((t, S(4)/5, 1), (x, -1, 1))
1/3
```

See also:

*sympy.integrals.trigonometry.trigintegrate* (page 648), *sympy.integrals.heurisch.heurisch* (page 655), *sympy.integrals.rationaltools.ratint* (page 646)

*as_sum* (page 660)

Approximate the integral using a sum

**Property free_symbols**

This method returns the symbols that will exist when the integral is evaluated. This is useful if one is trying to determine whether an integral depends on a certain symbol or not.

**Examples**

```python
>>> from sympy import Integral
>>> from sympy.abc import x, y
>>> Integral(x, (x, y, 1)).free_symbols
{y}
```

See also:

*principal_value(**kwargs**)*

Compute the Cauchy Principal Value of the definite integral of a real function in the given interval on the real axis.
**Explanation**

In mathematics, the Cauchy principal value, is a method for assigning values to certain improper integrals which would otherwise be undefined.

**Examples**

```python
>>> from sympy import Integral, oo
>>> from sympy.abc import x
>>> Integral(x+1, (x, -oo, oo)).principal_value()
oo
>>> f = 1 / (x**3)
>>> Integral(f, (x, -oo, oo)).principal_value()
0
>>> Integral(f, (x, -10, 10)).principal_value()
0
>>> Integral(f, (x, -10, oo)).principal_value() + Integral(f, (x, -oo, -10)).principal_value()
0
```

**References**

[R548], [R549]

**transform**(x, u)

Performs a change of variables from x to u using the relationship given by x and u which will define the transformations f and F (which are inverses of each other) as follows:

1) If x is a Symbol (which is a variable of integration) then u will be interpreted as some function, f(u), with inverse F(u). This, in effect, just makes the substitution of x with f(x).

2) If u is a Symbol then x will be interpreted as some function, F(x), with inverse f(u). This is commonly referred to as u-substitution.

Once f and F have been identified, the transformation is made as follows:

\[
\int_{a}^{b} x \, dx \rightarrow \int_{F(a)}^{F(b)} f(x) \frac{d}{dx}
\]

where \(F(x)\) is the inverse of \(f(x)\) and the limits and integrand have been corrected so as to retain the same value after integration.
Notes

The mappings, F(x) or f(u), must lead to a unique integral. Linear or rational linear expression, 2*x, 1/x and sqrt(x), will always work; quadratic expressions like x**2 - 1 are acceptable as long as the resulting integrand does not depend on the sign of the solutions (see examples).

The integral will be returned unchanged if x is not a variable of integration. x must be (or contain) only one of the integration variables. If u has more than one free symbol then it should be sent as a tuple (u, uvar) where uvar identifies which variable is replacing the integration variable. XXX can it contain another integration variable?

Examples

>>> from sympy.abc import a, x, u
>>> from sympy import Integral, cos, sqrt

>>> i = Integral(x*cos(x**2 - 1), (x, 0, 1))
transform can change the variable of integration

>>> i.transform(x, u)
Integral(u*cos(u**2 - 1), (u, 0, 1))
transform can perform u-substitution as long as a unique integrand is obtained:

>>> i.transform(x**2 - 1, u)
Integral(cos(u)/2, (u, -1, 0))

This attempt fails because x = +/-sqrt(u+1) and the sign does not cancel out of the integrand:

>>> Integral(cos(x**2 - 1), (x, 0, 1)).transform(x**2 - 1, u)
Traceback (most recent call last):
...
ValueError:
The mapping between F(x) and f(u) did not give a unique integrand.

transform can do a substitution. Here, the previous result is transformed back into the original expression using “u-substitution”:

>>> ui = _
>>> _.transform(sqrt(u + 1), x) == i
True

We can accomplish the same with a regular substitution:

>>> ui.transform(u, x**2 - 1) == i
True

If the x does not contain a symbol of integration then the integral will be returned unchanged. Integral i does not have an integration variable a so no change is made:
When \( u \) has more than one free symbol the symbol that is replacing \( x \) must be identified by passing \( u \) as a tuple:

\[
\text{Integral}(x, (x, 0, 1)).\text{transform}(x, (u + a, u))
\]
\[
\text{Integral}(a + u, (u, -a, 1 - a))
\]

\[
\text{Integral}(x, (x, 0, 1)).\text{transform}(x, (u + a, a))
\]
\[
\text{Integral}(a + u, (a, -u, 1 - u))
\]

- \textit{sympy.concrete.expr_with_limits.ExprWithLimits.variables} (page 667)
  Lists the integration variables
- \textit{as_dummy} (page 980)
  Replace integration variables with dummy ones

\textit{Integral} (page 660) subclasses from \textit{ExprWithLimits} (page 665), which is a common superclass of \textit{Integral} (page 660) and \textit{Sum} (page 952).

class \textit{sympy.concrete.expr_with_limits.ExprWithLimits}(function, *symbols, **assumptions)

property bound_symbols
Return only variables that are dummy variables.

Examples

\[
\text{Integral}(x**i, (i, 1, 3), (j, 2), k).\text{bound_symbols} = [i, j]
\]

See also:

- \textit{function} (page 666), \textit{limits} (page 667), \textit{free_symbols} (page 665)
- \textit{as_dummy} (page 980)
  Rename dummy variables
- \textit{sympy.integrals.integrals.Integral.transform} (page 663)
  Perform mapping on the dummy variable

property free_symbols
This method returns the symbols in the object, excluding those that take on a specific value (i.e. the dummy symbols).

5.8. Topics
Examples

```python
>>> from sympy import Sum
>>> from sympy.abc import x, y
>>> Sum(x, (x, y, 1)).free_symbols {y}
```

**property function**
Return the function applied across limits.

```python
>>> from sympy import Integral
>>> from sympy.abc import x
>>> Integral(x**2, (x,)).function
x**2
```

**See also:**
limits (page 667), variables (page 667), free_symbols (page 665)

**property has_finite_limits**
Returns True if the limits are known to be finite, either by the explicit bounds, assumptions on the bounds, or assumptions on the variables. False if known to be infinite, based on the bounds. None if not enough information is available to determine.

```python
>>> from sympy import Sum, Integral, Product, oo, Symbol
>>> x = Symbol('x')
>>> Sum(x, (x, 1, 8)).has_finite_limits
True

>>> Integral(x, (x, 1, oo)).has_finite_limits
False

>>> M = Symbol('M')
>>> Sum(x, (x, 1, M)).has_finite_limits

>>> N = Symbol('N', integer=True)
>>> Product(x, (x, 1, N)).has_finite_limits
True
```

**See also:**
has_reversed_limits (page 666)

**property has_reversed_limits**
Returns True if the limits are known to be in reversed order, either by the explicit bounds, assumptions on the bounds, or assumptions on the variables. False if known
to be in normal order, based on the bounds. None if not enough information is available to determine.

**Examples**

```python
>>> from sympy import Sum, Integral, Product, oo, Symbol
>>> x = Symbol('x')
>>> Sum(x, (x, 8, 1)).has_reversed_limits
True

>>> Sum(x, (x, 1, oo)).has_reversed_limits
False

>>> M = Symbol('M')
>>> Integral(x, (x, 1, M)).has_reversed_limits

>>> N = Symbol('N', integer=True, positive=True)
>>> Sum(x, (x, 1, N)).has_reversed_limits
False

>>> Product(x, (x, 2, N)).has_reversed_limits

>>> Product(x, (x, 2, N)).subs(N, N + 2).has_reversed_limits
False
```

See also:

- `sympy.concrete.expr_with_intlimits.ExprWithIntLimits. has_empty_sequence` (page 964)

**property is_number**

Return True if the Sum has no free symbols, else False.

**property limits**

Return the limits of expression.

**Examples**

```python
>>> from sympy import Integral
>>> from sympy.abc import x, i

>>> Integral(x**i, (i, 1, 3)).limits
((i, 1, 3),)
```

See also:

- `function` (page 666), `variables` (page 667), `free_symbols` (page 665)

**property variables**

Return a list of the limit variables.
>>> from sympy import Sum
>>> from sympy.abc import x, i
>>> Sum(x**i, (i, 1, 3)).variables
[i]

See also:
function (page 666), limits (page 667), free_symbols (page 665)

   Perform mapping on the dummy variable

TODO and Bugs

There are still lots of functions that SymPy does not know how to integrate. For bugs related to this module, see https://github.com/sympy/sympy/issues?q=is%3Aissue+is%3Aopen+labelintegrals

Numeric Integrals

SymPy has functions to calculate points and weights for Gaussian quadrature of any order and any precision:
sympy.integrals.quadrature.gauss_legendre(n, n_digits)
   Computes the Gauss-Legendre quadrature [R550] points and weights.

   Parameters
      n :
         The order of quadrature.

      n_digits :
         Number of significant digits of the points and weights to return.

   Returns
      (x, w) : the x and w are lists of points and weights as Floats.
      The points \( x_i \) and weights \( w_i \) are returned as \( (x, w) \) tuple of lists.

   Explanation

The Gauss-Legendre quadrature approximates the integral:

\[
\int_{-1}^{1} f(x) \, dx \approx \sum_{i=1}^{n} w_i f(x_i)
\]

The nodes \( x_i \) of an order \( n \) quadrature rule are the roots of \( P_n \) and the weights \( w_i \) are given by:

\[
w_i = \frac{2}{(1 - x_i^2)(P'_n(x_i))^2}
\]
Examples

```python
>>> from sympy.integrals.quadrature import gauss_legendre
>>> x, w = gauss_legendre(3, 5)
>>> x
[-0.7746, 0, 0.7746]
>>> w
[0.55556, 0.88889, 0.55556]
>>> x, w = gauss_legendre(4, 5)
>>> x
[-0.86114, -0.33998, 0.33998, 0.86114]
>>> w
[0.34785, 0.65215, 0.65215, 0.34785]
```

- `gauss_lobatto` (page 675)

References

[R550], [R551]

```python
from sympy.integrals.quadrature import gauss_legendre
```

Computes the Gauss-Laguerre quadrature [R552] points and weights.

Parameters

- **n**:
  - The order of quadrature.

- **n_digits**:
  - Number of significant digits of the points and weights to return.

Returns

- **(x, w)**: The x and w are lists of points and weights as Floats.
  - The points \(x_i\) and weights \(w_i\) are returned as \((x, w)\) tuple of lists.

Explanation

The Gauss-Laguerre quadrature approximates the integral:

\[
\int_0^\infty e^{-x} f(x) \, dx \approx \sum_{i=1}^{n} w_i f(x_i)
\]

The nodes \(x_i\) of an order \(n\) quadrature rule are the roots of \(L_n\) and the weights \(w_i\) are given by:

\[
w_i = \frac{x_i}{(n + 1)^2 (L_{n+1}(x_i))^2}
\]
Examples

```python
>>> from sympy.integrals.quadrature import gauss_laguerre
>>> x, w = gauss_laguerre(3, 5)
>>> x
[0.41577, 2.2943, 6.2899]
>>> w
[0.71109, 0.27852, 0.010389]
>>> x, w = gauss_laguerre(6, 5)
>>> x
[0.22285, 1.1889, 2.9927, 5.7751, 9.8375, 15.983]
>>> w
[0.45896, 0.417, 0.11337, 0.010399, 0.00026102, 8.9855e-7]
```

**sympy.integrals.quadrature.gauss_hermite**(n, n_digits)

Computes the Gauss-Hermite quadrature [R554] points and weights.

**Parameters**

- **n**:
  
  The order of quadrature.

- **n_digits**:
  
  Number of significant digits of the points and weights to return.

**Returns**

- **(x, w)**: The x and w are lists of points and weights as Floats.

  The points $x_i$ and weights $w_i$ are returned as $(x, w)$ tuple of lists.

**Explanation**

The Gauss-Hermite quadrature approximates the integral:

$$
\int_{-\infty}^{\infty} e^{-x^2} f(x) \, dx \approx \sum_{i=1}^{n} w_i f(x_i)
$$

The nodes $x_i$ of an order $n$ quadrature rule are the roots of $H_n$ and the weights $w_i$ are given by:

$$
w_i = \frac{2^{n-1}n!\sqrt{\pi}}{n^2 (H_{n-1}(x_i))^2}
$$
Examples

```python
>>> from sympy.integrals.quadrature import gauss_hermite
>>> x, w = gauss_hermite(3, 5)
>>> x
[-1.2247, 0, 1.2247]
>>> w
[0.29541, 1.1816, 0.29541]

>>> x, w = gauss_hermite(6, 5)
>>> x
[-2.3506, -1.3358, -0.43608, 0.43608, 1.3358, 2.3506]
>>> w
[0.00453, 0.15707, 0.72463, 0.72463, 0.15707, 0.00453]
```

```python
sympy.integrals.quadrature.gauss_gen_laguerre(n, alpha, n_digits)
```

Computes the generalized Gauss-Laguerre quadrature [R557] points and weights.

**Parameters**

- **n**: The order of quadrature.
- **alpha**: The exponent of the singularity, $\alpha > -1$.
- **n_digits**: Number of significant digits of the points and weights to return.

**Returns**

- **(x, w)**: the x and w are lists of points and weights as Floats.
  - The points $x_i$ and weights $w_i$ are returned as $(x, w)$ tuple of lists.

**Explanation**

The generalized Gauss-Laguerre quadrature approximates the integral:

$$\int_0^\infty x^\alpha e^{-x} f(x) \, dx \approx \sum_{i=1}^{n} w_i f(x_i)$$

The nodes $x_i$ of an order $n$ quadrature rule are the roots of $L_n^\alpha$ and the weights $w_i$ are given by:

$$w_i = \frac{\Gamma(\alpha + n)}{n! \Gamma(n) L_{n-1}^\alpha(x_i) L_{n-1}^{\alpha+1}(x_i)}$$
Examples

```python
>>> from sympy import S
>>> from sympy.integrals.quadrature import gauss_gen_laguerre
>>> x, w = gauss_gen_laguerre(3, -S.Half, 5)
>>> x
[0.19016, 1.7845, 5.5253]
>>> w
[1.4493, 0.31413, 0.00906]

>>> x, w = gauss_gen_laguerre(4, 3*S.Half, 5)
>>> x
[0.97851, 2.9904, 6.3193, 11.712]
>>> w
[0.53087, 0.67721, 0.11895, 0.0023152]
```

sympy.integrals.quadrature.**gauss_chebyshev_t**(n, n_digits)
Computes the Gauss-Chebyshev quadrature [R559] points and weights of the first kind.

**Parameters**

- **n** :
  The order of quadrature.

- **n_digits** :
  Number of significant digits of the points and weights to return.

**Returns**

- **(x, w)** : the x and w are lists of points and weights as Floats.
  The points $x_i$ and weights $w_i$ are returned as $(x, w)$ tuple of lists.

**Explanation**

The Gauss-Chebyshev quadrature of the first kind approximates the integral:

$$
\int_{-1}^{1} \frac{1}{\sqrt{1 - x^2}} f(x) \, dx \approx \sum_{i=1}^{n} w_i f(x_i)
$$

The nodes $x_i$ of an order $n$ quadrature rule are the roots of $T_n$ and the weights $w_i$ are given by:

$$
w_i = \frac{\pi}{n}
$$
Examples

```python
>>> from sympy.integrals.quadrature import gauss_chebyshev_t
>>> x, w = gauss_chebyshev_t(3, 5)
>>> x
[0.86602, 0, -0.86602]
>>> w
[1.0472, 1.0472, 1.0472]

>>> x, w = gauss_chebyshev_t(6, 5)
>>> x
[0.96593, 0.70711, 0.25882, -0.25882, -0.70711, -0.96593]
>>> w
[0.5236, 0.5236, 0.5236, 0.5236, 0.5236, 0.5236]
```

`sympy.integrals.quadrature.gauss_chebyshev_u(n, n_digits)`

Computes the Gauss-Chebyshev quadrature [R561] points and weights of the second kind.

**Parameters**

- `n`: the order of quadrature
- `n_digits`: number of significant digits of the points and weights to return

**Returns**

- `(x, w)`: the `x` and `w` are lists of points and weights as Floats.

  The points `x_i` and weights `w_i` are returned as `(x, w)` tuple of lists.

**Explanation**

The Gauss-Chebyshev quadrature of the second kind approximates the integral:

\[
\int_{-1}^{1} \sqrt{1-x^2} f(x) \, dx \approx \sum_{i=1}^{n} w_i f(x_i)
\]

The nodes `x_i` of an order `n` quadrature rule are the roots of `U_n` and the weights `w_i` are given by:

\[
w_i = \frac{\pi}{n+1} \sin^2 \left( \frac{i}{n+1} \pi \right)
\]
Examples

```python
>>> from sympy.integrals.quadrature import gauss_chebyshev_u
>>> x, w = gauss_chebyshev_u(3, 5)
>>> x
[0.70711, 0, -0.70711]
>>> w
[0.3927, 0.7854, 0.3927]

>>> x, w = gauss_chebyshev_u(6, 5)
>>> x
[0.90097, 0.62349, 0.22252, -0.22252, -0.62349, -0.90097]
>>> w
[0.084489, 0.27433, 0.42658, 0.42658, 0.27433, 0.084489]
```

References

[R561], [R562]

sympy.integrals.quadrature.gauss_jacobi(n, alpha, beta, n_digits)

Computes the Gauss-Jacobi quadrature [R563] points and weights.

**Parameters**

- `n`: the order of quadrature
- `alpha`: the first parameter of the Jacobi Polynomial, $\alpha > -1$
- `beta`: the second parameter of the Jacobi Polynomial, $\beta > -1$
- `n_digits`: number of significant digits of the points and weights to return

**Returns**

- `(x, w)`: the x and w are lists of points and weights as Floats.
  The points $x_i$ and weights $w_i$ are returned as $(x, w)$ tuple of lists.

**Explanation**

The Gauss-Jacobi quadrature of the first kind approximates the integral:

$$
\int_{-1}^{1} (1-x)^{\alpha}(1+x)^{\beta} f(x) \, dx \approx \sum_{i=1}^{n} w_i f(x_i)
$$

The nodes $x_i$ of an order $n$ quadrature rule are the roots of $P_n^{(\alpha,\beta)}$ and the weights $w_i$ are given by:

$$
w_i = -\frac{2n + \alpha + \beta + 2 \Gamma(n + \alpha + 1)\Gamma(n + \beta + 1)}{n + \alpha + \beta + 1 \Gamma(n + \alpha + \beta + 1)(n + 1)!} \frac{2^{\alpha+\beta}}{P_n'(x_i)P_n^{(\alpha,\beta)}(x_i)}
$$
Examples

```python
>>> from sympy import S
>>> from sympy.integrals.quadrature import gauss_jacobi
>>> x, w = gauss_jacobi(3, S.Half, -S.Half, 5)
>>> x
[-0.90097, -0.22252, 0.62349]
>>> w
[1.7063, 1.0973, 0.33795]
```

```python
>>> x, w = gauss_jacobi(6, 1, 1, 5)
>>> x
[-0.87174, -0.5917, -0.2093, 0.2093, 0.5917, 0.87174]
>>> w
[0.050584, 0.22169, 0.39439, 0.39439, 0.22169, 0.050584]
```

- `gauss_lobatto` (page 675)

References

[R563], [R564], [R565]

```python
sympy.integrals.quadrature.gauss_lobatto(n, n_digits)
```

Computes the Gauss-Lobatto quadrature [R566] points and weights.

**Parameters**
- `n`: the order of quadrature
- `n_digits`: number of significant digits of the points and weights to return

**Returns**
- `(x, w)`: the `x` and `w` are lists of points and weights as Floats.
  The points $x_i$ and weights $w_i$ are returned as `(x, w)` tuple of lists.

**Explanation**

The Gauss-Lobatto quadrature approximates the integral:

$$
\int_{-1}^{1} f(x) \, dx \approx \sum_{i=1}^{n} w_i f(x_i)
$$

The nodes $x_i$ of an order $n$ quadrature rule are the roots of $P_{n-1}(n-1)$ and the weights $w_i$ are given by:

$$
\begin{align*}
    w_i &= \frac{2}{n(n-1)} \frac{1}{[P_{n-1}(x_i)]^2}, \quad x \neq \pm 1 \\
    w_i &= \frac{2}{n(n-1)}, \quad x = \pm 1
\end{align*}
$$
Examples

```python
>>> from sympy.integrals.quadrature import gauss_lobatto
>>> x, w = gauss_lobatto(3, 5)
>>> x
[-1, 0, 1]
>>> w
[0.33333, 1.3333, 0.33333]
>>> x, w = gauss_lobatto(4, 5)
>>> x
[-1, -0.44721, 0.44721, 1]
>>> w
[0.16667, 0.83333, 0.83333, 0.16667]
```

Integration over Polytopes

The `intpoly` module in SymPy implements methods to calculate the integral of a polynomial over 2/3-Polytopes. Uses evaluation techniques as described in Chin et al. (2015) [1].

The input for 2-Polytope or Polygon uses the already existing `Polygon` data structure in SymPy. See `sympy.geometry.polygon` (page 2348) for how to create a polygon.

For the 3-Polytope or Polyhedron, the most economical representation is to specify a list of vertices and then to provide each constituting face(`Polygon`) as a list of vertex indices.

For example, consider the unit cube. Here is how it would be represented.

```python
unit_cube = [[(0, 0, 0), (0, 0, 1), (0, 1, 0), (0, 1, 1), (1, 0, 0), (1, 0, 1),
             (1, 1, 0), (1, 1, 1)],
            [3, 7, 6, 2], [1, 5, 7, 3], [5, 4, 6, 7], [0, 4, 5, 1], [2, 0, 1, 3], [2, 6, 4, 0]]
```

Here, the first sublist is the list of vertices. The other smaller lists such as [3, 7, 6, 2] represent a 2D face of the polyhedra with vertices having index 3, 7, 6 and 2 in the first sublist(in that order).

Principal method in this module is `polytope_integrate()` (page 678)

- `polytope_integrate(Polygon((0, 0), (0, 1), (1, 0)), x)` returns the integral of $x$ over the triangle with vertices (0,0), (0,1) and (1,0)
- `polytope_integrate(unit_cube, x + y + z)` returns the integral of $x + y + z$ over the unit cube.

Examples

For 2D Polygons

Single Polynomial:

```python
from sympy.integrals.intpoly import *
init_printing(use_unicode=False, wrap_line=False)
polytope_integrate(Polygon((0, 0), (0, 1), (1, 0)), x)
1/6
polytope_integrate(Polygon((0, 0), (0, 1), (1, 0)), x + x*y + y**2)
7/24
```

List of specified polynomials:

```python
polytope_integrate(Polygon((0, 0), (0, 1), (1, 0)), [3, x*y + y**2, x**4], max_degree=4)
{3: 3/2, x : 1/30, x*y + y : 1/8}
polytope_integrate(Polygon((0, 0), (0, 1), (1, 0)), [1.125, x, x**2, 6.89*x**3, x*y + y**2, x**4], max_degree=4)
{1.125: 9/16, x: 1/6, x : 1/12, x*y + y : 1/8}
```

Computing all monomials up to a maximum degree:

```python
polytope_integrate(Polygon((0, 0), (0, 1), (1, 0)), max_degree=3)
{0: 0, 1: 1/2, x: 1/6, x: 1/12, x: 1/20, y: 1/6, y: 1/12, y: 1/20, x*y: 1/24, x*y: 1/60, x*y: 1/60}
```

For 3-Polytopes/Polyhedra

Single Polynomial:

```python
from sympy.integrals.intpoly import *
cube = [(0, 0, 0), (0, 0, 5), (0, 5, 0), (0, 5, 5), (5, 0, 0), (5, 0, 5), (5, 5, 0), (5, 5, 5), [2, 6, 7, 3], [3, 7, 5, 1], [7, 6, 4, 5], [1, 5, 4, 0], [3, 1, 0, 2], [0, 4, 6, 2]]
polytope_integrate(cube, x**2 + y**2 + z**2 + x*y + y*z + x*z)
-21875/4
```

(continues on next page)
octahedron = [[[S(-1) / sqrt(2), 0, 0], (0, S(1) / sqrt(2), 0), (0, 0, S(-1) / sqrt(2))],
               [(0, 0, S(1) / sqrt(2)), (0, 0, S(1) / sqrt(2)), (S(1) / sqrt(2), 0, 0)],
               [(3, 4, 5), [3, 5, 1], [3, 1, 0], [3, 0, 4], [4, 0, 2], [4, 0, -2], 5], [2, 0, 1], [5, 2, 1]]

>>> polytope_integrate(octahedron, x**2 + y**2 + z**2 + x*y + y*z + x*z)

\[\frac{1}{2} - \frac{1}{20}\]

List of specified polynomials:

```python
>>> polytope_integrate(Polygon((0, 0), (0, 1), (1, 0), [3, x*y + y**2, x**4], max_degree=4)
{3: 3/2, x: 1/30, x*y + y: 1/8}
>>> polytope_integrate(Polygon((0, 0), (0, 1), (1, 0), [1.125, x, x**2, 6.89*x**3, x*y + y**2, x**4], max_degree=4)
{1.125: 9/16, x: 1/6, x: 1/12, 6.89*x: ----, x: 1/30, x**y + y: 1/8} 2000
```

Computing all monomials up to a maximum degree:

```python
>>> polytope_integrate(Polygon((0, 0), (0, 1), (1, 0), max_degree=3)
{0: 0, 1: 1/2, x: 1/6, x: 1/12, x: 1/20, y: 1/6, y: 1/12, y: 1/20, x*y: 1/24, x*y: 1/60, x*y: 1/60}
```

**API reference**

```python
sympy.integrals.intpoly.polytope_integrate(poly, expr=None, *, clockwise=False, max_degree=None)
```

Integrates polynomials over 2/3-Polytopes.

**Parameters**

- `poly` : The input Polygon.
- `expr` : The input polynomial.
- `clockwise` : Binary value to sort input points of 2-Polytope clockwise.(Optional)
- `max_degree` : The maximum degree of any monomial of the input polynomial.(Optional)
Explanation

This function accepts the polytope in `poly` and the function in `expr` (uni/bi/trivariate polynomials are implemented) and returns the exact integral of `expr` over `poly`.

Examples

```python
>>> from sympy.abc import x, y
>>> from sympy import Point, Polygon
>>> from sympy.integrals.intpoly import polytope_integrate
>>> polygon = Polygon(Point(0, 0), Point(0, 1), Point(1, 1), Point(1, 0))
>>> polys = [1, x, y, x*y, x**2*y, x*y**2]
>>> expr = x*y
>>> polytope_integrate(polygon, expr)
1/4
>>> polytope_integrate(polygon, polys, max_degree=3)
{1: 1, x: 1/2, y: 1/2, x*y: 1/4, x*y**2: 1/6, x**2*y: 1/6}
```

Series

The series module implements series expansions as a function and many related functions.

Contents

Series Expansions

Limits

The main purpose of this module is the computation of limits. sympy.series.limits.limit(e, z, z0, dir='+')

Computes the limit of `e(z)` at the point `z0`.

Parameters

- `e` : expression, the limit of which is to be taken
- `z` : symbol representing the variable in the limit.
  Other symbols are treated as constants. Multivariate limits are not supported.
- `z0` : the value toward which `z` tends. Can be any expression, including oo and -oo.
- `dir` : string, optional (default: “+”)
  The limit is bi-directional if `dir=’+-’`, from the right (`z->z0+`) if `dir=’+’`, and from the left (`z->z0-`) if `dir=’-’`. For infinite `z0` (oo or -oo), the `dir` argument is determined from the direction of the infinity (i.e., `dir=’-’` for oo).
Examples

```python
>>> from sympy import limit, sin, oo
>>> from sympy.abc import x
>>> limit(sin(x)/x, x, 0)
1
>>> limit(1/x, x, 0)  # default dir='+'
oo
>>> limit(1/x, x, 0, dir='-')
-oo
>>> limit(1/x, x, 0, dir='+-')
zoo
>>> limit(1/x, x, oo)
0
```

Notes

First we try some heuristics for easy and frequent cases like “x”, “1/x”, “x**2” and similar, so that it’s fast. For all other cases, we use the Gruntz algorithm (see the gruntz() function).

See also:

`limit_seq` (page 718)
returns the limit of a sequence.

class sympy.series.limits.Limit(e, z, z0, dir='+')
Represents an unevaluated limit.

Examples

```python
>>> from sympy import limit, sin
>>> from sympy.abc import x
>>> Limit(sin(x)/x, x, 0)
Limit(sin(x)/x, x, 0, dir='+')
>>> Limit(1/x, x, 0, dir='-')
Limit(1/x, x, 0, dir='-')
```

doit(**hints)
Evaluates the limit.

Parameters

- **deep**: bool, optional (default: True)
  Invoke the doit method of the expressions involved before taking the limit.

- **hints**: optional keyword arguments
  To be passed to doit methods; only used if deep is True.

As is explained above, the workhorse for limit computations is the function gruntz() which implements Gruntz’ algorithm for computing limits.
The Gruntz Algorithm

This section explains the basics of the algorithm used for computing limits. Most of the time the limit() function should just work. However it is still useful to keep in mind how it is implemented in case something does not work as expected.

First we define an ordering on functions. Suppose \( f(x) \) and \( g(x) \) are two real-valued functions such that \( \lim_{x \to \infty} f(x) = \infty \) and similarly \( \lim_{x \to \infty} g(x) = \infty \). We shall say that \( f(x) \) dominates \( g(x) \), written \( f(x) \succ g(x) \), if for all \( a, b \in \mathbb{R}_{>0} \) we have \( \lim_{x \to \infty} \frac{f(x)^a}{g(x)^b} = \infty \). We also say that \( f(x) \) and \( g(x) \) are of the same comparability class if neither \( f(x) \succ g(x) \) nor \( g(x) \succ f(x) \) and shall denote it as \( f(x) \sim g(x) \).

Note that whenever \( a, b \in \mathbb{R}_{>0} \) then \( af(x)^b = f(x) \), and we shall use this to extend the definition of \( \succ \) to all functions which tend to 0 or \( \pm \infty \) as \( x \to \infty \). Thus we declare that \( f(x) \sim 1/f(x) \) and \( f(x) \sim -f(x) \).

It is easy to show the following examples:

- \( e^x \succ x^m \)
- \( e^{x^2} \succ e^{mx} \)
- \( e^{e^x} \succ e^{x^m} \)
- \( x^m \succ x^n \)
- \( e^{x+1/2} \succ e^{x+\log x} \succ e^x \).

From the above definition, it is possible to prove the following property:

Suppose \( \omega, g_1, g_2, \ldots \) are functions of \( x \), \( \lim_{x \to \infty} \omega = 0 \) and \( \omega \succ g_i \) for all \( i \). Let \( c_1, c_2, \ldots \in \mathbb{R} \) with \( c_1 < c_2 < \cdots \).

Then \( \lim_{x \to \infty} \sum_i g_i \omega^{c_i} = \lim_{x \to \infty} g_1 \omega^{c_1} \).

For \( g_1 = g \) and \( \omega \) as above we also have the following easy result:

- \( \lim_{x \to \infty} g \omega^c = 0 \) for \( c > 0 \)
- \( \lim_{x \to \infty} g \omega^c = \pm \infty \) for \( c < 0 \), where the sign is determined by the (eventual) sign of \( g \)
- \( \lim_{x \to \infty} g \omega^0 = \lim_{x \to \infty} g \).

Using these results yields the following strategy for computing \( \lim_{x \to \infty} f(x) \):

1. Find the set of most rapidly varying subexpressions (MRV set) of \( f(x) \). That is, from the set of all subexpressions of \( f(x) \), find the elements that are maximal under the relation \( \succ \).
2. Choose a function \( \omega \) that is in the same comparability class as the elements in the MRV set, such that \( \lim_{x \to \infty} \omega = 0 \).
3. Expand \( f(x) \) as a series in \( \omega \) in such a way that the antecedents of the above theorem are satisfied.
4. Apply the theorem and conclude the computation of \( \lim_{x \to \infty} f(x) \), possibly by recursively working on \( g_1(x) \).
Notes

This exposition glossed over several details. Many are described in the file gruntz.py, and all can be found in Gruntz’ very readable thesis. The most important points that have not been explained are:

1. Given \( f(x) \) and \( g(x) \), how do we determine if \( f(x) \succ g(x) \), \( g(x) \succ f(x) \) or \( g(x) \sim f(x) \)?
2. How do we find the MRV set of an expression?
3. How do we compute series expansions?
4. Why does the algorithm terminate?

If you are interested, be sure to take a look at Gruntz Thesis.

Reference

```python
sympy.series.gruntz.gruntz(e, z, z0, dir='+')
```

Compute the limit of \( e(z) \) at the point \( z_0 \) using the Gruntz algorithm.

**Explanation**

\( z_0 \) can be any expression, including oo and -oo.

For \( \text{dir} = "+" \) (default) it calculates the limit from the right \( (z \rightarrow z_0^+) \) and for \( \text{dir} = "-" \) the limit from the left \( (z \rightarrow z_0^-) \). For infinite \( z_0 \) (oo or -oo), the dir argument does not matter.

This algorithm is fully described in the module docstring in the gruntz.py file. It relies heavily on the series expansion. Most frequently, gruntz() is only used if the faster limit() function (which uses heuristics) fails.

```python
sympy.series.gruntz.compare(a, b, x)
```

Returns "<" if \( a < b \), "=" for \( a == b \), "=" for \( a > b \)

```python
sympy.series.gruntz.rewrite(e, Omega, x, wsym)
```

\( e(x) \) ... the function Omega ... the mrv set wsym ... the symbol which is going to be used for w

Returns the rewritten \( e \) in terms of \( w \) and \( \log(w) \). See test_rewrite1() for examples and correct results.

```python
sympy.series.gruntz.build_expression_tree(Omega, rewrites)
```

Helper function for rewrite.

We need to sort Omega (mrv set) so that we replace an expression before we replace any expression in terms of which it has to be rewritten:

```
    e1 ---> e2 ---> e3
         \   
         \  
         -> e4
```

Here we can do \( e_1, e_2, e_3, e_4 \) or \( e_1, e_2, e_4, e_3 \). To do this we assemble the nodes into a tree, and sort them by height.

This function builds the tree, rewrites then sorts the nodes.
sympy.series.gruntz.mrv_leadterm(e, x)

Returns \( (c_0, e_0) \) for \( e \).

sympy.series.gruntz.calculate_series(e, x, logx=None)

Calculates at least one term of the series of \( e \) in \( x \).

This is a place that fails most often, so it is in its own function.

sympy.series.gruntz.limitinf(e, x)

Limit \( e(x) \) for \( x \to \infty \).

sympy.series.gruntz.sign(e, x)

Returns a sign of an expression \( e(x) \) for \( x \to \infty \).

\[
\begin{align*}
& e > 0 \text{ for } x \text{ sufficiently large } \ldots \ 1 \\
& e = 0 \text{ for } x \text{ sufficiently large } \ldots \ 0 \\
& e < 0 \text{ for } x \text{ sufficiently large } \ldots \ -1
\end{align*}
\]

The result of this function is currently undefined if \( e \) changes sign arbitrarily often for arbitrarily large \( x \) (e.g. \( \sin(x) \)).

Note that this returns zero only if \( e \) is \textit{constantly} zero for \( x \) sufficiently large. [If \( e \) is constant, of course, this is just the same thing as the sign of \( e \).]

sympy.series.gruntz.mrv(e, x)

Returns a SubsSet of most rapidly varying (mrv) subexpressions of \( 'e' \), and \( e \) rewritten in terms of these.

sympy.series.gruntz.mrv_max1(f, g, exps, x)

Computes the maximum of two sets of expressions \( f \) and \( g \), which are in the same comparability class, i.e. \( \text{mrv\_max1()} \) compares two elements of \( f \) and \( g \) and returns the set, which is in the higher comparability class of the union of both, if they have the same order of variation. Also returns \( \text{exp}s \), with the appropriate substitutions made.

sympy.series.gruntz.mrv_max3(f, expsf, g, expsg, union, expsboth, x)

Computes the maximum of two sets of expressions \( f \) and \( g \), which are in the same comparability class, i.e. \( \text{max()} \) compares two elements of \( f \) and \( g \) and returns either \( (f, \text{expsf}) \) [if \( f \) is larger], \( (g, \text{expsg}) \) [if \( g \) is larger] or \( \text{(union, expsboth)} \) [if \( f, g \) are of the same class].

\textbf{class} sympy.series.gruntz.SubsSet

Stores (expr, dummy) pairs, and how to rewrite expr-s.

\textbf{Explanation}

The gruntz algorithm needs to rewrite certain expressions in term of a new variable \( w \). We cannot use \text{subs}, because it is just too smart for us. For example:

\[
\begin{align*}
& \Omega = [\exp(\exp(-p) - \exp(-p))/(1 - 1/p), \exp(\exp(p))] \\
& 02 = [\exp(-exp(-p)) + \exp(-exp(-p)*exp(p)/(1 - 1/p))/w, 1/w] \\
& e = \exp(\exp(-p) - \exp(-p))/(1 - 1/p) - \exp(\exp(p)) \\
& e . \text{subs}(\Omega[0],02[0]).\text{subs}(\Omega[1],02[1]) \\
& \phantom{e} -1/w + \exp(exp(p)*exp(-exp(-p))/(1 - 1/p))
\end{align*}
\]

is really not what we want!

So we do it the hard way and keep track of all the things we potentially want to substitute by dummy variables. Consider the expression:
\[ \exp(x - \exp(-x)) + \exp(x) + x. \]

The mrv set is \{\exp(x), \exp(-x), \exp(x - \exp(-x))\}. We introduce corresponding dummy variables \(d_1, d_2, d_3\) and rewrite:

\[ d_3 + d_1 + x. \]

This class first of all keeps track of the mapping expr->variable, i.e. will at this stage be a dictionary:

\[
\{\exp(x): d_1, \exp(-x): d_2, \exp(x - \exp(-x)): d_3\}.
\]

[It turns out to be more convenient this way round.] But sometimes expressions in the mrv set have other expressions from the mrv set as subexpressions, and we need to keep track of that as well. In this case, \(d_3\) is really \(\exp(x - d_2)\), so rewrites at this stage is:

\[
\{d_3: \exp(x-d_2)\}.
\]

The function rewrite uses all this information to correctly rewrite our expression in terms of \(w\). In this case \(w\) can be chosen to be \(\exp(-x)\), i.e. \(d_2\). The correct rewriting then is:

\[ \exp(-w)/w + 1/w + x. \]

**copy()**

Create a shallow copy of SubsSet

**do_subs(e)**

Substitute the variables with expressions

**meets(s2)**

Tell whether or not self and s2 have non-empty intersection

**union(s2, exps=None)**

Compute the union of self and s2, adjusting exps

**More Intuitive Series Expansion**

This is achieved by creating a wrapper around Basic.series(). This allows for the use of series(x*cos(x),x), which is possibly more intuitive than (x*cos(x)).series(x).

**Examples**

```python
>>> from sympy import Symbol, cos, series
>>> x = Symbol('x')
>>> series(cos(x),x)
1 - x**2/2 + x**4/24 + O(x**6)
```
SymPy Documentation, Release 1.12.1

Reference

sympy.series.series.series(expr, x=None, x0=0, n=6, dir='+')

Series expansion of expr around point \( x = x_0 \).

**Parameters**

- **expr**: Expression
  - The expression whose series is to be expanded.
- **x**: Symbol
  - It is the variable of the expression to be calculated.
- **x0**: Value
  - The value around which \( x \) is calculated. Can be any value from \(-\infty\) to \(\infty\).
- **n**: Value
  - The number of terms upto which the series is to be expanded.
- **dir**: String, optional
  - The series-expansion can be bi-directional. If \( \text{dir}="+" \), then \((x-x0+)\). If \( \text{dir}="-" \), then \((x->x0-)\). For infinite \( \text{\`\`x0 (oo or -oo)\} \), the \( \text{dir} \) argument is determined from the direction of the infinity (i.e., \( \text{dir}="-" \) for \( \infty \)).

**Returns**

- Expr
  - Series expansion of the expression about \( x_0 \)

**Examples**

```python
>>> from sympy import series, tan, oo
>>> from sympy.abc import x
>>> f = tan(x)
>>> series(f, x, 2, 6, "+")
tan(2) + (1 + tan(2)**2)**(x - 2) + (x - 2)**2*(tan(2)**3 + tan(2)) +
(x - 2)**3*(1/3 + 4*tan(2)**2/3 + tan(2)**4) + (x - 2)**4*(tan(2)**5 +
5*tan(2)**3/3 + 2*tan(2)/3) + (x - 2)**5*(2/15 + 17*tan(2)**2/15 +
2*tan(2)**4 + tan(2)**6) + O((x - 2)**6, (x, 2))
```

```python
>>> series(f, x, 2, 3, "-")
tan(2) + (2 - x)**(-tan(2)**2 - 1) + (2 - x)**2*(tan(2)**3 + tan(2)) +
0((x - 2)**3, (x, 2))
```

```python
>>> series(f, x, 2, oo, "+")
Traceback (most recent call last):
...
TypeError: 'Infinity' object cannot be interpreted as an integer
```

**See also:**

5.8. Topics 685
**SymPy Documentation, Release 1.12.1**

**SymPy.core.expr.Expr.series** *(page 1025)*

See the docstring of Expr.series() for complete details of this wrapper.

### Order Terms

This module also implements automatic keeping track of the order of your expansion.

### Examples

```python
>>> from sympy import Symbol, Order
>>> x = Symbol('x')
>>> Order(x) + x**2
0(x)
>>> Order(x) + 1
1 + 0(x)
```

### Reference

**class sympy.series.order.Order** *(expr, *args, **kwargs)*

Represents the limiting behavior of some function.

### Explanation

The order of a function characterizes the function based on the limiting behavior of the function as it goes to some limit. Only taking the limit point to be a number is currently supported. This is expressed in big O notation [R767].

The formal definition for the order of a function \( g(x) \) about a point \( a \) is such that \( g(x) = O(f(x)) \) as \( x \to a \) if and only if there exists a \( \delta > 0 \) and an \( M > 0 \) such that \( |g(x)| \leq M|f(x)| \) for \( |x - a| < \delta \). This is equivalent to \( \limsup_{x \to a} |g(x)/f(x)| < \infty \).

Let’s illustrate it on the following example by taking the expansion of \( \sin(x) \) about 0:

\[
\sin(x) = x - x^3/3! + O(x^5)
\]

where in this case \( O(x^5) = x^5/5! - x^7/7! + \cdots \). By the definition of \( O \), there is a \( \delta > 0 \) and an \( M \) such that:

\[
|x^5/5! - x^7/7! + \cdots| \leq M|x^5| \text{ for } |x| < \delta
\]

or by the alternate definition:

\[
\lim_{x \to 0} |(x^5/5! - x^7/7! + \cdots)/x^5| < \infty
\]

which surely is true, because

\[
\lim_{x \to 0} |(x^5/5! - x^7/7! + \cdots)/x^5| = 1/5!
\]

As it is usually used, the order of a function can be intuitively thought of representing all terms of powers greater than the one specified. For example, \( O(x^3) \) corresponds to any terms proportional to \( x^3, x^4, \ldots \) and any higher power. For a polynomial, this leaves terms proportional to \( x^2, x \) and constants.
Examples

```python
>>> from sympy import O, oo, cos, pi
>>> from sympy.abc import x, y

>>> O(x + x**2)
O(x)
>>> O(x + x**2, (x, 0))
O(x)
>>> O(x + x**2, (x, oo))
O(x**2, (x, oo))

>>> O(1 + x*y)
O(1, x, y)
>>> O(1 + x*y, (x, 0), (y, 0))
O(1 + x*y, (x, oo), (y, oo))

>>> 0(1) in 0(1, x)
True
>>> 0(1, x) in 0(1)
False
>>> 0(x) in 0(1, x)
True
>>> 0(x**2) in 0(x)
True

>>> 0(x)*x
O(x**2)
>>> 0(x) - 0(x)
O(x)
>>> 0(cos(x))
O(1)
>>> 0(cos(x), (x, pi/2))
O(x - pi/2, (x, pi/2))
```

Notes

In \(O(f(x), x)\) the expression \(f(x)\) is assumed to have a leading term. \(O(f(x), x)\) is automatically transformed to \(O(f(x).as\_leading\_term(x), x)\).

- \(0(expr*f(x), x)\) is \(0(f(x), x)\)
- \(0(expr, x)\) is \(0(1)\)
- \(0(0, x)\) is \(0\).

Multivariate \(O\) is also supported:

- \(O(f(x, y), x, y)\) is transformed to \(O(f(x, y).as\_leading\_term(x,y).as\_leading\_term(y), x, y)\)
In the multivariate case, it is assumed the limits w.r.t. the various symbols commute.
If no symbols are passed then all symbols in the expression are used and the limit point
is assumed to be zero.

References

[R767]

contains(expr)

Return True if expr belongs to Order(self.expr, *self.variables). Return False if self
belongs to expr. Return None if the inclusion relation cannot be determined (e.g.
when self and expr have different symbols).

Series Acceleration

TODO

Reference

sympy.series.acceleration.richardson(A, k, n, N)

Calculate an approximation for lim k->oo A(k) using Richardson extrapolation with the
terms A(n), A(n+1), ..., A(n+N+1). Choosing N ~ 2^n often gives good results.

Examples

A simple example is to calculate exp(1) using the limit definition. This limit converges
slowly; n = 100 only produces two accurate digits:

```python
>>> from sympy.abc import n
>>> e = (1 + 1/n)**n
>>> print(round(e.subs(n, 100).evalf(), 10))
2.7048138294
```

Richardson extrapolation with 11 appropriately chosen terms gives a value that is accu-
rate to the indicated precision:

```python
>>> from sympy import E
>>> from sympy.series.acceleration import richardson
>>> print(round(richardson(e, n, 10, 20).evalf(), 10))
2.7182818285
>>> print(round(E.evalf(), 10))
2.7182818285
```

Another useful application is to speed up convergence of series. Computing 100 terms
of the zeta(2) series 1/k**2 yields only two accurate digits:
>> from sympy import k, n
>> from sympy import Sum
>> A = Sum(k**2, (k, 1, n))
>> print(round(A.subs(n, 100).evalf(), 10))
1.6349839002

Richardson extrapolation performs much better:

>> from sympy import pi
>> print(round(richardson(A, n, 10, 20).evalf(), 10))
1.6449340668
>> print(round(((pi**2)/6).evalf(), 10))  # Exact value
1.6449340668

sympy.series.acceleration.shanks(A, k, n, m=1)
Calculate an approximation for \( \lim_{k \to \infty} A(k) \) using the \( n \)-term Shanks transformation \( S(A)(n) \). With \( m > 1 \), calculate the \( m \)-fold recursive Shanks transformation \( S(S(\ldots S(A)\ldots))(n) \).

The Shanks transformation is useful for summing Taylor series that converge slowly near a pole or singularity, e.g. for \( \log(2) \):

>> from sympy import k, n
>> from sympy import Sum, Integer
>> from sympy.series.acceleration import shanks
>> A = Sum(Integer(-1)**(k+1)/k, (k, 1, n))
>> print(round(A.subs(n, 100).doit().evalf(), 10))
0.6881721793
>> print(round(shanks(A, n, 25).evalf(), 10))
0.6931396564
>> print(round(shanks(A, n, 25, 5).evalf(), 10))
0.6931471806

The correct value is 0.6931471805599453094172321215.

Residues

TODO

Reference

sympy.series.residues.residue(expr, x, x0)

Finds the residue of \( expr \) at the point \( x=x0 \).

The residue is defined as the coefficient of \( 1/(x-x0) \) in the power series expansion about \( x=x0 \).
Examples

```python
>>> from sympy import Symbol, residue, sin
>>> x = Symbol("x")
>>> residue(1/x, x, 0)
1
>>> residue(1/x**2, x, 0)
0
>>> residue(2/sin(x), x, 0)
2
```

This function is essential for the Residue Theorem [1].

References

[R768]

Sequences

A sequence is a finite or infinite lazily evaluated list.

`sympy.series.sequences.sequence(seq, limits=None)`

Returns appropriate sequence object.

Explanation

If `seq` is a SymPy sequence, returns `SeqPer` (page 693) object otherwise returns `SeqFormula` (page 692) object.

Examples

```python
>>> from sympy import sequence
>>> from sympy.abc import n
>>> sequence(n**2, (n, 0, 5))
SeqFormula(n**2, (n, 0, 5))
>>> sequence((1, 2, 3), (n, 0, 5))
SeqPer((1, 2, 3), (n, 0, 5))
```

See also:

`sympy.series.sequences.SeqPer` (page 693), `sympy.series.sequences.SeqFormula` (page 692)
Sequences Base

class sympy.series.sequences.SeqBase(*args)

Base class for sequences

coeff(pt)

Returns the coefficient at point pt

coeff_mul(other)

Should be used when other is not a sequence. Should be defined to define custom behaviour.

Examples

>>> from sympy import SeqFormula

>>> from sympy import n

>>> SeqFormula(n**2).coeff_mul(2)
SeqFormula(2*n**2, (n, 0, oo))

Notes

'*' defines multiplication of sequences with sequences only.

find_linear_recurrence(n, d=None, gfvar=None)

Finds the shortest linear recurrence that satisfies the first n terms of sequence of order \( \leq \frac{n}{2} \) if possible. If d is specified, find shortest linear recurrence of order \( \leq \min(d, \frac{n}{2}) \) if possible. Returns list of coefficients \( [b(1), b(2), \ldots] \) corresponding to the recurrence relation \( x(n) = b(1)*x(n-1) + b(2)*x(n-2) + \ldots \). Returns [ ] if no recurrence is found. If gfvar is specified, also returns ordinary generating function as a function of gfvar.

Examples

>>> from sympy import sequence, sqrt, oo, lucas

>>> from sympy import n, x, y

>>> sequence(n**2).find_linear_recurrence(10, 2)
[ ]

>>> sequence(n**2).find_linear_recurrence(10)
[3, -3, 1]

>>> sequence(2**n).find_linear_recurrence(10)
[2]

>>> sequence(23*n**4+91*n**2).find_linear_recurrence(10)
[5, -10, 10, -5, 1]

>>> sequence(sqrt(5)**((-1 + sqrt(5))/2)**n - ((1 + sqrt(5))/2)**(-n))/5).find_linear_recurrence(10)
[1, 1]

>>> sequence(x+y+(-2)**(-n), (n, 0, oo)).find_linear_recurrence(30)
[1/2, 1/2]

>>> sequence(3*5**n + 12).find_linear_recurrence(20, gfvar=x)
sequence(lucas(n)).find_linear_recurrent(15, gfvar=x)

sequence(lucas(n)).find_linear_recurrent(15, gfvar=x)

property free_symbols
This method returns the symbols in the object, excluding those that take on a specific value (i.e. the dummy symbols).

Examples

>>> from sympy import SeqFormula
>>> from sympy.abc import n, m
>>> SeqFormula(m*n**2, (n, 0, 5)).free_symbols
{m}

property gen
Returns the generator for the sequence

property interval
The interval on which the sequence is defined

property length
Length of the sequence

property start
The starting point of the sequence. This point is included

property stop
The ending point of the sequence. This point is included

property variables
Returns a tuple of variables that are bounded

Elementary Sequences

class sympy.series.sequences.SeqFormula(formula, limits=None)
Represents sequence based on a formula.
Elements are generated using a formula.

Examples

>>> from sympy import SeqFormula, oo, Symbol
>>> n = Symbol('n')
>>> s = SeqFormula(n**2, (n, 0, 5))
>>> s.formula
n**2

For value at a particular point
>>> s.coeff(3)
9

supports slicing

>>> s[:]
[0, 1, 4, 9, 16, 25]

iterable

>>> list(s)
[0, 1, 4, 9, 16, 25]

sequence starts from negative infinity

>>> SeqFormula(n**2, (-oo, 0))[0:6]
[0, 1, 4, 9, 16, 25]

See also:

sympy.series.sequences.SeqPer (page 693)

coeff_mul(coeff)

See docstring of SeqBase.coeff_mul

class sympy.series.sequences.SeqPer(periodical, limits=None)

Represents a periodic sequence.
The elements are repeated after a given period.

Examples

>>> from sympy import SeqPer, oo
>>> from sympy.abc import k

>>> s = SeqPer((1, 2, 3), (0, 5))
>>> s.periodical
(1, 2, 3)

For value at a particular point

>>> s.coeff(3)
1

supports slicing

>>> s[:]
[1, 2, 3, 1, 2, 3]

iterable
sequence starts from negative infinity

Periodic formulas

See also:

sympy.series.sequences.SeqFormula (page 692)

coeff_mul(coef)

Singleton Sequences

class sympy.series.sequences.EmptySequence

Represents an empty sequence.

The empty sequence is also available as a singleton as S.EmptySequence.

Examples

coeff_mul(coef)

See docstring of SeqBase.coeff_mul
**Compound Sequences**

```python
class sympy.series.sequences.SeqAdd(*args, **kwargs)
```

Represents term-wise addition of sequences.

**Rules:**
- The interval on which sequence is defined is the intersection of respective intervals of sequences.
- Anything + *EmptySequence* (page 694) remains unchanged.
- Other rules are defined in `_add` methods of sequence classes.

**Examples**

```python
>>> from sympy import EmptySequence, oo, SeqAdd, SeqPer, SeqFormula
>>> from sympy.abc import n
>>> SeqAdd(SeqPer((1, 2), (n, 0, oo)), EmptySequence)
SeqPer((1, 2), (n, 0, oo))
>>> SeqAdd(SeqPer((1, 2), (n, 0, 5)), SeqPer((1, 2), (n, 6, 10)))
EmptySequence
>>> SeqAdd(SeqPer((1, 2), (n, 0, oo)), SeqFormula(n**2, (n, 0, oo)))
SeqAdd(SeqFormula(n**2, (n, 0, oo)), SeqPer((1, 2), (n, 0, oo)))
>>> SeqAdd(SeqFormula(n**3), SeqFormula(n**2))
SeqFormula(n**3 + n**2, (n, 0, oo))
```

**See also:**

`sympy.series.sequences.SeqMul` (page 695)

**static reduce**(*args*)

Simplify *SeqAdd* (page 695) using known rules.

Iterates through all pairs and ask the constituent sequences if they can simplify themselves with any other constituent.

**Notes**

adapted from Union.reduce

```python
class sympy.series.sequences.SeqMul(*args, **kwargs)
```

Represents term-wise multiplication of sequences.

**Explanation**

Handles multiplication of sequences only. For multiplication with other objects see *SeqBase.coeff_mul()* (page 691).

**Rules:**
- The interval on which sequence is defined is the intersection of respective intervals of sequences.
- Anything * EmptySequence* (page 694) returns *EmptySequence* (page 694).
• Other rules are defined in `_mul` methods of sequence classes.

Examples

```python
>>> from sympy import EmptySequence, oo, SeqMul, SeqPer, SeqFormula
>>> from sympy.abc import n
>>> SeqMul(SeqPer((1, 2), (n, 0, oo)), EmptySequence)
EmptySequence
>>> SeqMul(SeqPer((1, 2), (n, 0, 5)), SeqPer((1, 2), (n, 6, 10)))
EmptySequence
>>> SeqMul(SeqPer((1, 2), (n, 0, oo)), SeqFormula(n**2))
SeqMul(SeqFormula(n**2, (n, 0, oo)), SeqPer((1, 2), (n, 0, oo)))
>>> SeqMul(SeqFormula(n**3), SeqFormula(n**2))
SeqFormula(n**5, (n, 0, oo))
```

See also:

`sympy.series.sequences.SeqAdd` (page 695)

```python
static reduce(args)
```

Simplify a `SeqMul` (page 695) using known rules.

Explanation

Iterates through all pairs and ask the constituent sequences if they can simplify themselves with any other constituent.

Notes

adapted from Union.reduce

Recursive Sequences

class sympy.series.sequences.RecursiveSeq(recurrence, yn, n, initial=None, start=0)

A finite degree recursive sequence.

Parameters

recurrence : SymPy expression defining recurrence

This is not an equality, only the expression that the nth term is equal to. For example, if \( a(n) = f(a(n - 1), \ldots, a(n - d)) \), then the expression should be \( f(a(n - 1), \ldots, a(n - d)) \).

yn : applied undefined function

Represents the nth term of the sequence as e.g. \( y(n) \) where \( y \) is an undefined function and \( n \) is the sequence index.

n : symbolic argument

The name of the variable that the recurrence is in, e.g., \( n \) if the recurrence function is \( y(n) \).
**initial**: iterable with length equal to the degree of the recurrence

The initial values of the recurrence.

**start**: start value of sequence (inclusive)

### Explanation

That is, a sequence \( a(n) \) that depends on a fixed, finite number of its previous values. The general form is

\[
a(n) = f(a(n - 1), a(n - 2), \ldots, a(n - d))
\]

for some fixed, positive integer \( d \), where \( f \) is some function defined by a SymPy expression.

### Examples

```python
>>> from sympy import Function, symbols
>>> from sympy.series.sequences import RecursiveSeq
>>> y = Function("y")
>>> n = symbols("n")
>>> fib = RecursiveSeq(y(n - 1) + y(n - 2), y(n), n, [0, 1])
```

```python
>>> fib.coeff(3) # Value at a particular point
2
```

```python
>>> fib[:6] # supports slicing
[0, 1, 1, 2, 3, 5]
```

```python
>>> fib.recurrent # inspect recurrence
Eq(y(n), y(n - 2) + y(n - 1))
```

```python
>>> fib.degree # automatically determine degree
2
```

```python
>>> for x in zip(range(10), fib): # supports iteration
...       print(x)
```

```
(0, 0)
(1, 1)
(2, 1)
(3, 2)
(4, 3)
(5, 5)
(6, 8)
(7, 13)
(8, 21)
(9, 34)
```

**See also:**

*sympy.series.sequences.SeqFormula* (page 692)
property initial
    The initial values of the sequence

property interval
    Interval on which sequence is defined.

property n
    Sequence index symbol

property recurrence
    Equation defining recurrence.

property start
    The starting point of the sequence. This point is included

property stop
    The ending point of the sequence. (oo)

property y
    Undefined function for the nth term of the sequence

property yn
    Applied function representing the nth term

Fourier Series

Provides methods to compute Fourier series.

class sympy.series.fourier.FourierSeries(*args)
    Represents Fourier sine/cosine series.

Explanation

This class only represents a fourier series. No computation is performed.

For how to compute Fourier series, see the fourier_series() (page 701) docstring.

See also:

sympy.series.fourier.fourier_series (page 701)

scale(s)
    Scale the function by a term independent of x.

Explanation

f(x) -> s * f(x)

This is fast, if Fourier series of f(x) is already computed.
Examples

```python
>>> from sympy import fourier_series, pi
>>> from sympy.abc import x
>>> s = fourier_series(x**2, (x, -pi, pi))
>>> s.scale(2).truncate()
-8*cos(x) + 2*cos(2*x) + 2*pi**2/3
```

scalex(s)
Scale x by a term independent of x.

Explanation

f(x) -> f(s*x)
This is fast, if Fourier series of f(x) is already computed.

Examples

```python
>>> from sympy import fourier_series, pi
>>> from sympy.abc import x
>>> s = fourier_series(x**2, (x, -pi, pi))
>>> s.scalex(2).truncate()
-4*cos(2*x) + cos(4*x) + pi**2/3
```

shift(s)
Shift the function by a term independent of x.

Explanation

f(x) -> f(x) + s
This is fast, if Fourier series of f(x) is already computed.

Examples

```python
>>> from sympy import fourier_series, pi
>>> from sympy.abc import x
>>> s = fourier_series(x**2, (x, -pi, pi))
>>> s.shift(1).truncate()
-4*cos(x) + cos(2*x) + 1 + pi**2/3
```

shiftx(s)
Shift x by a term independent of x.
Explanation

\( f(x) \rightarrow f(x + s) \)

This is fast, if Fourier series of \( f(x) \) is already computed.

Examples

```python
>>> from sympy import fourier_series, pi
>>> from sympy.abc import x
>>> s = fourier_series(x**2, (x, -pi, pi))
>>> s.shiftx(1).truncate()
-4*cos(x + 1) + cos(2*x + 2) + pi**2/3
```

\texttt{sigma\_approximation}(n=3)

Return \( \sigma \)-approximation of Fourier series with respect to order \( n \).

**Parameters**

\( n \) : int

Highest order of the terms taken into account in approximation.

**Returns**

Expr :

Sigma approximation of function expanded into Fourier series.

Explanation

Sigma approximation adjusts a Fourier summation to eliminate the Gibbs phenomenon which would otherwise occur at discontinuities. A sigma-approximated summation for a Fourier series of a \( T \)-periodical function can be written as

\[
s(\theta) = \frac{1}{2}a_0 + \sum_{k=1}^{m-1} \text{sinc}\left(\frac{k}{m}\right) \cdot \left[ a_k \cos\left(\frac{2\pi k}{T}\theta\right) + b_k \sin\left(\frac{2\pi k}{T}\theta\right) \right],
\]

where \( a_0, a_k, b_k, k = 1, \ldots, m - 1 \) are standard Fourier series coefficients and \( \text{sinc}\left(\frac{k}{m}\right) \) is a Lanczos \( \sigma \) factor (expressed in terms of normalized sinc function).

Examples

```python
>>> from sympy import fourier_series, pi
>>> from sympy.abc import x
>>> s = fourier_series(x, (x, -pi, pi))
>>> s.sigma_approximation(4)
2*sin(x)*sinc(pi/4) - 2*sin(2*x)/pi + 2*sin(3*x)*sinc(3*pi/4)/3
```
Notes

The behaviour of `sigma_approximation()` (page 700) is different from `truncate()` (page 701) - it takes all nonzero terms of degree smaller than n, rather than first n nonzero ones.

See also:

`sympy.series.fourier.FourierSeries.truncate` (page 701)

References

[R762], [R763]

`truncate(n=3)`

Return the first n nonzero terms of the series.

If n is None return an iterator.

Parameters

- `n : int or None`
  - Amount of non-zero terms in approximation or None.

Returns

- `Expr or iterator`:
  - Approximation of function expanded into Fourier series.

Examples

```python
>>> from sympy import fourier_series, pi
>>> from sympy.abc import x
>>> s = fourier_series(x, (x, -pi, pi))
>>> s.truncate(4)
2*sin(x) - sin(2*x) + 2*sin(3*x)/3 - sin(4*x)/2
```

See also:

`sympy.series.fourier.FourierSeries.sigma_approximation` (page 700)

`sympy.series.fourier.FourierSeries`(`f, limits=None, finite=True`)

Computes the Fourier trigonometric series expansion.

Parameters

- `limits : (sym, start, end), optional`
  - `sym` denotes the symbol the series is computed with respect to.
  - `start` and `end` denotes the start and the end of the interval where the fourier series converges to the given function.

Default range is specified as $-\pi$ and $\pi$.

Returns

- `FourierSeries`:
  - A symbolic object representing the Fourier trigonometric series.
Explanation

Fourier trigonometric series of $f(x)$ over the interval $(a, b)$ is defined as:

$$
\frac{a_0}{2} + \sum_{n=1}^{\infty} (a_n \cos\left(\frac{2n\pi x}{L}\right) + b_n \sin\left(\frac{2n\pi x}{L}\right))
$$

where the coefficients are:

$$
L = b - a
$$

$$
a_0 = \frac{2}{L} \int_{a}^{b} f(x) dx
$$

$$
a_n = \frac{2}{L} \int_{a}^{b} f(x) \cos\left(\frac{2n\pi x}{L}\right) dx
$$

$$
b_n = \frac{2}{L} \int_{a}^{b} f(x) \sin\left(\frac{2n\pi x}{L}\right) dx
$$

The condition whether the function $f(x)$ given should be periodic or not is more than necessary, because it is sufficient to consider the series to be converging to $f(x)$ only in the given interval, not throughout the whole real line.

This also brings a lot of ease for the computation because you do not have to make $f(x)$ artificially periodic by wrapping it with piecewise, modulo operations, but you can shape the function to look like the desired periodic function only in the interval $(a, b)$, and the computed series will automatically become the series of the periodic version of $f(x)$.

This property is illustrated in the examples section below.

Examples

Computing the Fourier series of $f(x) = x^2$:

```python
>>> from sympy import fourier_series, pi
>>> from sympy.abc import x
>>> f = x**2
>>> s = fourier_series(f, (x, -pi, pi))
>>> s1 = s.truncate(n=3)
>>> s1
-4*cos(x) + cos(2*x) + pi**2/3
```

Shifting of the Fourier series:

```python
>>> s.shift(1).truncate()
-4*cos(x) + cos(2*x) + 1 + pi**2/3
>>> s.shiftx(1).truncate()
-4*cos(x + 1) + cos(2*x + 2) + pi**2/3
```

Scaling of the Fourier series:

```python
>>> s.scale(2).truncate()
-8*cos(x) + 2*cos(2*x) + 2*pi**2/3
>>> s.scalex(2).truncate()
-4*cos(2*x) + cos(4*x) + pi**2/3
```
Computing the Fourier series of $f(x) = x$:

This illustrates how truncating to the higher order gives better convergence.

```python
from sympy import fourier_series, pi, plot
from sympy.abc import x

f = x
s = fourier_series(f, (x, -pi, pi))
s1 = s.truncate(n=3)
s2 = s.truncate(n=5)
s3 = s.truncate(n=7)
p = plot(f, s1, s2, s3, (x, -pi, pi), show=False, legend=True)
```

```python
>>> p[0].line_color = (0, 0, 0)
>>> p[0].label = 'x'
>>> p[1].line_color = (0.7, 0.7, 0.7)
>>> p[1].label = 'n=3'
>>> p[2].line_color = (0.5, 0.5, 0.5)
>>> p[2].label = 'n=5'
>>> p[3].line_color = (0.3, 0.3, 0.3)
>>> p[3].label = 'n=7'

>>> p.show()
```
This illustrates how the series converges to different sawtooth waves if the different ranges are specified.

```python
>>> s1 = fourier_series(x, (x, -1, 1)).truncate(10)
>>> s2 = fourier_series(x, (x, -pi, pi)).truncate(10)
>>> s3 = fourier_series(x, (x, 0, 1)).truncate(10)
>>> p = plot(x, s1, s2, s3, (x, -5, 5), show=False, legend=True)

>>> p[0].line_color = (0, 0, 0)
>>> p[0].label = 'x'
>>> p[1].line_color = (0.7, 0.7, 0.7)
>>> p[1].label = '[-1, 1]'
>>> p[2].line_color = (0.5, 0.5, 0.5)
>>> p[2].label = '[-pi, pi]'
>>> p[3].line_color = (0.3, 0.3, 0.3)
>>> p[3].label = '[0, 1]'

>>> p.show()
```
Notes

Computing Fourier series can be slow due to the integration required in computing $a_n$, $b_n$.

It is faster to compute Fourier series of a function by using shifting and scaling on an already computed Fourier series rather than computing again.

e.g. If the Fourier series of $x**2$ is known the Fourier series of $x**2 - 1$ can be found by shifting by -1.

See also:

* `sympy.series.fourier.FourierSeries` (page 698)

References

[R764]

Formal Power Series

Methods for computing and manipulating Formal Power Series.

```python
class sympy.series.formal.FormalPowerSeries(*args)

    Represents Formal Power Series of a function.
```

Explanation

No computation is performed. This class should only to be used to represent a series. No checks are performed.

For computing a series use `fps()` (page 708).

See also:

* `sympy.series.formal.fps` (page 708)

`coeff_bell(n)`

self.coeff_bell(n) returns a sequence of Bell polynomials of the second kind. Note that $n$ should be a integer.

The second kind of Bell polynomials (are sometimes called “partial” Bell polynomials or incomplete Bell polynomials) are defined as

$$B_{n,k}(x_1, x_2, \ldots x_{n-k+1}) = \sum_{j_1 + j_2 + \cdots + j_{n-k+1} = n} \frac{n!}{j_1!j_2!\cdots j_{n-k+1}!} \left( \frac{x_1}{1!} \right)^{j_1} \left( \frac{x_2}{2!} \right)^{j_2} \cdots \left( \frac{x_{n-k+1}}{(n-k+1)!} \right)^{j_{n-k+1}}.$$

• `bell(n, k, (x1, x2, ...))` gives Bell polynomials of the second kind, $B_{n,k}(x_1, x_2, \ldots, x_{n-k+1})$.

See also:

* `sympy.functions.combinatorial.numbers.bell` (page 483)
compose\((\text{other, x=None, n=6})\)

Returns the truncated terms of the formal power series of the composed function, up to specified \(n\).

**Parameters**

- \(n\) : Number, optional
  
  Specifies the order of the term up to which the polynomial should be truncated.

**Explanation**

If \(f\) and \(g\) are two formal power series of two different functions, then the coefficient sequence \(a_k\) of the composed formal power series \(f \circ g\) will be as follows.

\[
\sum_{k=0}^{n} b_k B_{n,k}(x_1, x_2, \ldots, x_{n-k+1})
\]

**Examples**

```python
>>> from sympy import fps, sin, exp
>>> from sympy.abc import x
>>> f1 = fps(exp(x))
>>> f2 = fps(sin(x))

>>> f1.compose(f2, x).truncate()
1 + x + x**2/2 - x**4/8 - x**5/15 + O(x**6)

>>> f1.compose(f2, x).truncate(8)
1 + x + x**2/2 - x**4/8 - x**5/15 - x**6/240 + x**7/90 + O(x**8)
```

See also:

- `sympy.functions.combinatorial.numbers.bell` (page 483),
- `sympy.series.formal.FormalPowerSeriesCompose` (page 711)

**References**

[R756]

**property infinite**

Returns an infinite representation of the series

**integrate\((x=None, **kwargs)\)**

Integrate Formal Power Series.
Examples

```python
from sympy import fps, sin, integrate
from sympy.abc import x
f = fps(sin(x))
f.integrate(x).truncate()
-1 + x**2/2 - x**4/24 + O(x**6)
integrate(f, (x, 0, 1))
1 - cos(1)
```

**inverse**($x$=None, $n$=6)

Returns the truncated terms of the inverse of the formal power series, up to specified $n$.

**Parameters**

- **n**: Number, optional
  
  Specifies the order of the term up to which the polynomial should be truncated.

**Explanation**

If $f$ and $g$ are two formal power series of two different functions, then the coefficient sequence $a_k$ of the composed formal power series $fp$ will be as follows.

$$
\sum_{k=0}^{n} (-1)^k x_0^{-k-1} B_{n,k}(x_1, x_2, \ldots, x_{n-k+1})
$$

**Examples**

```python
from sympy import fps, exp, cos
from sympy.abc import x
f1 = fps(exp(x))
f2 = fps(cos(x))
f1.inverse(x).truncate()
1 - x + x**2/2 - x**3/6 + x**4/24 - x**5/120 + O(x**6)
f2.inverse(x).truncate(8)
1 + x**2/2 + 5*x**4/24 + 61*x**6/720 + O(x**8)
```

See also:

- `sympy.functions.combinatorial.numbers.bell` (page 483)
- `sympy.series.formal.FormalPowerSeriesInverse` (page 711)
References

[R757]
polynomial \((n=6)\)
Truncated series as polynomial.

Explanation

Returns series expansion of \(f\) upto order \(O(x^n)\) as a polynomial(without 0 term).

product \((other, x=\text{None}, n=6)\)
Multiplies two Formal Power Series, using discrete convolution and return the truncated terms upto specified order.

Parameters

- \(n\) : Number, optional
  Specifies the order of the term up to which the polynomial should be truncated.

Examples

```python
>>> from sympy import fps, sin, exp
>>> from sympy.abc import x
>>> f1 = fps(sin(x))
>>> f2 = fps(exp(x))
>>> f1.product(f2, x).truncate(4)
x + x**2 + x**3/3 + O(x**4)
```

See also:

- `sympy.discrete.convolutions` (page 1133), `sympy.series.formal.FormalPowerSeriesProduct` (page 711)

truncate \((n=6)\)
Truncated series.

Explanation

Returns truncated series expansion of \(f\) upto order \(O(x^n)\).

If \(n\) is None, returns an infinite iterator.

```python
sympy.series.formal.fps(f, x=\text{None}, x0=0, dir=1, hyper=True, order=4, rational=True, full=False)
```

Generates Formal Power Series of \(f\).

Parameters

- \(x\) : Symbol, optional
  If \(x\) is None and \(f\) is univariate, the univariate symbols will be supplied, otherwise an error will be raised.
**SymPy Documentation, Release 1.12.1**

**x0**: number, optional
Point to perform series expansion about. Default is 0.

**dir**: {1, -1, ‘+’, ‘-’}, optional
If dir is 1 or ‘+’ the series is calculated from the right and for -1 or ‘-’ the series is calculated from the left. For smooth functions this flag will not alter the results. Default is 1.

**hyper**: {True, False}, optional
Set hyper to False to skip the hypergeometric algorithm. By default it is set to False.

**order**: int, optional
Order of the derivative of f, Default is 4.

**rational**: {True, False}, optional
Set rational to False to skip rational algorithm. By default it is set to True.

**full**: {True, False}, optional
Set full to True to increase the range of rational algorithm. See `rational_algorithm()` (page 712) for details. By default it is set to False.

**Explanation**

Returns the formal series expansion of f around \(x = x_0\) with respect to x in the form of a FormalPowerSeries object.

Formal Power Series is represented using an explicit formula computed using different algorithms.

See `compute_fps()` (page 710) for the more details regarding the computation of formula.

**Examples**

```python
>>> from sympy import fps, ln, atan, sin
>>> from sympy.abc import x, n
```

**Rational Functions**

```python
>>> fps(ln(1 + x)).truncate()
\(x - x^2/2 + x^3/3 - x^4/4 + x^5/5 + O(x^6)\)
```

```python
>>> fps(atan(x), full=True).truncate()
\(x - x^3/3 + x^5/5 + O(x^6)\)
```

**Symbolic Functions**

```python
>>> fps(x**n*sin(x**2), x).truncate(8)
\(-x^n(n + 6)/6 + x^n(n + 2) + O(x^n(n + 8))\)
```
sympy.series.formal.FormalPowerSeries (page 705), sympy.series.formal.compute_fps (page 710)

sympy.series.formal.compute_fps(f, x, x0=0, dir=1, hyper=True, order=4, rational=True, full=False)

Computes the formula for Formal Power Series of a function.

**Parameters**

- **x** : Symbol
- **x0** : number, optional
  
  Point to perform series expansion about. Default is 0.
- **dir** : {1, -1, ‘+’, ‘-’}, optional
  
  If dir is 1 or ‘+’ the series is calculated from the right and for -1 or ‘-‘ the series is calculated from the left. For smooth functions this flag will not alter the results. Default is 1.
- **hyper** : {True, False}, optional
  
  Set hyper to False to skip the hypergeometric algorithm. By default it is set to False.
- **order** : int, optional
  
  Order of the derivative of \( f \), Default is 4.
- **rational** : {True, False}, optional
  
  Set rational to False to skip rational algorithm. By default it is set to True.
- **full** : {True, False}, optional
  
  Set full to True to increase the range of rational algorithm. See rational_algorithm() (page 712) for details. By default it is set to False.

**Returns**

- **ak** : sequence
  
  Sequence of coefficients.
- **xk** : sequence
  
  Sequence of powers of \( x \).
- **ind** : Expr
  
  Independent terms.
- **mul** : Pow
  
  Common terms.
Explanation

Tries to compute the formula by applying the following techniques (in order):

- rational_algorithm
- Hypergeometric algorithm

See also:

sympy.series.formal.rational_algorithm (page 712), sympy.series.formal.hyper_algorithm (page 716)

class sympy.series.formal.FormalPowerSeriesCompose(*args)

Represents the composed formal power series of two functions.

Explanation

No computation is performed. Terms are calculated using a term by term logic, instead of a point by point logic.

There are two differences between a FormalPowerSeries (page 705) object and a FormalPowerSeriesCompose (page 711) object. The first argument contains the outer function and the inner function involved in the composition. Also, the coefficient sequence contains the generic sequence which is to be multiplied by a custom bell_seq finite sequence. The finite terms will then be added up to get the final terms.

See also:

property function

Function for the composed formal power series.

class sympy.series.formal.FormalPowerSeriesInverse(*args)

Represents the Inverse of a formal power series.

Explanation

No computation is performed. Terms are calculated using a term by term logic, instead of a point by point logic.

There is a single difference between a FormalPowerSeries (page 705) object and a FormalPowerSeriesInverse (page 711) object. The coefficient sequence contains the generic sequence which is to be multiplied by a custom bell_seq finite sequence. The finite terms will then be added up to get the final terms.

See also:

property function

Function for the inverse of a formal power series.

class sympy.series.formal.FormalPowerSeriesProduct(*args)

Represents the product of two formal power series of two functions.
Explanation

No computation is performed. Terms are calculated using a term by term logic, instead of point by point logic.

There are two differences between a `FormalPowerSeries` (page 705) object and a `FormalPowerSeriesProduct` (page 711) object. The first argument contains the two functions involved in the product. Also, the coefficient sequence contains both the coefficient sequence of the formal power series of the involved functions.

See also:

- `sympy.series.formal.FormalPowerSeries` (page 705)
- `sympy.series.formal.FiniteFormalPowerSeries` (page 712)

**property function**

Function of the product of two formal power series.

```python
class sympy.series.formal.FiniteFormalPowerSeries(*args)
```

Base Class for Product, Compose and Inverse classes

---

Rational Algorithm

```python
sympy.series.formal.rational_independent(terms, x)
```

Returns a list of all the rationally independent terms.

**Examples**

```python
>>> from sympy import sin, cos
>>> from sympy.series.formal import rational_independent
>>> from sympy.abc import x

>>> rational_independent([cos(x), sin(x)], x)
[cos(x), sin(x)]

>>> rational_independent([x**2, sin(x), x*sin(x), x**3], x)
[x**3 + x**2, x*sin(x) + sin(x)]
```

```python
sympy.series.formal.rational_algorithm(f, x, k, order=4, full=False)
```

**Parameters**

- `x`: Symbol
- `order`: int, optional
  Order of the derivative of f, Default is 4.
- `full`: bool

**Returns**

- `formula`: Expr
- `ind`: Expr
  Independent terms.
order : int
full : bool

Explanation

Applicable when \( f(x) \) or some derivative of \( f(x) \) is a rational function in \( x \).

`rational_algorithm()` (page 712) uses `apart()` (page 2522) function for partial fraction decomposition. `apart()` (page 2522) by default uses ‘undetermined coefficients method’. By setting `full=True`, ‘Bronstein’s algorithm’ can be used instead.

Looks for derivative of a function up to 4'th order (by default). This can be overridden using order option.

Examples

```python
>>> from sympy import log, atan
>>> from sympy.series.formal import rational_algorithm as ra
>>> from sympy.abc import x, k

>>> ra(1 / (1 - x), x, k)
(1, 0, 0)
>>> ra(log(1 + x), x, k)
((-1/((-1)**k*k), 0, 1)

>>> ra(atan(x), x, k, full=True)
(((-I/(2*(-I)**k) + I/(2*I**k))/k, 0, 1)

Notes

By setting `full=True`, range of admissible functions to be solved using `rational_algorithm` can be increased. This option should be used carefully as it can significantly slow down the computation as do it is performed on the `RootSum` (page 2512) object returned by the `apart()` (page 2522) function. Use `full=False` whenever possible.

Hypergeometric Algorithm

sympy.series.formal.simpleDE(f, x, g, order=4)
Generates simple DE.

**Explanation**

DE is of the form

\[ f^k(x) + \sum_{j=0}^{k-1} A_j f^j(x) = 0 \]

where \( A_j \) should be rational function in \( x \).

Generates DE’s upto order 4 (default). DE’s can also have free parameters.

By increasing order, higher order DE’s can be found.

Yields a tuple of (DE, order).

sympy.series.formal.exp_re(DE, r, k)
Converts a DE with constant coefficients (explike) into a RE.

**Explanation**

Performs the substitution:

\[ f^j(x) \to r(k + j) \]

Normalises the terms so that lowest order of a term is always \( r(k) \).

**Examples**

```python
>>> from sympy import Function, Derivative
>>> from sympy.series.formal import exp_re
>>> from sympy.abc import x, k
>>> f, r = Function('f'), Function('r')

>>> exp_re(-f(x) + Derivative(f(x)), r, k)
-r(k) + r(k + 1)

>>> exp_re(Derivative(f(x), x) + Derivative(f(x), (x, 2)), r, k)
r(k) + r(k + 1)
```

**See also:**

* sympy.series.formal.hyper_re (page 714)

sympy.series.formal.hyper_re(DE, r, k)
Converts a DE into a RE.
**Explanation**

Performs the substitution:

\[ x^l f^j(x) \rightarrow (k + 1 - l) a_{k + j - l} \]

Normalises the terms so that lowest order of a term is always r(k).

**Examples**

```python
>>> from sympy import Function, Derivative
>>> from sympy.series.formal import hyper_re
>>> from sympy.abc import x, k
>>> f, r = Function('f'), Function('r')

>>> hyper_re(-f(x) + Derivative(f(x)), r, k)
(k + 1)*r(k + 1) - r(k)

>>> hyper_re(-x*f(x) + Derivative(f(x), (x, 2)), r, k)
(k + 2)*(k + 3)*r(k + 3) - r(k)
```

See also:

- `sympy.series.formal.exp_re` (page 714)
- `sympy.series.formal.rsolve_hypergeometric(f, x, P, Q, k, m)` Solves RE of hypergeometric type.

**Returns**

- `formula` : Expr
- `ind` : Expr
  - Independent terms.
- `order` : int

**Explanation**

Attempts to solve RE of the form

\[ Q(k) a(k + m) - P(k) a(k) \]

Transformations that preserve Hypergeometric type:

- a. \( x^n f(x) \): \( b(k + m) = R(k - n) b(k) \)
- b. \( f(Ax) \): \( b(k + m) = A^m R(k) b(k) \)
- c. \( f(x^n) \): \( b(k + n*m) = R(k/n) b(k) \)
- d. \( f(x^{1/m}) \): \( b(k + 1) = R(k*m) b(k) \)
- e. \( f'(x) \): \( b(k + m) = ((k + m + 1)/(k + 1))*R(k + 1) b(k) \)

Some of these transformations have been used to solve the RE.
Examples

```python
>>> from sympy import exp, ln, S
>>> from sympy.series.formal import rsolve_hypergeometric as rh
>>> from sympy.abc import x, k

>>> rh(exp(x), x, -S.One, (k + 1), k, 1)
(Piecewise((1/factorial(k), Eq(Mod(k, 1), 0)), (0, True)), 1, 1)

>>> rh(ln(1 + x), x, k**2, k*(k + 1), k, 1)
(Piecewise((((-1)**(k - 1)*factorial(k - 1)/RisingFactorial(2, k - 1),
  Eq(Mod(k, 1), 0)), (0, True)), x, 2)
```

References

[R760], [R761]
sympy.series.formal.solve_de(f, x, DE, order, g, k)
Solves the DE.

Returns

- formula : Expr
- ind : Expr
  Independent terms.
- order : int

Explanation

Tries to solve DE by either converting into a RE containing two terms or converting into a DE having constant coefficients.

Examples

```python
>>> from sympy import Derivative as D, Function
>>> from sympy import exp, ln
>>> from sympy.series.formal import solve_de
>>> from sympy.abc import x, k

>>> f = Function('f')

>>> solve_de(exp(x), x, D(f(x), x) - f(x), 1, f, k)
(Piecewise((1/factorial(k), Eq(Mod(k, 1), 0)), (0, True)), 1, 1)

>>> solve_de(ln(1 + x), x, (x + 1)*D(f(x), x, 2) + D(f(x)), 2, f, k)
(Piecewise((((-1)**(k - 1)*factorial(k - 1)/RisingFactorial(2, k - 1),
  Eq(Mod(k, 1), 0)), (0, True)), x, 2)
```

sympy.series.formal.hyper_algorithm(f, x, k, order=4)
Hypergeometric algorithm for computing Formal Power Series.
**Explanation**

**Steps:**
- Generates DE
- Convert the DE into RE
- Solves the RE

**Examples**

```python
>>> from sympy import exp, ln
>>> from sympy.series.formal import hyper_algorithm
>>> from sympy.abc import x, k

>>> hyper_algorithm(exp(x), x, k)
(Piecewise((1/factorial(k), Eq(Mod(k, 1), 0)), (0, True)), 1, 1)

>>> hyper_algorithm(ln(1 + x), x, k)
(Piecewise((-1)**(k - 1)*factorial(k - 1)/RisingFactorial(2, k - 1),
Eq(Mod(k, 1), 0)), (0, True)), x, 2)
```

**See also:**
- `sympy.series.formal.simpleDE` (page 714),
- `sympy.series.formal.solve_de` (page 716)

**Limits of Sequences**

Provides methods to compute limit of terms having sequences at infinity.

```python
sympy.series.limitseq.difference_delta(expr, n=None, step=1)
```

Differential Operator.

**Explanation**

Discrete analog of differential operator. Given a sequence x[n], returns the sequence x[n + step] - x[n].

**Examples**

```python
>>> from sympy import difference_delta as dd
>>> from sympy.abc import n

>>> dd(n*(n + 1), n)
2*n + 2

>>> dd(n*(n + 1), n, 2)
4*n + 6
```
**sympy.series.limitseq.dominant(expr, n)**

Finds the dominant term in a sum, that is a term that dominates every other term.

**Explanation**

If \( \lim(a/b, n, \infty) = \infty \) then \( a \) dominates \( b \). If \( \lim(a/b, n, \infty) = 0 \) then \( b \) dominates \( a \). Otherwise, \( a \) and \( b \) are comparable.

If there is no unique dominant term, then returns `None`.

**Examples**

```python
>>> from sympy import Sum
>>> from sympy.series.limitseq import dominant
>>> from sympy.abc import n, k
>>> dominant(5*n**3 + 4*n**2 + n + 1, n)
5*n**3
>>> dominant(2**n + Sum(k, (k, 0, n)), n)
2**n
```

**See also:**

* `sympy.series.limitseq.dominant` (page 718)

**sympy.series.limitseq.limit_seq(expr, n=None, trials=5)**

Finds the limit of a sequence as index \( n \) tends to infinity.

**Parameters**

- `expr` : Expr
  
  SymPy expression for the \( n \)-th term of the sequence

- `n` : Symbol, optional
  
  The index of the sequence, an integer that tends to positive infinity. If None, inferred from the expression unless it has multiple symbols.

- `trials` : int, optional
  
  The algorithm is highly recursive. `trials` is a safeguard from infinite recursion in case the limit is not easily computed by the algorithm. Try increasing `trials` if the algorithm returns `None`. 
**Admissible Terms**

The algorithm is designed for sequences built from rational functions, indefinite sums, and indefinite products over an indeterminate \( n \). Terms of alternating sign are also allowed, but more complex oscillatory behavior is not supported.

**Examples**

```python
>>> from sympy import limit_seq, Sum, binomial
>>> from sympy.abc import n, k, m

>>> limit_seq((5*n**3 + 3*n**2 + 4) / (3*n**3 + 4*n - 5), n)
5/3
>>> limit_seq(binomial(2*n, n) / Sum(binomial(2*k, k), (k, 1, n)), n)
3/4
>>> limit_seq(Sum(k**2 * Sum(2^m/m, (m, 1, k)), (k, 1, n)) / (2^n*n), n)
4
```

**Simplify**

**Explanation**

Simplification is not a well defined term and the exact strategies this function tries can change in the future versions of SymPy. If your algorithm relies on “simplification” (whatever it is), try to determine what you need exactly - is it powsimp()?, radsimp()?, together()?, logcombine()?, or something else? And use this particular function directly, because those are well defined and thus your algorithm will be robust.

Nonetheless, especially for interactive use, or when you do not know anything about the structure of the expression, simplify() tries to apply intelligent heuristics to make the input expression “simpler”. For example:

```python
>>> from sympy import simplify, cos, sin
>>> from sympy.abc import x, y

>>> a = (x + x**2)/(x*sin(y)**2 + x*cos(y)**2)
```

(continues on next page)
Note that we could have obtained the same result by using specific simplification functions:

```python
>>> from sympy import trigsimp, cancel
>>> trigsimp(a)
(x**2 + x)/x
>>> cancel(_)
x + 1
```

In some cases, applying `simplify()` (page 719) may actually result in some more complicated expression. The default ratio=1.7 prevents more extreme cases: if (result length)/(input length) > ratio, then input is returned unmodified. The measure parameter lets you specify the function used to determine how complex an expression is. The function should take a single argument as an expression and return a number such that if expression a is more complex than expression b, then measure(a) > measure(b). The default measure function is `count_ops()` (page 1105), which returns the total number of operations in the expression.

For example, if ratio=1, simplify output cannot be longer than input.

```python
>>> from sympy import sqrt, simplify, count_ops, oo
>>> root = 1/(sqrt(2)+3)
```

Since `simplify(root)` would result in a slightly longer expression, root is returned unchanged instead:

```python
>>> simplify(root, ratio=1) == root
True
```

If ratio=oo, simplify will be applied anyway:

```python
>>> count_ops(simplify(root, ratio=oo)) > count_ops(root)
True
```

Note that the shortest expression is not necessary the simplest, so setting ratio to 1 may not be a good idea. Heuristically, the default value ratio=1.7 seems like a reasonable choice.

You can easily define your own measure function based on what you feel should represent the “size” or “complexity” of the input expression. Note that some choices, such as `lambda expr: len(str(expr))` may appear to be good metrics, but have other problems (in this case, the measure function may slow down simplify too much for very large expressions). If you do not know what a good metric would be, the default, `count_ops`, is a good one.

For example:
So you can see that \( h \) is simpler than \( g \) using the \texttt{count_ops} metric. However, we may not like how \texttt{simplify} (in this case, using \texttt{logcombine}) has created the \( b^{**(\log(1/a) + 1)} \) term. A simple way to reduce this would be to give more weight to powers as operations in \texttt{count_ops}. We can do this by using the \texttt{visual=True} option:

```
>>> print(count_ops(g, visual=True))
2*ADD + DIV + 4*LOG + MUL
>>> print(count_ops(h, visual=True))
2*LOG + MUL + POW + SUB
```

Note that because \texttt{simplify()} internally tries many different simplification strategies and then compares them using the measure function, we get a completely different result that is still different from the input expression by doing this.

If \texttt{rational=True}, Floats will be recast as Rationals before simplification. If \texttt{rational=None}, Floats will be recast as Rationals but the result will be recast as Floats. If \texttt{rational=False} (default) then nothing will be done to the Floats.

If \texttt{inverse=True}, it will be assumed that a composition of inverse functions, such as \( \sin \) and \( \arcsin \), can be cancelled in any order. For example, \( \arcsin(\sin(x)) \) will yield \( x \) without checking whether \( x \) belongs to the set where this relation is true. The default is False.

Note that \texttt{simplify()} automatically calls \texttt{doit()} on the final expression. You can avoid this behavior by passing \texttt{doit=False} as an argument.

Also, it should be noted that simplifying a boolean expression is not well defined. If the expression prefers automatic evaluation (such as \texttt{Eq()} (page 1070) or \texttt{Or()} (page 1211)), simplification will return True or False if truth value can be determined. If the expression is not evaluated by default (such as \texttt{Predicate()} (page 253)), simplification will not
reduce it and you should use `refine()` (page 255) or `ask()` (page 249) function. This inconsistency will be resolved in future version.

**See also:**

- `sympy.assumptions.refine.refine` *(page 255)*
  - Simplification using assumptions.

- `sympy.assumptions.ask.ask` *(page 249)*
  - Query for boolean expressions using assumptions.

`sympy.simplify.simplify.separatevars(expr, symbols=[], dict=False, force=False)`

Separates variables in an expression, if possible. By default, it separates with respect to all symbols in an expression and collects constant coefficients that are independent of symbols.

**Explanation**

If `dict=True` then the separated terms will be returned in a dictionary keyed to their corresponding symbols. By default, all symbols in the expression will appear as keys; if symbols are provided, then all those symbols will be used as keys, and any terms in the expression containing other symbols or non-symbols will be returned keyed to the string 'coeff'. (Passing None for symbols will return the expression in a dictionary keyed to 'coeff'.)

If `force=True`, then bases of powers will be separated regardless of assumptions on the symbols involved.

**Notes**

The order of the factors is determined by Mul, so that the separated expressions may not necessarily be grouped together.

Although factoring is necessary to separate variables in some expressions, it is not necessary in all cases, so one should not count on the returned factors being factored.

**Examples**

```python
>>> from sympy.abc import x, y, z, alpha
>>> from sympy import separatevars, sin
>>> separatevars((x*y)**y)
(x*y)**y
>>> separatevars((x*y)**y, force=True)
x**y*y**y
```

```python
>>> e = 2*x**2*z*sin(y)+2*z*x**2
>>> separatevars(e)
2*x**2*z*(sin(y) + 1)
>>> separatevars(e, symbols=(x, y), dict=True)
{'coeff': 2*z, x: x**2, y: sin(y) + 1}
>>> separatevars(e, [x, y, alpha], dict=True)
{'coeff': 2*z, alpha: 1, x: x**2, y: sin(y) + 1}
```
If the expression is not really separable, or is only partially separable, separatevars will do the best it can to separate it by using factoring.

```python
>>> separatevars(x + x*y - 3*x**2)
-x*(3*x - y - 1)
```

If the expression is not separable then expr is returned unchanged or (if dict=True) then None is returned.

```python
>>> eq = 2*x + y*sin(x)
>>> separatevars(eq) == eq
True
>>> separatevars(2*x + y*sin(x), symbols=(x, y), dict=True) is None
True
```

```python
sympy.simplify.simplify.nthroot(expr, n, max_len=4, prec=15)
Compute a real nth-root of a sum of surds.

Parameters
expr : sum of surds
n : integer
max_len : maximum number of surds passed as constants to nsimplify

Algorithm
First nsimplify is used to get a candidate root; if it is not a root the minimal polynomial is computed; the answer is one of its roots.

Examples
```python
>>> from sympy.simplify.simplify import nthroot
>>> nthroot(90 + 34*sqrt(7), 3)
sqrt(7) + 3
```

```python
sympy.simplify.simplify.kroneckersimp(expr)
Simplify expressions with KroneckerDelta.
The only simplification currently attempted is to identify multiplicative cancellation:

Examples
```python
>>> from sympy.abc import i
>>> kroneckersimp(1 + KroneckerDelta(0, i) * KroneckerDelta(1, i))
1
```

```python
sympy.simplify.simplify.besselsimp(expr)
Simplify bessel-type functions.

5.8. Topics
Explanation

This routine tries to simplify bessel-type functions. Currently it only works on the Bessel J and I functions, however. It works by looking at all such functions in turn, and eliminating factors of "I" and "-1" (actually their polar equivalents) in front of the argument. Then, functions of half-integer order are rewritten using strigonometric functions and functions of integer order (> 1) are rewritten using functions of low order. Finally, if the expression was changed, compute factorization of the result with factor().

```python
>>> from sympy import besselj, besseli, besselsimp, polar_lift, I, S
>>> from sympy.abc import z, nu
>>> besselsimp(besselj(nu, z*polar_lift(-1)))
exp(I*pi*nu)*besselj(nu, z)
>>> besselsimp(besseli(nu, z*polar_lift(-I)))
exp(-I*pi*nu/2)*besselj(nu, z)
>>> besselsimp(besseli(S(-1)/2, z))
sqrt(2)*cosh(z)/(sqrt(pi)*sqrt(z))
>>> besselsimp(z*besseli(0, z) + z*(besseli(2, z))/2 + besseli(1, z))
3*z*besseli(0, z)/2
```

sympy.simplify.simplify.hypersimp(f, k)

Given combinatorial term f(k) simplify its consecutive term ratio i.e. f(k+1)/f(k). The input term can be composed of functions and integer sequences which have equivalent representation in terms of gamma special function.

Explanation

The algorithm performs three basic steps:

1. Rewrite all functions in terms of gamma, if possible.
2. Rewrite all occurrences of gamma in terms of products of gamma and rising factorial with integer, absolute constant exponent.
3. Perform simplification of nested fractions, powers and if the resulting expression is a quotient of polynomials, reduce their total degree.

If f(k) is hypergeometric then as result we arrive with a quotient of polynomials of minimal degree. Otherwise None is returned.

For more information on the implemented algorithm refer to:

sympy.simplify.simplify.hypersimilar(f, g, k)

Returns True if f and g are hyper-similar.
Explanation

Similarity in hypergeometric sense means that a quotient of \( f(k) \) and \( g(k) \) is a rational function in \( k \). This procedure is useful in solving recurrence relations.

For more information see hypersimp().

```
sympy.simplify.simplify nsimplify(expr, constants=(), tolerance=None, full=False, rational=None, rational_conversion='base10')
```

Find a simple representation for a number or, if there are free symbols or if rational=True, then replace Floats with their Rational equivalents. If no change is made and rational is not False then Floats will at least be converted to Rationals.

Explanation

For numerical expressions, a simple formula that numerically matches the given numerical expression is sought (and the input should be possible to evafl to a precision of at least 30 digits).

Optionally, a list of (rationally independent) constants to include in the formula may be given.

A lower tolerance may be set to find less exact matches. If no tolerance is given then the least precise value will set the tolerance (e.g. Floats default to 15 digits of precision, so would be tolerance=10**-15).

With full=True, a more extensive search is performed (this is useful to find simpler numbers when the tolerance is set low).

When converting to rational, if rational_conversion='base10' (the default), then convert floats to rationals using their base-10 (string) representation. When rational_conversion='exact' it uses the exact, base-2 representation.

Examples

```python
>>> from sympy import nsimplify, sqrt, GoldenRatio, exp, I, pi
>>> nsimplify(4/(1+sqrt(5)), [GoldenRatio])
-2 + 2*GoldenRatio
>>> nsimplify((1/(exp(3*pi*I/5)+1)))
1/2 - I*sqrt(sqrt(5)/10 + 1/4)
>>> nsimplify(I**I, [pi])
exp(-pi/2)
>>> nsimplify(pi, tolerance=0.01)
22/7
>>> nsimplify(0.333333333333333, rational=True, rational_conversion='exact')
0.333333333333333
>>> nsimplify(0.333333333333333, rational=True)
1/3
```

See also:

sympy.core.function.nfloat (page 1110)
sympy.simplify.simplify.posify(eq)

Return eq (with generic symbols made positive) and a dictionary containing the mapping between the old and new symbols.

**Explanation**

Any symbol that has positive=None will be replaced with a positive dummy symbol having the same name. This replacement will allow more symbolic processing of expressions, especially those involving powers and logarithms.

A dictionary that can be sent to subs to restore eq to its original symbols is also returned.

```python
from sympy import posify, Symbol, log, solve
from sympy.abc import x

posify(x + Symbol('p', positive=True) + Symbol('n', negative=True))
(_x + n + p, {_x: x})

>> eq = 1/x
log(eq).expand()
log(1/x)
log(posify(eq)[0]).expand()
-log(_x)

p, rep = posify(eq)
log(p).expand().subs(rep)
-log(x)
```

It is possible to apply the same transformations to an iterable of expressions:

```python
>> eq = x**2 - 4
solve(eq, x)
[-2, 2]

>> solve(posify([eq, x]); eq)
[2]
```

sympy.simplify.simplify.logcombine(expr, force=False)

Takes logarithms and combines them using the following rules:

- \( \log(x) + \log(y) = \log(xy) \) if both are positive
- \( a \log(x) = \log(x^a) \) if \( x \) is positive and \( a \) is real

If force is True then the assumptions above will be assumed to hold if there is no assumption already in place on a quantity. For example, if \( a \) is imaginary or the argument negative, force will not perform a combination but if \( a \) is a symbol with no assumptions the change will take place.
Examples

```python
>>> from sympy import Symbol, symbols, log, logcombine, I
>>> from sympy.abc import a, x, y, z
>>> logcombine(a*log(x) + log(y) - log(z))
a*log(x) + log(y) - log(z)
>>> logcombine(a*log(x) + log(y) - log(z), force=True)
log(x**a*y/z)
>>> x, y, z = symbols('x, y, z', positive=True)
>>> a = Symbol('a', real=True)
>>> logcombine(a*log(x) + log(y) - log(z))
log(x**a*y/z)
```

The transformation is limited to factors and/or terms that contain logs, so the result depends on the initial state of expansion:

```python
>>> eq = (2 + 3*I)*log(x)
>>> logcombine(eq, force=True) == eq
True
>>> logcombine(eq.expand(), force=True)
log(x**2) + I*log(x**3)
```

See also:

- **posify** *(page 725)*
  replace all symbols with symbols having positive assumptions

- **sympy.core.function.expand_log** *(page 1107)*
  expand the logarithms of products and powers; the opposite of logcombine

**sympy.simplify.radsimp** *(page 725)*

Rationalize the denominator by removing square roots.

Explanation

The expression returned from radsimp must be used with caution since if the denominator contains symbols, it will be possible to make substitutions that violate the assumptions of the simplification process: that for a denominator matching a + b*sqrt(c), a != +/-b*sqrt(c). (If there are no symbols, this assumptions is made valid by collecting terms of sqrt(c) so the match variable a does not contain sqrt(c).) If you do not want the simplification to occur for symbolic denominators, set symbolic to False.

If there are more than max_terms radical terms then the expression is returned unchanged.
Examples

```python
>>> from sympy import radsimp, sqrt, Symbol, pprint
>>> from sympy import factor_terms, fraction, signsimp
>>> from sympy.simplify.radsimp import collect_sqrt
>>> from sympy.abc import a, b, c

>>> radsimp(1/(2 + sqrt(2)))
(2 - sqrt(2))/2
>>> x, y = map(Symbol, 'xy')
>>> e = ((2 + 2*sqrt(2))*x + (2 + sqrt(8))*y)/(2 + sqrt(2))
>>> radsimp(e)
sqrt(2)*(x + y)

No simplification beyond removal of the gcd is done. One might want to polish the result a little, however, by collecting square root terms:

```python
>>> r2 = sqrt(2)
>>> r5 = sqrt(5)
>>> ans = radsimp(1/(y*r2 + x*r2 + a*r5 + b*r5)); pprint(ans)

\[
\frac{\sqrt{5}a + \sqrt{5}b - \sqrt{2}x - \sqrt{2}y}{5*a + 10*a*b + 5*b - 2*x - 4*x*y - 2*y}
\]

```python
>>> n, d = fraction(ans)
>>> pprint(factor_terms(signsimp(collect_sqrt(n))/d, radical=True))

\[
\frac{\sqrt{5}(a + b) - \sqrt{2}(x + y)}{5*a + 10*a*b + 5*b - 2*x - 4*x*y - 2*y}
\]

If radicals in the denominator cannot be removed or there is no denominator, the original expression will be returned.

```python
>>> radsimp(sqrt(2)*x + sqrt(2))
sqrt(2)*x + sqrt(2)

Results with symbols will not always be valid for all substitutions:

```python
>>> eq = 1/(a + b*sqrt(c))
>>> eq.subs(a, b*sqrt(c))
1/(2*b*sqrt(c))
>>> radsimp(eq).subs(a, b*sqrt(c))
nan
```

If symbolic=False, symbolic denominators will not be transformed (but numeric denominators will still be processed):

```python
>>> radsimp(eq, symbolic=False)
1/(a + b*sqrt(c))
```
**rad_rationalize** *(num, den)*

Rationalize num/den by removing square roots in the denominator; num and den are sum of terms whose squares are positive rationals.

**Examples**

```python
>>> from sympy import sqrt
>>> from sympy.simplify.radsimp import rad_rationalize
>>> rad_rationalize(sqrt(3), 1 + sqrt(2)/3)
(-sqrt(3) + sqrt(6)/3, -7/9)
```

**collect**(expr, syms, func=None, evaluate=None, exact=False, distribute_order_term=True)

Collect additive terms of an expression.

**Explanation**

This function collects additive terms of an expression with respect to a list of expression up to powers with rational exponents. By the term symbol here are meant arbitrary expressions, which can contain powers, products, sums etc. In other words symbol is a pattern which will be searched for in the expression’s terms.

The input expression is not expanded by *collect()* (page 729), so user is expected to provide an expression in an appropriate form. This makes *collect()* (page 729) more predictable as there is no magic happening behind the scenes. However, it is important to note, that powers of products are converted to products of powers using the *expand_power_base()* (page 1109) function.

There are two possible types of output. First, if evaluate flag is set, this function will return an expression with collected terms or else it will return a dictionary with expressions up to rational powers as keys and collected coefficients as values.

**Examples**

```python
>>> from sympy import S, collect, expand, factor, Wild
>>> from sympy.abc import a, b, c, x, y
```

This function can collect symbolic coefficients in polynomials or rational expressions. It will manage to find all integer or rational powers of collection variable:

```python
>>> collect(a*x**2 + b*x**2 + a*x - b*x + c, x)  
c + x**2*(a + b) + x*(a - b)
```

The same result can be achieved in dictionary form:

```python
>>> d = collect(a*x**2 + b*x**2 + a*x - b*x + c, x, evaluate=False)  
>>> d[x**2]  
a + b  
>>> d[x]  
a - b
```

(continues on next page)
You can also work with multivariate polynomials. However, remember that this function is greedy so it will care only about a single symbol at time, in specification order:

```
>>> collect(x**2 + y*x**2 + x*y + y + a*y, [x, y])
x**2*(y + 1) + x*y + y*(a + 1)
```

Also more complicated expressions can be used as patterns:

```
>>> from sympy import sin, log
>>> collect(a*sin(2*x) + b*sin(2*x), sin(2*x))
(a + b)*sin(2*x)
>>> collect(a*x*log(x) + b*(x*log(x)), x*log(x))
x*(a + b)*log(x)
```

You can use wildcards in the pattern:

```
>>> w = Wild('w1')
>>> collect(a*x**y - b*x**y, w**y)
x**y*(a - b)
```

It is also possible to work with symbolic powers, although it has more complicated behavior, because in this case power’s base and symbolic part of the exponent are treated as a single symbol:

```
>>> collect(a*x**c + b*x**c, x)
a*x**c + b*x**c
>>> collect(a*x**c + b*x**c, x**c)
x**c*(a + b)
```

However if you incorporate rationals to the exponents, then you will get well known behavior:

```
>>> collect(a*x**(2*c) + b*x**(2*c), x**c)
x**(2*c)*(a + b)
```

Note also that all previously stated facts about `collect()` (page 729) function apply to the exponential function, so you can get:

```
>>> from sympy import exp
>>> collect(a*exp(2*x) + b*exp(2*x), exp(x))
(a + b)*exp(2*x)
```

If you are interested only in collecting specific powers of some symbols then set exact flag to True:

```
>>> collect(a*x**7 + b*x**7, x, exact=True)
a*x**7 + b*x**7
>>> collect(a*x**7 + b*x**7, x**7, exact=True)
x**7*(a + b)
```
If you want to collect on any object containing symbols, set exact to None:

```python
>>> collect(x*exp(x) + sin(x)*y + sin(x)*2 + 3*x, x, exact=None)
```

```
x*exp(x) + 3*x + (y + 2)*sin(x)
```  

```python
>>> collect(a*x*y + x*y + b*x + x, [x, y], exact=None)
```

```
x*y*(a + 1) + x*(b + 1)
```  

You can also apply this function to differential equations, where derivatives of arbitrary order can be collected. Note that if you collect with respect to a function or a derivative of a function, all derivatives of that function will also be collected. Use exact=True to prevent this from happening:

```python
>>> from sympy import Derivative as D, collect, Function
```

```python
>>> f = Function('f')(x)
```

```python
>>> collect(a*D(f,x) + b*D(f,x), D(f,x))
```

```
(a + b)*Derivative(f(x), x)
```  

```python
>>> collect(a*D(D(f,x),x) + b*D(D(f,x),x), f)
```

```
(a + b)*Derivative(f(x), (x, 2))
```  

```python
>>> collect(a*D(D(f,x),x) + b*D(D(f,x),x), D(f,x), exact=True)
```

```
a*Derivative(f(x), (x, 2)) + b*Derivative(f(x), (x, 2))
```  

```python
>>> collect(a*D(f,x) + b*D(f,x) + a*f + b*f, f)
```

```
(a + b)*f(x) + (a + b)*Derivative(f(x), x)
```  

Or you can even match both derivative order and exponent at the same time:

```python
>>> collect(a*D(D(f,x),x)**2 + b*D(D(f,x),x)**2, D(f,x))
```

```
(a + b)*Derivative(f(x), (x, 2))**2
```  

Finally, you can apply a function to each of the collected coefficients. For example you can factorize symbolic coefficients of polynomial:

```python
>>> f = expand((x + a + 1)**3)
```

```python
>>> collect(f, x, factor)
```

```
x**3 + 3*x**2*(a + 1) + 3*x*(a + 1)**2 + (a + 1)**3
```  

**Note:** Arguments are expected to be in expanded form, so you might have to call `expand()` (page 1099) prior to calling this function.

**See also:**

- `collect_const` (page 732)
- `collect_sqrt` (page 732)
- `rcollect` (page 731)
- `sympy.simplify.radsimp.rcollect(expr, *vars)`

Recursively collect sums in an expression.
Examples

```python
>>> from sympy.simplify import rcollect
>>> from sympy.abc import x, y

>>> expr = (x**2*y + x*y + x + y)/(x + y)

>>> rcollect(expr, y)
(x + y*(x**2 + x + 1))/(x + y)
```

See also:

- `collect` (page 729), `collect_const` (page 732), `collect_sqrt` (page 732)

```
sympy.simplify.radsimp.collect_sqrt(expr, evaluate=None)
```

Return `expr` with terms having common square roots collected together. If `evaluate` is `False` a count indicating the number of sqrt-containing terms will be returned and, if non-zero, the terms of the Add will be returned, else the expression itself will be returned as a single term. If `evaluate` is `True`, the expression with any collected terms will be returned.

Note: since I = sqrt(-1), it is collected, too.

Examples

```python
>>> from sympy import sqrt

>>> from sympy.simplify.radsimp import collect_sqrt
>>> from sympy.abc import a, b

>>> r2, r3, r5 = [sqrt(i) for i in [2, 3, 5]]
>>> collect_sqrt(a*r2 + b*r2)
sqrt(2)*(a + b)
>>> collect_sqrt(a*r2 + b*r2 + a*r3 + b*r3)
sqrt(2)*(a + b) + sqrt(3)*(a + b)
>>> collect_sqrt(a*r2 + b*r2 + a*r3 + b*r5)
sqrt(2)*a + sqrt(5)*b + sqrt(2)*(a + b)
```

If `evaluate` is `False` then the arguments will be sorted and returned as a list and a count of the number of sqrt-containing terms will be returned:

```python
>>> collect_sqrt(a*r2 + b*r2 + a*r3 + b*r5, evaluate=False)
((sqrt(3)*a, sqrt(5)*b, sqrt(2)*(a + b)), 3)
>>> collect_sqrt(a*sqrt(2) + b, evaluate=False)
((b, sqrt(2)*a), 1)
>>> collect_sqrt(a + b, evaluate=False)
((a + b,), 0)
```

See also:

- `collect` (page 729), `collect_const` (page 732), `rcollect` (page 731)

```
sympy.simplify.radsimp.collect_const(expr, *vars, Numbers=True)
```

A non-greedy collection of terms with similar number coefficients in an Add `expr`. If
vars is given then only those constants will be targeted. Although any Number can also be targeted, if this is not desired set Numbers=False and no Float or Rational will be collected.

**Parameters**

**expr** : SymPy expression

This parameter defines the expression the expression from which terms with similar coefficients are to be collected. A non-Add expression is returned as it is.

**vars** : variable length collection of Numbers, optional

Specifies the constants to target for collection. Can be multiple in number.

**Numbers** : bool

Specifies to target all instance of sympy.core.numbers.Number (page 1033) class. If Numbers=False, then no Float or Rational will be collected.

**Returns**

**expr** : Expr

Returns an expression with similar coefficient terms collected.

**Examples**

```python
>>> from sympy import sqrt
>>> from sympy.abc import s, x, y, z
>>> from sympy.simplify.radsimp import collect_const
>>> collect_const(sqrt(3) + sqrt(3)*(1 + sqrt(2)))
sqrt(3)*(sqrt(2) + 2)
```

The collection is sign-sensitive, giving higher precedence to the unsigned values:

```python
>>> collect_const(x - y - z)
x - (y + z)
>>> collect_const(-y - z)
-(y + z)
```

See also:

collect (page 729), collect_sqrt (page 732), rcollect (page 731)
sympy.simplify.radsimp.fraction(expr, exact=False)

Returns a pair with expression’s numerator and denominator. If the given expression is not a fraction then this function will return the tuple (expr, 1).

This function will not make any attempt to simplify nested fractions or to do any term rewriting at all.

If only one of the numerator/denominator pair is needed then use numer(expr) or denom(expr) functions respectively.

```python
>>> from sympy import fraction, Rational, Symbol
>>> from sympy.abc import x, y

>>> fraction(x/y)
(x, y)
>>> fraction(x)
(x, 1)

>>> fraction(1/y**2)
(1, y**2)
>>> fraction(x*y/2)
(x*y, 2)
>>> fraction(Rational(1, 2))
(1, 2)
```

This function will also work fine with assumptions:

```python
>>> k = Symbol('k', negative=True)
>>> fraction(x * y**k)
(x, y**(k))
```

If we know nothing about sign of some exponent and exact flag is unset, then structure this exponent’s structure will be analyzed and pretty fraction will be returned:

```python
>>> from sympy import exp, Mul

>>> fraction(2*x**(y))
(2, x**y)

>>> fraction(exp(-x))
(1, exp(x))

>>> fraction(exp(-x), exact=True)
(exp(-x), 1)
```

The exact flag will also keep any unevaluated Muls from being evaluated:

```python
>>> u = Mul(2, x + 1, evaluate=False)
>>> fraction(u)
(2*x + 2, 1)
>>> fraction(u, exact=True)
(2*(x + 1), 1)
```
sympy.simplify.ratsimp.ratsimp(expr)

Put an expression over a common denominator, cancel and reduce.

**Examples**

```python
>>> from sympy import ratsimp
>>> from sympy.abc import x, y
>>> ratsimp(1/x + 1/y)
(x + y)/(x*y)
```

sympy.simplify.ratsimp.ratsimpmodprime(expr, G, *gens, quick=True, polynomial=False, **args)

Simplifies a rational expression expr modulo the prime ideal generated by G. G should be a Groebner basis of the ideal.

**Examples**

```python
>>> from sympy.simplify.ratsimp import ratsimpmodprime
>>> from sympy.abc import x, y
>>> eq = (x + y**5 + y)/(x - y)
>>> ratsimpmodprime(eq, [x*y**5 - x - y], x, y, order='lex')
(-x**2 - x*y - x - y)/(-x**2 + x*y)
```

If polynomial is False, the algorithm computes a rational simplification which minimizes the sum of the total degrees of the numerator and the denominator.

If polynomial is True, this function just brings numerator and denominator into a canonical form. This is much faster, but has potentially worse results.

**References**

[R787]

sympy.simplify.trigsimp.trigsimp(expr, inverse=False, **opts)

Returns a reduced expression by using known trig identities.

**Parameters**

- inverse : bool, optional
  If inverse=True, it will be assumed that a composition of inverse functions, such as sin and asin, can be cancelled in any order. For example, asin(sin(x)) will yield x without checking whether x belongs to the set where this relation is true. The default is False. Default : True

- method : string, optional
  Specifies the method to use. Valid choices are:
  - 'matching', default
  - 'groebner'
  - 'combined'
• 'fu'
• 'old'

If 'matching', simplify the expression recursively by targeting common patterns. If 'groebner', apply an experimental groebner basis algorithm. In this case further options are forwarded to trigsimp_groebner, please refer to its docstring. If 'combined', it first runs the groebner basis algorithm with small default parameters, then runs the 'matching' algorithm. If 'fu', run the collection of trigonometric transformations described by Fu, et al. (see the fu() (page 768) docstring). If 'old', the original SymPy trig simplification function is run.

**opts:**

Optional keyword arguments passed to the method. See each method's function docstring for details.

**Examples**

```python
>>> from sympy import trigsimp, sin, cos, log
>>> from sympy.abc import x
>>> e = 2*sin(x)**2 + 2*cos(x)**2
>>> trigsimp(e)
2

Simplification occurs wherever trigonometric functions are located.

```python
>>> trigsimp(log(e))
log(2)
```

Using method='groebner' (or method='combined') might lead to greater simplification. The old trigsimp routine can be accessed as with method method='old'.

```python
>>> from sympy import coth, tanh
>>> t = 3*tanh(x)**7 - 2/coth(x)**7
>>> trigsimp(t, method='old') == t
True
>>> trigsimp(t)
tanh(x)**7
```

**sympy.simplify.powsimp.powsimp**(expr, deep=False, combine='all', force=False, measure=<function count_ops>)

Reduce expression by combining powers with similar bases and exponents.
Explanation

If deep is True then powsimp() will also simplify arguments of functions. By default deep is set to False.

If force is True then bases will be combined without checking for assumptions, e.g. sqrt(x)*sqrt(y) -> sqrt(x*y) which is not true if x and y are both negative.

You can make powsimp() only combine bases or only combine exponents by changing combine='base' or combine='exp'. By default, combine='all', which does both. combine='base' will only combine:

\[
\begin{array}{ccl}
\ a\ a\ a & & 2x \ x \\
x \ast \ y & => & (x \ast y)
\end{array}
\]
as well as things like 2 => 4

and combine='exp' will only combine

\[
\begin{array}{ccl}
\ a\ b & & (a + b) \\
x \ast \ x & => & x
\end{array}
\]

combine='exp' will strictly only combine exponents in the way that used to be automatic. Also use deep=True if you need the old behavior.

When combine='all', 'exp' is evaluated first. Consider the first example below for when there could be an ambiguity relating to this. This is done so things like the second example can be completely combined. If you want 'base' combined first, do something like powsimp(powsimp(expr, combine='base'), combine='exp').

Examples

```python
>>> from sympy import powsimp, exp, log, symbols
>>> from sympy.abc import x, y, z, n

>>> powsimp(x**y*x**z*y**z, combine='all')
\(x^{y + z} y^{y + z}\)

>>> powsimp(x**y*x**z*y**z, combine='exp')
\(x^{y + z} y^{y + z}\)

>>> powsimp(x**y*x**z*y**z, combine='base', force=True)
\(x^y (x + y)^z\)

>>> powsimp(x**z*x**y*n**z*n**y, combine='all', force=True)
\((n x)^{y + z}\)

>>> powsimp(x**z*x**y*n**z*n**y, combine='exp')
\(n^{y + z} x^{y + z}\)

>>> powsimp(x**z*x**y*n**z*n**y, combine='base', force=True)
\((n x)^y (n x)^z\)

>>> x, y = symbols('x y', positive=True)

>>> powsimp(log(exp(x)*exp(y)))
\(\log(e^x e^y)\)

>>> powsimp(log(exp(x)*exp(y)), deep=True)
\(x + y\)
```

Radicals with Mul bases will be combined if combine='exp'
Two radicals are automatically joined through Mul:

```python
>>> a = sqrt(x*sqrt(y))
>>> a**3 == a**4
True
```

But if an integer power of that radical has been autoexpanded then Mul does not join the resulting factors:

```python
>>> a**4  # auto expands to a Mul, no longer a Pow
x**2*y
>>> _a  # so Mul doesn't combine them
x**2*y*sqrt(x*sqrt(y))
```

**Explanation**

Given \((bb**be)**e\), this can be simplified as follows:

- if \(bb\) is positive, or
- \(e\) is an integer, or
- \(|be| < 1\) then this simplifies to \(bb**(be*e)\)

Given a product of powers raised to a power, \((bb1**be1 * bb2**be2...)**e\), simplification can be done as follows:

- if \(e\) is positive, the gcd of all \(bei\) can be joined with \(e\);
- all non-negative \(bb\) can be separated from those that are negative and their gcd can be joined with \(e\); autosimplification already handles this separation.
- integer factors from powers that have integers in the denominator of the exponent can be removed from any term and the gcd of such integers can be joined with \(e\)

Setting `force` to `True` will make symbols that are not explicitly negative behave as though they are positive, resulting in more denesting.

Setting `polar` to `True` will do simplifications on the Riemann surface of the logarithm, also resulting in more denestings.

When there are sums of logs in `exp()` then a product of powers may be obtained e.g. `exp(3*(log(a) + 2*log(b)))` -> \(a**3*b**6\).
Examples

```python
>>> from sympy.abc import a, b, x, y, z
>>> from sympy import Symbol, exp, log, sqrt, symbols, powdenest

>>> powdenest((x**2*a/3)**(3*x))
(x**(2*a/3))**(3*x)
>>> powdenest(exp(3*x*log(2)))
2**(3*x)

Assumptions may prevent expansion:

>>> powdenest(sqrt(x**2))
sqrt(x**2)

>>> p = symbols('p', positive=True)
>>> powdenest(sqrt(p**2))
p

No other expansion is done.

>>> i, j = symbols('i,j', integer=True)
>>> powdenest((x**x)**(i + j)) # -X-> (x**x)**i*(x**x)**j
x**(x*(i + j))

But exp() will be denested by moving all non-log terms outside of the function; this may result in the collapsing of the exp to a power with a different base:

>>> powdenest(exp(3*y*log(x)))
x**(3*y)
>>> powdenest(exp(y*(log(a) + log(b))))
(a*b)**y
>>> powdenest(exp(3*(log(a) + log(b))))
a**3*b**3

If assumptions allow, symbols can also be moved to the outermost exponent:

>>> i = Symbol('i', integer=True)
>>> powdenest(((x**(2*i))**(3*y))**x)
((x**(2*i))**(3*y))**x
>>> powdenest(((x**(2*i))**(3*y))**x, force=True)
x**(6*i*x*y)

>>> powdenest(((x**(2*a/3))**(3*y/i))**x)
((x**(2*a/3))**(3*y/i))**x
>>> powdenest(((x**(2*i)*y**(4*i))**z, force=True)
(x*y**(2*i)*y**(4*i))**z

>>> n = Symbol('n', negative=True)

>>> powdenest((x**i)**y, force=True)
x**(i*y)
```

(continues on next page)
sympy.simplify.combsimp.combsimp(expr)

Simplify combinatorial expressions.

Explanation

This function takes as input an expression containing factorials, binomials, Pochhammer symbol and other “combinatorial” functions, and tries to minimize the number of those functions and reduce the size of their arguments.

The algorithm works by rewriting all combinatorial functions as gamma functions and applying gammasimp() except simplification steps that may make an integer argument non-integer. See docstring of gammasimp for more information.

Then it rewrites expression in terms of factorials and binomials by rewriting gammas as factorials and converting (a+b)!/a!/b! into binomials.

If expression has gamma functions or combinatorial functions with non-integer argument, it is automatically passed to gammasimp.

Examples

```python
>>> from sympy.simplify import combsimp
>>> from sympy import factorial, binomial, symbols
>>> n, k = symbols('n k', integer=True)

>>> combsimp(factorial(n)/factorial(n - 3))
n*(n - 2)*(n - 1)

>>> combsimp(binomial(n+1, k+1)/binomial(n, k))
(n + 1)/(k + 1)
```

sympy.simplify.sqrtdenest.sqrtdenest(expr, max_iter=3)

Denests sqrts in an expression that contain other square roots if possible, otherwise returns the expr unchanged. This is based on the algorithms of [1].

Examples

```python
>>> from sympy.simplify.sqrtdenest import sqrtdenest
>>> from sympy import sqrt

>>> sqrtdenest(sqrt(5 + 2 * sqrt(6)))
sqrt(2) + sqrt(3)
```

References

[R788], [R789]

`sympy.simplify.cse_main.cse(exprs, symbols=None, optimizations=None, postprocess=None, order='canonical', ignore=(), list=True)`

Perform common subexpression elimination on an expression.

**Parameters**

- **exprs**: list of SymPy expressions, or a single SymPy expression
  
The expressions to reduce.

- **symbols**: infinite iterator yielding unique Symbols
  
The symbols used to label the common subexpressions which are pulled out. The numbered_symbols generator is useful. The default is a stream of symbols of the form “x0”, “x1”, etc. This must be an infinite iterator.

- **optimizations**: list of (callable, callable) pairs
  
The (preprocessor, postprocessor) pairs of external optimization functions. Optionally ‘basic’ can be passed for a set of predefined basic optimizations. Such ‘basic’ optimizations were used by default in old implementation, however they can be really slow on larger expressions. Now, no pre or post optimizations are made by default.

- **postprocess**: a function which accepts the two return values of cse and returns the desired form of output from cse, e.g. if you want the replacements reversed the function might be the following lambda: lambda r, e: return reversed(r), e

- **order**: string, ‘none’ or ‘canonical’
  
The order by which Mul and Add arguments are processed. If set to ‘canonical’, arguments will be canonically ordered. If set to ‘none’, ordering will be faster but dependent on expressions hashes, thus machine dependent and variable. For large expressions where speed is a concern, use the setting order='none'.

- **ignore**: iterable of Symbols
  
Substitutions containing any Symbol from ignore will be ignored.

- **list**: bool, (default True)
  
Returns expression in list or else with same type as input (when False).

**Returns**

- **replacements**: list of (Symbol, expression) pairs
  
All of the common subexpressions that were replaced. Subexpressions earlier in this list might show up in subexpressions later in this list.

- **reduced_exprs**: list of SymPy expressions
  
The reduced expressions with all of the replacements above.
Examples

```python
>>> from sympy import cse, SparseMatrix
>>> from sympy.abc import x, y, z, w

>>> cse(((w + x + y + z)*(w + y + z))/(w + x)**3)

([(x0, y + z), (x1, w + x)], [(w + x0)*(x0 + x1)/x1**3])

List of expressions with recursive substitutions:

```python
>>> m = SparseMatrix([[x + y, x + y + z]])
>>> cse([[(x+y)**2, x + y + z, y + z, x + z + y, m]]

([(x0, x + y), (x1, x0 + z)], [x0**2, x1, y + z, x1, Matrix([[x0], [x1]]))]

Note: the type and mutability of input matrices is retained.

```python
>>> isinstance(_[1][-1], SparseMatrix)
True

The user may disallow substitutions containing certain symbols:

```python
>>> cse([(y**2*(x + 1), 3*y**2*(x + 1)], ignore=(y,))

([(x0, x + 1)], [x0*y**2, 3*x0*y**2])

The default return value for the reduced expression(s) is a list, even if there is only one expression. The `list` flag preserves the type of the input in the output:

```python
>>> cse(x)

([], [x])

```python
>>> cse(x, list=False)

([], x)
```

sympy.simplify.cse_main.opt_cse(exprs, order='canonical')

Find optimization opportunities in Adds, Muls, Pows and negative coefficient Muls.

**Parameters**

- **exprs**: list of SymPy expressions
  The expressions to optimize.

- **order**: string, ‘none’ or ‘canonical’
  The order by which Mul and Add arguments are processed. For large expressions where speed is a concern, use the setting order=’none’.

**Returns**

- **opt_subs**: dictionary of expression substitutions
  The expression substitutions which can be useful to optimize CSE.
Examples

```python
>>> from sympy.simplify.cse_main import opt_cse
>>> from sympy.abc import x
>>> opt_subs = opt_cse([x**2])
>>> k, v = list(opt_subs.keys())[0], list(opt_subs.values())[0]
>>> print((k, v.as_unevaluated_basic()))
(x**(-2), 1/(x**2))
```

sympy.simplify.cse_main.tree_cse(exprs, symbols, opt_subs=None, order='canonical', ignore=())

Perform raw CSE on expression tree, taking opt_subs into account.

**Parameters**
- **exprs** : list of SymPy expressions
  The expressions to reduce.
- **symbols** : infinite iterator yielding unique Symbols
  The symbols used to label the common subexpressions which are pulled out.
- **opt_subs** : dictionary of expression substitutions
  The expressions to be substituted before any CSE action is performed.
- **order** : string, ‘none’ or ‘canonical’
  The order by which Mul and Add arguments are processed. For large expressions where speed is a concern, use the setting order=‘none’.
- **ignore** : iterable of Symbols
  Substitutions containing any Symbol from ignore will be ignored.

sympy.simplify.hyperexpand.hyperexpand(f, allow_hyper=False, rewrite='default', place=None)

Expand hypergeometric functions. If allow_hyper is True, allow partial simplification (that is a result different from input, but still containing hypergeometric functions).

If a G-function has expansions both at zero and at infinity, place can be set to 0 or zoo to indicate the preferred choice.

Examples

```python
>>> from sympy.simplify.hyperexpand import hyperexpand
>>> from sympy.functions import hyper
>>> from sympy.abc import z
>>> hyperexpand(hyper([], [], z))
exp(z)
```

Non-hypergeometric parts of the expression and hypergeometric expressions that are not recognised are left unchanged:
class sympy.simplify.epathtools.EPath(path)
Manipulate expressions using paths.

EPath grammar in EBNF notation:

literal ::= /[A-Za-z_][A-Za-z_0-9]*/
number ::= /-?\d+/
type ::= literal
attribute ::= literal "?"
all ::= "*"
slice ::= "[" number? (":" number? (":" number?)?)? "]"
range ::= all | slice
query ::= (type | attribute) ("|") (type | attribute))*
selector ::= range | query range?
path ::= "/" selector ("/") selector)*

See the docstring of the epath() function.

apply(expr, func, args=None, kwargs=None)
Modify parts of an expression selected by a path.

Examples

```python
>>> from sympy.simplify.epathtools import EPath
>>> from sympy import sin, cos, E
>>> from sympy.abc import x, y, z, t

>>> path = EPath("/*/0\Symbol")
>>> expr = [[[x, 1], 2], [(3, y, z)]

>>> path.apply(expr, lambda expr: expr**2)
[[(x**2, 1), 2], [(3, y**2), z]]

>>> path = EPath("/*/\Symbol")
>>> expr = t + sin(x + 1) + cos(x + y + E)

>>> path.apply(expr, lambda expr: 2*expr)
t + sin(2*x + 1) + cos(2*x + 2*y + E)
```
Examples

```python
>>> from sympy.simplify.epathtools import EPath
>>> from sympy import sin, cos, E
>>> from sympy.abc import x, y, z, t

>>> path = EPath("/*/[0]/Symbol")
>>> expr = [((x, 1), 2), ((3, y), z)]

>>> path.select(expr)
[x, y]

>>> path = EPath("/*/*/Symbol")
>>> expr = t + sin(x + 1) + cos(x + y + E)

>>> path.select(expr)
[x, x, y]
```

```python
sympy.simplify.epathtools.epath(path, expr=None, func=None, args=None, kwargs=None)
```

Manipulate parts of an expression selected by a path.

**Parameters**

- **path**: str | EPath
  - A path as a string or a compiled EPath.
- **expr**: Basic | iterable
  - An expression or a container of expressions.
- **func**: callable (optional)
  - A callable that will be applied to matching parts.
- **args**: tuple (optional)
  - Additional positional arguments to `func`.
- **kwargs**: dict (optional)
  - Additional keyword arguments to `func`.

**Explanation**

This function allows to manipulate large nested expressions in single line of code, utilizing techniques to those applied in XML processing standards (e.g. XPath).

If `func` is None, `epath()` (page 745) retrieves elements selected by the `path`. Otherwise it applies `func` to each matching element.

Note that it is more efficient to create an EPath object and use the select and apply methods of that object, since this will compile the path string only once. This function should only be used as a convenient shortcut for interactive use.

This is the supported syntax:
• **select all:** /* Equivalent of for arg in args:.

• **select slice:** /[0] or /[1:5] or /[1:5:2]
   Supports standard Python’s slice syntax.

• **select by type:** /list or /list|tuple
   Emulates isinstance().

• **select by attribute:** /__iter__?
   Emulates hasattr().

**Examples**

```python
>>> from sympy.simplify.epathtools import epath
>>> from sympy import sin, cos, E
>>> from sympy.abc import x, y, z, t

>>> path = "/*/0/ Symbol"
>>> expr = [[[x, 1], 2], [(3, y), z]]

>>> epath(path, expr)
[x, y]
```

```python
>>> epath(path, expr, lambda expr: expr**2)
[[[x**2, 1], 2], [(3, y**2), z]]
```

```python
>>> path = "/*/0/ Symbol"
>>> expr = t + sin(x + 1) + cos(x + y + E)

>>> epath(path, expr)
[x, x, y]
```

```python
>>> epath(path, expr, lambda expr: 2*expr)
t + sin(2*x + 1) + cos(2*x + 2*y + E)
```

**Hypergeometric Expansion**

This page describes how the function `hyperexpand()` (page 743) and related code work. For usage, see the documentation of the `simplify` module.

**Hypergeometric Function Expansion Algorithm**

This section describes the algorithm used to expand hypergeometric functions. Most of it is based on the papers [Roach1996] and [Roach1997].

Recall that the hypergeometric function is (initially) defined as

\[ \sum_{n=0}^{\infty} \frac{(a_1)_n \cdots (a_p)_n}{(b_1)_n \cdots (b_q)_n} \frac{z^n}{n!} \]

It turns out that there are certain differential operators that can change the \(a_p\) and \(p_q\) parameters by integers. If a sequence of such operators is known that converts the set of indices...
$a_r^n$ and $b_r^n$ into $a_p$ and $b_q$, then we shall say the pair $a_p, b_q$ is reachable from $a_r^n, b_r^n$. Our general strategy is thus as follows: given a set $a_p, b_q$ of parameters, try to look up an origin $a_r^n, b_r^n$ for which we know an expression, and then apply the sequence of differential operators to the known expression to find an expression for the Hypergeometric function we are interested in.

**Notation**

In the following, the symbol $a$ will always denote a numerator parameter and the symbol $b$ will always denote a denominator parameter. The subscripts $p, q, r, s$ denote vectors of that length, so e.g. $a_p$ denotes a vector of $p$ numerator parameters. The subscripts $i$ and $j$ denote "running indices", so they should usually be used in conjunction with a "for all $i$". E.g. $a_i < 4$ for all $i$. Uppercase subscripts $I$ and $J$ denote a chosen, fixed index. So for example $a_I > 0$ is true if the inequality holds for the one index $I$ we are currently interested in.

**Incrementing and decrementing indices**

Suppose $a_i \neq 0$. Set $A(a_i) = \frac{e_i \cdot d}{e_i + 1}$. It is then easy to show that $A(a_i) \cdot F_q(a_p|b_q) = F_q(a_p + e_i|b_q)$, where $e_i$ is the $i$-th unit vector. Similarly for $b_j \neq 1$ we set $B(b_j) = \frac{b_j \cdot d}{b_j - 1} + 1$ and find $B(b_j) \cdot F_q(a_p|b_q) = F_q(a_p|b_q - e_i)$. Thus we can increment upper and decrement lower indices at will, as long as we don’t go through zero. The $A(a_i)$ and $B(b_j)$ are called shift operators.

It is also easy to show that $\frac{d}{dz} F_q(a_p|b_q) = F_q(a_p + 1|b_q)$, where $a_p + 1$ is the vector $a_1 + 1, a_2 + 1, \ldots$ and similarly for $b_q + 1$. Combining this with the shift operators, we arrive at one form of the Hypergeometric differential equation: $\frac{d}{dz} \prod_{j=1}^q B(b_j) - \prod_{i=1}^q A(a_i) F_q(a_p|b_q) = 0$. This holds if all shift operators are defined, i.e. if no $a_i = 0$ and no $b_j = 1$. Clearing denominators and multiplying through by $z$ we arrive at the following equation: $z \frac{d}{dz} \prod_{j=1}^q (z \frac{d}{dz} + b_j - 1) - \prod_{i=1}^q (z \frac{d}{dz} + a_i) F_q(a_p|b_q) = 0$. Even though our derivation does not show it, it can be checked that this equation holds whenever the $F_q$ is defined.

Notice that, under suitable conditions on $a_I, b_J$, each of the operators $A(a_i)$, $B(b_j)$ and $\frac{d}{dz}$ can be expressed in terms of $A(a_I)$ or $B(b_J)$. Our next aim is to write the Hypergeometric differential equation as follows: $[X \cdot A(a_I) - r] F_q(a_p|b_q) = 0$, for some operator $X$ and some constant $r$ to be determined. If $r \neq 0$, then we can write this as $z \frac{d}{dz} F_q(a_p|b_q) = r F_q(a_p|b_q)$, and so $\frac{1}{r} X$ undoes the shifting of $A(a_I)$, whence it will be called an inverse-shift operator.

Now $A(a_I)$ exists if $a_I \neq 0$, and then $z \frac{d}{dz} = a_I A(a_I) - r$. Observe also that all the operators $A(a_i)$, $B(b_j)$ and $\frac{d}{dz}$ commute. We have $\prod_{i=1}^p (z \frac{d}{dz} + a_i) = (\prod_{i=1, i \neq I}^p (z \frac{d}{dz} + a_i)) a_I A(a_I)$, so this gives us the first half of $X$. The other half does not have such a nice expression. We find $z \frac{d}{dz} \prod_{j=1}^q (z \frac{d}{dz} + b_j - 1) = (a_I A(a_I) - a_I) \prod_{j=1}^q (a_I A(a_I) - a_I + b_j - 1)$. Since the first half had no constant term, we infer $r = -a_I \prod_{j=1}^q (b_j - 1 - a_I)$.

This tells us under which conditions we can “un-shift” $A(a_I)$, namely when $a_I \neq 0$ and $r \neq 0$. Substituting $a_I - 1$ for $a_I$ then tells us under what conditions we can decrement the index $a_I$. Doing a similar analysis for $B(b_j)$, we arrive at the following rules:

- An index $a_I$ can be decremented if $a_I \neq 1$ and $a_I \neq b_j$ for all $b_j$.
- An index $b_j$ can be incremented if $b_j \neq -1$ and $b_j \neq a_I$ for all $a_I$.
Combined with the conditions (stated above) for the existence of shift operators, we have thus established the rules of the game!

**Reduction of Order**

Notice that, quite trivially, if \( a_I = b_J \), we have \( pF_q \left( \frac{a_p}{b_q} \big| z \right) = p_{-1}F_{q-1} \left( \frac{a_p}{b_q} \big| z \right) \), where \( a_p \) means \( a_p \) with \( a_I \) omitted, and similarly for \( b_q^* \). We call this reduction of order.

In fact, we can do even better. If \( a_I - b_J \in \mathbb{Z}_{>0} \), then it is easy to see that \( \frac{(a_I)_n}{(b_J)_n} \) is actually a polynomial in \( n \). It is also easy to see that \( (z \frac{d}{dz})^k z^n = n^k z^n \). Combining these two remarks we find:

If \( a_I - b_J \in \mathbb{Z}_{>0} \), then there exists a polynomial \( p(n) = p_0 + p_1 n + \cdots \) (of degree \( a_I - b_J \)) such that \( \frac{(a_I)_n}{(b_J)_n} = p(n) \) and \( pF_q \left( \frac{a_p}{b_q} \big| z \right) = \left( p_0 + p_1 z \frac{d}{dz} + p_2 \left(z \frac{d}{dz}\right)^2 + \cdots \right) p_{-1}F_{q-1} \left( \frac{a_p}{b_q} \big| z \right) \).

Thus any set of parameters \( a_p, b_q \) is reachable from a set of parameters \( c_r, d_s \) where \( c_i - d_j \in \mathbb{Z} \) implies \( c_i < d_j \). Such a set of parameters \( c_r, d_s \) is called suitable. Our database of known formulae should only contain suitable origins. The reasons are twofold: firstly, working from suitable origins is easier, and secondly, a formula for a non-suitable origin can be deduced from a lower order formula, and we should put this one into the database instead.

**Moving Around in the Parameter Space**

It remains to investigate the following question: suppose \( a_p, b_q \) and \( a_p^0, b_q^0 \) are both suitable, and also \( a_i - a_i^0 \in \mathbb{Z}, b_j - b_j^0 \in \mathbb{Z} \). When is \( a_p, b_q \) reachable from \( a_p^0, b_q^0 \)? It is clear that we can treat all parameters independently that are incongruent mod 1. So assume that \( a_i \) and \( b_j \) are congruent to \( r \mod 1 \), for all \( i \) and \( j \). The same then follows for \( a_i^0 \) and \( b_j^0 \).

If \( r \neq 0 \), then any such \( a_p, b_q \) is reachable from any \( a_p^0, b_q^0 \). To see this notice that there exist constants \( c, e^0 \), congruent mod 1, such that \( a_i < c < b_j \) for all \( i \) and \( j \), and similarly \( a_i^0 < e^0 < b_j^0 \). If \( n = c - e^0 > 0 \) then we first inverse-shift all the \( b_j^0 \) \( n \) times up, and then similarly shift up all the \( a_i^0 \) \( n \) times. If \( n < 0 \) then we first inverse-shift down the \( a_i^0 \) and then shift down the \( b_j^0 \). This reduces to the case \( c = e^0 \). But evidently we can now shift or inverse-shift around the \( e^0 \) arbitrarily so long as we keep them less than \( c \), and similarly for the \( b_j^0 \) so long as we keep them bigger than \( c \). Thus \( a_p, b_q \) is reachable from \( a_p^0, b_q^0 \).

If \( r = 0 \) then the problem is slightly more involved. WLOG no parameter is zero. We now have one additional complication: no parameter can ever move through zero. Hence \( a_p, b_q \) is reachable from \( a_p^0, b_q^0 \) if and only if the number of \( a_i < 0 \) equals the number of \( a_i^0 < 0 \), and similarly for the \( b_j \) and \( b_j^0 \). But in a suitable set of parameters, all \( b_j > 0 \)! This is because the Hypergeometric function is undefined if one of the \( b_j \) is a non-positive integer and all \( a_i \) are smaller than the \( b_j \). Hence the number of \( b_j \leq 0 \) is always zero.

We can thus associate to every suitable set of parameters \( a_p, b_q \), where no \( a_i = 0 \), the following invariants:

- For every \( r \in [0, 1) \) the number \( \alpha_r \) of parameters \( a_i \equiv r \mod 1 \), and similarly the number \( \beta_r \) of parameters \( b_i \equiv r \mod 1 \).
- The number \( \gamma \) of integers \( a_i \) with \( a_i < 0 \).
The above reasoning shows that $a_p, b_q$ is reachable from $a^0_p, b^0_q$ if and only if the invariants $\alpha_r, \beta_r, \gamma$ all agree. Thus in particular “being reachable from” is a symmetric relation on suitable parameters without zeros.

**Applying the Operators**

If all goes well then for a given set of parameters we find an origin in our database for which we have a nice formula. We now have to apply (potentially) many differential operators to it. If we do this blindly then the result will be very messy. This is because with Hypergeometric type functions, the derivative is usually expressed as a sum of two contiguous functions. Hence if we compute $N$ derivatives, then the answer will involve $2N$ contiguous functions! This is clearly undesirable. In fact we know from the Hypergeometric differential equation that we need at most $\max(p, q + 1)$ contiguous functions to express all derivatives.

Hence instead of differentiating blindly, we will work with a $\mathbb{C}(z)$-module basis: for an origin $a^0_r, b^0_s$ we either store (for particularly pretty answers) or compute a set of $N$ functions (typically $N = \max(r, s + 1)$) with the property that the derivative of any of them is a $\mathbb{C}(z)$-linear combination of them. In formulae, we store a vector $B$ of $N$ functions, a matrix $M$ and a vector $C$ (the latter two with entries in $\mathbb{C}(z)$), with the following properties:

- $z^{F_b(a^0_r | b^0_s)} = CB$
- $z^{\frac{d}{dz}} B = MB$.

Then we can compute as many derivatives as we want and we will always end up with $\mathbb{C}(z)$-linear combination of at most $N$ special functions.

As hinted above, $B$, $M$ and $C$ can either all be stored (for particularly pretty answers) or computed from a single $_pF_q$ formula.

**Loose Ends**

This describes the bulk of the hypergeometric function algorithm. There a few further tricks, described in the hyperexpand.py source file. The extension to Meijer G-functions is also described there.

**Meijer G-Functions of Finite Confluence**

Slater’s theorem essentially evaluates a $G$-function as a sum of residues. If all poles are simple, the resulting series can be recognised as hypergeometric series. Thus a $G$-function can be evaluated as a sum of Hypergeometric functions.

If the poles are not simple, the resulting series are not hypergeometric. This is known as the “confluent” or “logarithmic” case (the latter because the resulting series tend to contain logarithms). The answer depends in a complicated way on the multiplicities of various poles, and there is no accepted notation for representing it (as far as I know). However if there are only finitely many multiple poles, we can evaluate the $G$ function as a sum of hypergeometric functions, plus finitely many extra terms. I could not find any good reference for this, which is why I work it out here.

Recall the general setup. We define
\[
G(z) = \frac{1}{2\pi i} \int_L \prod_{j=1}^{m} \Gamma(b_j - s) \prod_{j=1}^{n} \Gamma(1 - a_j + s) \prod_{j=m+1}^{p} \Gamma(1 - b_j + s) \prod_{j=n+1}^{p} \Gamma(a_j - s) z^s ds,
\]

5.8. Topics 749
where $L$ is a contour starting and ending at $+\infty$, enclosing all of the poles of $\Gamma(b_j - s)$ for $j = 1, \ldots, n$ once in the negative direction, and no other poles. Also the integral is assumed absolutely convergent.

In what follows, for any complex numbers $a, b$, we write $a \equiv b \pmod{1}$ if and only if there exists an integer $k$ such that $a - b = k$. Thus there are double poles iff $a_i \equiv a_j \pmod{1}$ for some $i \neq j \leq n$.

We now assume that whenever $b_j \equiv a_i \pmod{1}$ for $i \leq m$, $j > n$ then $b_j < a_i$. This means that no quotient of the relevant gamma functions is a polynomial, and can always be achieved by "reduction of order". Fix a complex number $c$ such that $\{b_i | b_i \equiv c \pmod{1}, i \leq m\}$ is not empty. Enumerate this set as $b_i, b_i + k_1, \ldots, b_i + k_u$, with $k_i$ non-negative integers. Enumerate similarly $\{a_j | a_j \equiv c \pmod{1}, j > n\}$ as $a_l, a_l + u_1, \ldots, a_l + u_v$. Then $a_l > k_j$ for all $i, j$. For finite confluence, we need to assume $v \geq u$ for all such $c$.

Let $c_1, \ldots, c_u$ be distinct $\pmod{1}$ and exhaust the congruence classes of the $b_i$. I claim

$$G(z) = - \sum_{j=1}^u (F_j(z) + R_j(z)),$$

where $F_j(z)$ is a hypergeometric function and $R_j(z)$ is a finite sum, both to be specified later. Indeed corresponding to every $c_j$ there is a sequence of poles, at mostly finitely many of them multiple poles. This is where the $j$-th term comes from.

Hence fix again $c$, enumerate the relevant $b_i$ as $b_i + k_1, \ldots, b_i + k_u$. We will look at the $a_j$ corresponding to $a_l + l_1, \ldots, a_l + l_u$. The other $a_i$ are not treated specially. The corresponding gamma functions have poles at (potentially) $s = b + r$ for $r = 0, 1, \ldots$. For $r \geq l_u$, pole of the integrand is simple. We thus set

$$R(z) = \sum_{r=0}^{l_u-1} \text{Res}_{s=r+b}.$$

We finally need to investigate the other poles. Set $r = l_u + t$, $t \geq 0$. A computation shows

$$\frac{\Gamma(k_i - l_u - t)}{\Gamma(l_i - l_u - t)} = \frac{1}{(k_i - l_u - t)_{l_i - k_i}} = \frac{(-1)^{l_i}}{(l_u - l_i + 1)_{l_i} (l_u - k_i + 1)_{l_i}},$$

where $\delta_i = l_i - k_i$.

Also

$$\Gamma(b_j - l_u - b - t) = \frac{\Gamma(b_j - l_u - b)}{(-1)^t (l_u + b + 1 - b_j)_t},$$

$$\Gamma(1 - a_j + l_u + b + t) = \Gamma(1 - a_j + l_u + b)(1 - a_j + l_u + b)_t$$

and

$$\text{Res}_{s=b+l_u+t} \Gamma(b - s) = \frac{(-1)^{l_u+t}}{(l_u+t)!} = - \frac{(-1)^{l_u}}{l_u!} \frac{(-1)^t}{(l_u+1)_t}. $$

Hence

$$\text{Res}_{s=b+l_u+t} = - z^{b+l_u} \frac{(-1)^{l_u}}{l_u!} \prod_{i=1}^u \frac{(-1)^{l_i}}{(l_u - k_i + 1)_{l_i} (l_u - k_i + 1)_{l_i}} \prod_{j=1}^n \Gamma(1 - a_j + l_u + b) \prod_{j=m+1}^{n+u} \Gamma(b_j - l_u - b) \prod_{j=m+1}^n \Gamma(1 - b_j + l_u + b) \prod_{j=m+1}^n (l_u + b + 1 - b_j)_t \prod_{j=m+1}^n (l_u + b + 1 - b_j)_t.$$
where the * means to omit the terms we treated specially.

We thus arrive at

\[ F(z) = C \times {}_{p+1}F_q \left( \begin{array}{c} \frac{1}{1} \left( 1 + l_u - l_i \right), \left( 1 + l_u + b - a_i \right)^* \frac{1}{1 + l_u, \left( 1 + l_u - k_i \right), \left( 1 + l_u + b - b_i \right)^*} \right) (-1)^{p-m-n} z \right), \]

where \( C \) designates the factor in the residue independent of \( t \). (This result can also be written in slightly simpler form by converting all the \( l_u \) etc back to \( a_1 - b_1 \), but doing so is going to require more notation still and is not helpful for computation.)

### Extending The Hypergeometric Tables

Adding new formulae to the tables is straightforward. At the top of the file `sympy/simplify/hyperexpand.py`, there is a function called `add_formulae()`. Nested in it are defined two helpers, `add(ap, bq, res)` and `addb(ap, bq, B, C, M)`, as well as dummy's a, b, c, and z.

The first step in adding a new formula is by using `add(ap, bq, res)`. This declares `hyper(ap, bq, z) == res`. Here ap and bq may use the dummy's a, b, and c as free symbols. For example the well-known formula \( \sum_{n=0}^{\infty} \frac{(-a)^n z^n}{n!} = (1 - z)^a \) is declared by the following line: `add((-a, ), (), (1-z)**a)`.

From the information provided, the matrices \( B, C \) and \( M \) will be computed, and the formula is now available when expanding hypergeometric functions. Next the test file `sympy/simplify/tests/test_hyperexpand.py` should be run, in particular the test `test_formulae()`. This will test the newly added formula numerically. If it fails, there is (presumably) a typo in what was entered.

Since all newly-added formulae are probably relatively complicated, chances are that the automatically computed basis is rather suboptimal (there is no good way of testing this, other than observing very messy output). In this case the matrices \( B, C \) and \( M \) should be computed by hand. Then the helper `addb` can be used to declare a hypergeometric formula with hand-computed basis.

### An example

Because this explanation so far might be very theoretical and difficult to understand, we walk through an explicit example now. We take the Fresnel function \( C(z) \) which obeys the following hypergeometric representation:

\[ C(z) = z \cdot {}_{1}F_{2} \left( \begin{array}{c} \frac{1}{4} \frac{5}{4} \left| - \frac{\pi^2 z^4}{16} \right. \right). \]

First we try to add this formula to the lookup table by using the (simpler) function `add(ap, bq, res)`. The first two arguments are simply the lists containing the parameter sets of \( 1F2 \). The `res` argument is a little bit more complicated. We only know \( C(z) \) in terms of \( 1F2(\ldots|f(z)) \) with \( f \) a function of \( z \), in our case

\[ f(z) = -\frac{\pi^2 z^4}{16}. \]

What we need is a formula where the hypergeometric function has only \( z \) as argument \( 1F2(\ldots|z) \). We introduce the new complex symbol \( w \) and search for a function \( g(w) \) such that

\[ f(g(w)) = w. \]
holds. Then we can replace every $z$ in $C(z)$ by $g(w)$. In the case of our example the function $g$ could look like

$$g(w) = \frac{2}{\sqrt{\pi}} \exp \left( \frac{i\pi}{4} \right) w^\frac{1}{4}.$$

We get these functions mainly by guessing and testing the result. Hence we proceed by computing $f(g(w))$ (and simplifying naively)

$$f(g(w)) = \frac{\pi^2 g(w)^4}{16}$$

$$= \frac{\pi^2 g \left( \frac{2}{\sqrt{\pi}} \exp \left( \frac{i\pi}{4} \right) w^\frac{1}{4} \right)^4}{16}$$

$$= \frac{\pi^2 \frac{1}{\sqrt{\pi}} \exp \left( \frac{i\pi}{4} \right)^4 w^{\frac{1}{4}}}{16}$$

$$= - \exp \left( i\pi \right) w$$

$$= w$$

and indeed get back $w$. (In case of branched functions we have to be aware of branch cuts. In that case we take $w$ to be a positive real number and check the formula. If what we have found works for positive $w$, then just replace $\exp$ (page 468) inside any branched function by $\exp_polar$ (page 471) and what we get is right for all $w$.) Hence we can write the formula as

$$C(g(w)) = g(w) \cdot {}_1F_2 \left( \begin{array}{c} \frac{1}{2}, \frac{5}{4} \\ \frac{1}{2}, \frac{7}{4} \end{array} | w \right)$$

and trivially

$${}_1F_2 \left( \begin{array}{c} \frac{1}{2}, \frac{5}{4} \\ \frac{1}{2}, \frac{7}{4} \end{array} | w \right) = \frac{C(g(w))}{g(w)} = \frac{\frac{2}{\sqrt{\pi}} \exp \left( \frac{i\pi}{4} \right) w^\frac{1}{4}}{\frac{2}{\sqrt{\pi}} \exp \left( \frac{i\pi}{4} \right) w^\frac{1}{4}}$$

which is exactly what is needed for the third parameter, $res$, in add. Finally, the whole function call to add this rule to the table looks like:

```python
add([S(1)/4],
    [S(1)/2, S(5)/4],
    fresnelc(exp(pi*I/4)*root(z,4)*2/sqrt(pi)) / (exp(pi*I/4)*root(z,4)*2/sqrt(pi))
)
```

Using this rule we will find that it works but the results are not really nice in terms of simplicity and number of special function instances included. We can obtain much better results by adding the formula to the lookup table in another way. For this we use the (more complicated) function addb(ap, bq, B, C, M). The first two arguments are again the lists containing the parameter sets of $F_2$. The remaining three are the matrices mentioned earlier on this page.

We know that the $n = \max (p, q + 1)$-th derivative can be expressed as a linear combination of lower order derivatives. The matrix $B$ contains the basis $\{B_0, B_1, \ldots\}$ and is of shape $n \times 1$. The best way to get $B_i$ is to take the first $n = \max (p, q + 1)$ derivatives of the expression for $pF_q$ and take out useful pieces. In our case we find that $n = \max (1, 2 + 1) = 3$. For computing the derivatives, we have to use the operator $\frac{d}{dz}$. The first basis element $B_0$ is set to the expression for $F_2$ from above:

$$B_0 = \sqrt{\pi} \exp \left( -\frac{i\pi}{4} \right) C \left( \frac{2}{\sqrt{\pi}} \exp \left( \frac{i\pi}{4} \right) z^\frac{1}{4} \right)$$
Next we compute $z \frac{d}{dz} B_0$. For this we can directly use SymPy!

```python
>>> from sympy import Symbol, sqrt, exp, I, pi, fresnelc, root, diff, expand
>>> z = Symbol("z")
>>> B0 = sqrt(pi)*exp(-I*pi/4)*fresnelc(2*root(z, 4)*exp(I*pi/4)/sqrt(pi)) / 
... (2*root(z, 4))
>>> z * diff(B0, z)
z*(cosh(2*sqrt(z))/(4*z) - sqrt(pi)*exp(-I*pi/4)*fresnelc(2*z**(1/4)*exp(I*pi/4)/sqrt(pi))/(8*z**(5/4)))
>>> expand(_)
cosh(2*sqrt(z))/4 - sqrt(pi)*exp(-I*pi/4)*fresnelc(2*z**(1/4)*exp(I*pi/4)/sqrt(pi))/(8*z**(5/4))
```

Formatting this result nicely we obtain

$$B_1' = \frac{\sqrt{\pi}}{4} \exp\left(-\frac{\pi i}{4}\right) C \left(\frac{2}{\sqrt{\pi}} \exp\left(\frac{\pi i}{4}\right) z^{\frac{1}{4}}\right) + \frac{1}{4} \cosh(2\sqrt{z})$$

Computing the second derivative we find

```python
>>> from sympy import cosh, sqrt, pi, exp, I, fresnelc, root, diff, expand
>>> z = Symbol("z")
>>> B1prime = cosh(2*sqrt(z))/4 - sqrt(pi)*exp(-I*pi/4)*fresnelc(2*z**(1/4)*exp(I*pi/4)/sqrt(pi))/(32*z**(1/4))
>>> z * diff(B1prime, z)
\sqrt{z} \sinh(2\sqrt{z})/4 - \cosh(2\sqrt{z})/16 + \sqrt{\pi} \exp(-\frac{\pi i}{4}) \frac{\cosh(2\sqrt{z})}{\sqrt{\pi}}/(8z^{1/4})
>>> expand(_)
\frac{\sqrt{\pi}}{16} \exp\left(-\frac{\pi i}{4}\right) C \left(\frac{2}{\sqrt{\pi}} \exp\left(\frac{\pi i}{4}\right) z^{\frac{1}{4}}\right) - \frac{1}{16} \cosh(2\sqrt{z}) + \frac{1}{4} \sinh(2\sqrt{z}) \sqrt{z}
```

which can be printed as

$$B_2' = \frac{\sqrt{\pi}}{16} \exp\left(-\frac{\pi i}{4}\right) C \left(\frac{2}{\sqrt{\pi}} \exp\left(\frac{\pi i}{4}\right) z^{\frac{1}{4}}\right) - \frac{1}{16} \cosh(2\sqrt{z}) + \frac{1}{4} \sinh(2\sqrt{z}) \sqrt{z}$$

We see the common pattern and can collect the pieces. Hence it makes sense to choose $B_1$ and $B_2$ as follows

$$B = \begin{bmatrix} B_0 \\ B_1 \\ B_2 \end{bmatrix} = \begin{bmatrix} \sqrt{\pi} \exp\left(-\frac{\pi i}{4}\right) C \left(\frac{2}{\sqrt{\pi}} \exp\left(\frac{\pi i}{4}\right) z^{\frac{1}{4}}\right) \\ \cosh(2\sqrt{z}) \\ \sinh(2\sqrt{z}) \sqrt{z} \end{bmatrix}$$

(This is in contrast to the basis $B = (B_0, B_1', B_2')$ that would have been computed automatically if we used just `add(ap, bq, res)`.)

Because it must hold that $\mu F_q (\cdots |z) = CB$ the entries of $C$ are obviously

$$C = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}$$

Finally we have to compute the entries of the $3 \times 3$ matrix $M$ such that $z \frac{d}{dz} B = MB$ holds. This is easy. We already computed the first part $z \frac{d}{dz} B_0$ above. This gives us the first row of $M$. For the second row we have:

### 5.8. Topics
and for the third one

```python
>>> from sympy import Symbol, sinh, sqrt, expand, diff
>>> z = Symbol("z")
>>> B2 = sinh(2*sqrt(z))*sqrt(z)
>>> expand(z * diff(B2, z))
sqrt(z)*sinh(2*sqrt(z))/2 + z*cosh(2*sqrt(z))
```

Now we have computed the entries of this matrix to be

\[
M = \begin{pmatrix}
-\frac{1}{2} & \frac{1}{2} & 0 \\
0 & 0 & 1 \\
0 & z & \frac{1}{2}
\end{pmatrix}
\]

Note that the entries of \( C \) and \( M \) should typically be rational functions in \( z \), with rational coefficients. This is all we need to do in order to add a new formula to the lookup table for \hyperexp\.

**Implemented Hypergeometric Formulae**

A vital part of the algorithm is a relatively large table of hypergeometric function representations. The following automatically generated list contains all the representations implemented in SymPy (of course many more are derived from them). These formulae are mostly taken from [Luke1969] and [Prudnikov1990]. They are all tested numerically.

\[
\begin{align*}
_0F_0 (|z|) &= e^z \\
_1F_0 (a|z) &= (1 - z)^{-a} \\
_2F_1 \left( \frac{a, a - \frac{1}{2}}{2a} \right| z \right) &= 2^{2a-1} \left( \sqrt{1 - z} + 1 \right)^{1-2a} \\
_2F_1 \left( \frac{1, 1}{2} \right| z \right) &= -\frac{\log(1 - z)}{z} \\
_2F_1 \left( \frac{1}{2}, \frac{1}{4} \left| z \right. \right) &= \frac{\operatorname{atanh}(\sqrt{z})}{\sqrt{z}} \\
_2F_1 \left( \frac{1}{2}, \frac{3}{4} \right| z \right) &= \frac{\operatorname{asin}(\sqrt{z})}{\sqrt{z}} \\
_2F_1 \left( a, a + \frac{1}{2} \right| z \right) &= \frac{(\sqrt{z} + 1)^{-2a}}{2} + \frac{(1 - \sqrt{z})^{-2a}}{2} \\
_2F_1 \left( a, -a \left| z \right. \right) &= \cos \left( 2a \operatorname{asin} \left( \sqrt{z} \right) \right) \\
_2F_1 \left( \frac{1}{2}, \frac{1}{2} \right| z \right) &= \frac{\operatorname{asin}(\sqrt{z})}{\sqrt{z} \sqrt{1 - z}}
\end{align*}
\]
\[
\begin{align*}
2F_1\left(\frac{1}{2}, \frac{1}{2} \middle| \frac{1}{2}, 2z \right) &= \frac{2K(z)}{\pi} \\
2F_1\left(-\frac{1}{2}, \frac{1}{2} \middle| \frac{1}{2}, 2z \right) &= \frac{2E(z)}{\pi} \\
3F_2\left(-\frac{1}{2}, 1, \frac{1}{2} \middle| \frac{1}{2}, 2 \right) &= -2\sqrt{z} \text{atanh}(\sqrt{z}) + \frac{2}{3} \log(1 - z) \\
3F_2\left(-\frac{1}{2}, 1, \frac{1}{2} \middle| \frac{1}{2}, 2 \right) &= \left(\frac{4 - 16z}{9z}\right) \sqrt{1 - z} + \frac{4\log(\sqrt{1 - z} + 1)}{3z} + 169z \\
1F_1\left(\frac{1}{2} \middle| \frac{1}{2}, 2 \right) &= \Gamma\left(\frac{a + 1}{2}\right) \\
1F_1\left(\frac{a}{2a} \middle| \frac{1}{2}, 2 \right) &= 4^{a-rac{1}{2}}z^{\frac{1}{2}-a}e^{\frac{z}{2}}I_{a-rac{1}{2}}\left(\frac{z}{2}\right) \\
1F_1\left(\frac{a}{a + 1} \middle| \frac{1}{2}, 2 \right) &= a(ze^{i\pi})^{-a} \gamma(a, ze^{i\pi}) \\
1F_1\left(-\frac{1}{2} \middle| \frac{1}{2}, 2 \right) &= \sqrt{\pi} i \sqrt{\pi} \text{erf}(\sqrt{z}i) + e^z \\
1F_2\left(\frac{1}{4}, \frac{1}{2} \middle| \frac{1}{2}, 2 \right) &= \frac{\sqrt{\pi} \sinh(2\sqrt{z})S\left(\frac{2\sqrt{z}e^{i\pi}}{\sqrt{\pi}}\right) + \cosh(2\sqrt{z})C\left(\frac{2\sqrt{z}e^{i\pi}}{\sqrt{\pi}}\right)}{2\sqrt{z}} \\
2F_2\left(\frac{1}{2}, a \middle| \frac{1}{2}, 2 \right) &= -\frac{ai\sqrt{\pi}i \frac{2}{2a} \text{erf}(\sqrt{z}i)}{2a - 1} - \frac{a(ze^{i\pi})^{-a} \gamma(a, ze^{i\pi})}{2a - 1} \\
2F_2\left(\frac{1}{2}, 1 \middle| \frac{1}{2}, 2 \right) &= -\log(z) + \text{Ei}(z) - \frac{\gamma}{z} \\
oF_1\left(\frac{1}{2} \middle| \frac{1}{2}, 2 \right) &= \text{cosh}(2\sqrt{z}) \\
oF_1\left(\frac{1}{2} \middle| \frac{1}{2}, 2 \right) &= z^{\frac{1}{2}+\frac{1}{2}}I_{b-1} \left(2\sqrt{z}\right) \Gamma(b) \\
oF_3\left(\frac{1}{2}, a, \frac{1}{2} \middle| \frac{1}{2}, 2 \right) &= 2^{-2a}z^{\frac{1}{2}-\frac{1}{2}} \left(I_{2a-1} \left(4\sqrt{z}\right) + J_{2a-1} \left(4\sqrt{z}\right)\right) \Gamma(2a) \\
oF_3\left(\frac{1}{2}, a + \frac{1}{2}, \frac{1}{2} \middle| \frac{1}{2}, 2 \right) &= \left(2\sqrt{z}e^{i\pi}\right)^{1-2a} I_{a-1} \left(2\sqrt{2}\sqrt{z}e^{i\pi}\right) J_{a-1} \left(2\sqrt{2}\sqrt{z}e^{i\pi}\right) \Gamma^2(2a) \\
1F_2\left(a - \frac{a}{2} \middle| \frac{1}{2}, 2 \right) &= 2 \left(4^{-a-1} z^{1-a} I_{a-\frac{1}{2}}(\sqrt{z}) I_{a-\frac{1}{2}}(\sqrt{z}) \Gamma(a - \frac{1}{2}) \Gamma(a + \frac{1}{2}) - 4^{a-\frac{1}{2}} z^{\frac{1}{2}+a} J_{a-\frac{1}{2}}(\sqrt{z}) \Gamma^2(a + \frac{1}{2})\right) \\
1F_2\left(\frac{1}{2}, b \middle| \frac{1}{2}, 2 \right) &= \text{pi}(1 - b) \Pi_{1-b}(\sqrt{z}) I_{b-1}(\sqrt{z}) \\
1F_2\left(\frac{1}{2}, \frac{1}{2} \middle| \frac{1}{2}, 2 \right) &= \frac{\text{Shi}(2\sqrt{z})}{2\sqrt{z}} \\
1F_2\left(\frac{1}{2}, \frac{1}{2} \middle| \frac{1}{2}, 2 \right) &= \frac{3 \sqrt{\pi} e^{-\frac{3\pi}{4}} S\left(\frac{2\sqrt{z}e^{i\pi}}{\sqrt{\pi}}\right)}{4z^\frac{3}{4}} \\
1F_2\left(\frac{1}{2}, \frac{1}{2} \middle| \frac{1}{2}, 2 \right) &= \frac{\sqrt{\pi} e^{-\frac{3\pi}{4}} C\left(\frac{2\sqrt{z}e^{i\pi}}{\sqrt{\pi}}\right)}{2\sqrt{z}}
\end{align*}
\]
\[ 2F_3 \left( \frac{a, a + \frac{1}{2}, \frac{1}{2}}{2a, b, 2a - b + 1} \mid z \right) = \left( \frac{\sqrt{z}}{2} \right)^{1-2a} I_{2a-b} \left( \sqrt{z} \right) I_{b-1} \left( \sqrt{z} \right) \Gamma \left( b \right) \Gamma \left( 2a - b + 1 \right) \]

\[ 2F_3 \left( \frac{1, 1, \frac{1}{2}}{2, 2, \frac{3}{2}} \mid z \right) = -\frac{\log \left( 2\sqrt{z} \right) + \text{Chi} \left( 2\sqrt{z} \right) - \gamma}{z} \]

\[ 3F_3 \left( \frac{1, 1, a}{2, 2, a + 1} \mid z \right) = \frac{a (-z)^{-a} \left( \Gamma \left( a \right) - \Gamma \left( a, -z \right) \right)}{(a - 1)^2} + \frac{a (1 - a) \left( \log \left( -z \right) + \text{Ei} \left( -z \right) + \gamma \right)}{z (a^2 - 2a + 1)} - \frac{ae^z}{z (a^2 - 2a + 1)} + \frac{a}{z (a^2 - 2a + 1)} \]

Hongguang Fu’s Trigonometric Simplification

Implementation of the trigsimp algorithm by Fu et al.

The idea behind the Fu algorithm is to use a sequence of rules that students learn during their pre-calculus courses. The rules are applied heuristically and it uses a greedy algorithm to apply multiple rules simultaneously and choose the result with the least leaf counts.

There are transform rules in which a single rule is applied to the expression tree. The following are just mnemonic in nature; see the docstrings for examples.

- **TR0()** (page 759) - simplify expression
- **TR1()** (page 759) - sec-csc to cos-sin
- **TR2()** (page 759) - tan-cot to sin-cos ratio
- **TR2i()** (page 759) - sin-cos ratio to tan
- **TR3()** (page 760) - angle canonicalization
- **TR4()** (page 760) - functions at special angles
- **TR5()** (page 761) - powers of sin to powers of cos
- **TR6()** (page 761) - powers of cos to powers of sin
- **TR7()** (page 762) - reduce cos power (increase angle)
- **TR8()** (page 762) - expand products of sin-cos to sums
- **TR9()** (page 762) - contract sums of sin-cos to products
- **TR10()** (page 762) - separate sin-cos arguments
- **TR10i()** (page 763) - collect sin-cos arguments
- **TR11()** (page 763) - reduce double angles
- **TR12()** (page 764) - separate tan arguments
- **TR12i()** (page 764) - collect tan arguments
- **TR13()** (page 764) - expand product of tan-cot
- **TRmorrie()** (page 765) - prod(cos(x*2**i)), (i, 0, k - 1) -> sin(2**k*x)/(2**k*sin(x))
- **TR14()** (page 766) - factored powers of sin or cos to cos or sin power
- **TR15()** (page 766) - negative powers of sin to cot power
- **TR16()** (page 766) - negative powers of cos to tan power
- **TR22()** (page 767) - tan-cot powers to negative powers of sec-csc functions
There are 4 combination transforms (CTR1 - CTR4) in which a sequence of transformations are applied and the simplest expression is selected from a few options.

Finally, there are the 2 rule lists (RL1 and RL2), which apply a sequence of transformations and combined transformations, and the fu algorithm itself, which applies rules and rule lists and selects the best expressions. There is also a function L which counts the number of trigonometric functions that appear in the expression.

Other than TR0, re-writing of expressions is not done by the transformations. e.g. TR10i finds pairs of terms in a sum that are in the form like \( \cos(x) \cdot \cos(y) + \sin(x) \cdot \sin(y) \). Such expression are targeted in a bottom-up traversal of the expression, but no manipulation to make them appear is attempted. For example,

Set-up for examples below:

```python
>>> from sympy.simplify import fu, L, TR9, TR10i, TR11
>>> from sympy import factor, sin, cos, powsimp
>>> from sympy.abc import x, y, z, a
>>> from time import time

>>> eq = cos(x + y)/cos(x)
>>> TR10i(eq.expand(trig=True))
-sin(x)*sin(y)/cos(x) + cos(y)
```

If the expression is put in “normal” form (with a common denominator) then the transformation is successful:

```python
>>> TR10i(_.normal())
cos(x + y)/cos(x)
```

TR11’s behavior is similar. It rewrites double angles as smaller angles but doesn’t do any simplification of the result.

```python
>>> TR11(sin(2)**a*cos(1)**(-a), 1)
(2*sin(1)**a*cos(1)**(-a)
```

The temptation is to try make these TR rules “smarter” but that should really be done at a higher level; the TR rules should try maintain the “do one thing well” principle. There is one exception, however. In TR10i and TR9 terms are recognized even when they are each multiplied by a common factor:

```python
>>> fu(a*cos(x)*cos(y) + a*sin(x)*sin(y))
a*cos(x - y)
```

Factoring with factor_terms is used but it is “JIT”-like, being delayed until it is deemed necessary. Furthermore, if the factoring does not help with the simplification, it is not retained, so \( a \cdot \cos(x) \cdot \cos(y) + a \cdot \sin(x) \cdot \sin(z) \) does not become a factored (but unsimplified in the trigonometric sense) expression:

```python
>>> fu(a*cos(x)*cos(y) + a*sin(x)*sin(z))
a*sin(x)*sin(z) + a*cos(x)*cos(y)
```
In some cases factoring might be a good idea, but the user is left to make that decision. For example:

```python
>>> expr=(15*sin(2*x) + 19*sin(x + y) + 17*sin(x + z) + 19*cos(x - z) +
... 25)*(20*sin(2*x) + 15*sin(x + y) + sin(y + z) + 14*cos(x - z) +
... 14*cos(y - z))*(9*sin(2*y) + 12*sin(y + z) + 10*cos(x - y) + 2*cos(y -
... z) + 18)).expand(trig=True).expand()
```

In the expanded state, there are nearly 1000 trig functions:

```python
>>> L(expr)
932
```

If the expression where factored first, this would take time but the resulting expression would be transformed very quickly:

```python
>>> def clock(f, n=2):
...     t=time(); f(); return round(time()-t, n)
...
>>> clock(lambda: factor(expr))
0.86
>>> clock(lambda: TR10i(expr), 3)
0.016
```

If the unexpanded expression is used, the transformation takes longer but not as long as it took to factor it and then transform it:

```python
>>> clock(lambda: TR10i(expr), 2)
0.28
```

So neither expansion nor factoring is used in TR10i: if the expression is already factored (or partially factored) then expansion with `trig=True` would destroy what is already known and take longer; if the expression is expanded, factoring may take longer than simply applying the transformation itself.

Although the algorithms should be canonical, always giving the same result, they may not yield the best result. This, in general, is the nature of simplification where searching all possible transformation paths is very expensive. Here is a simple example. There are 6 terms in the following sum:

```python
>>> expr = (sin(x)**2*cos(y)*cos(z) + sin(x)*sin(y)*cos(x)*cos(z) +
... sin(x)*sin(z)*cos(x)*cos(y) + sin(y)*sin(z)*cos(x)**2 + sin(y)*sin(z) +
... cos(y)*cos(z))
>>> args = expr.args
```

Serendipitously, fu gives the best result:

```python
>>> fu(expr)
3*cos(y - z)/2 - cos(2*x + y + z)/2
```

But if different terms were combined, a less-optimal result might be obtained, requiring some additional work to get better simplification, but still less than optimal. The following shows an alternative form of `expr` that resists optimal simplification once a given step is taken since it leads to a dead end:
Here is a smaller expression that exhibits the same behavior:

```python
>>> a = sin(x)*sin(z)*cos(x)*cos(y) + sin(x)*sin(y)*cos(x)*cos(z)
```

```python
>>> TR10i(a)
```

```python
sin(x)*sin(y + z)*cos(x)
```

```python
>>> newa =
```

```python
>>> TR10i(expr - a)  # this combines two more of the remaining terms
```

```python
sin(x)**2*cos(y)*cos(z) + sin(y)*sin(z)*cos(x)**2 + cos(y - z)
```

```python
>>> TR10i(_ + newa) == _ + newa  # but now there is no more simplification
```

```python
True
```

Without getting lucky or trying all possible pairings of arguments, the final result may be less than optimal and impossible to find without better heuristics or brute force trial of all possibilities.

**Rules**

`sympy.simplify.fu.TR0(rv)`

Simplification of rational polynomials, trying to simplify the expression, e.g. combine things like 3*x + 2*x, etc.

`sympy.simplify.fu.TR1(rv)`

Replace sec, csc with 1/cos, 1/sin

**Examples**

```python
>>> from sympy.simplify.fu import TR1, sec, csc
>>> from sympy.abc import x
>>> TR1(2*csc(x) + sec(x))
```

`1/cos(x) + 2/sin(x)`

`sympy.simplify.fu.TR2(rv)`

Replace tan and cot with sin/cos and cos/sin

**Examples**

```python
>>> from sympy.simplify.fu import TR2
>>> from sympy.abc import x
>>> from sympy import tan, cot, sin, cos
>>> TR2(tan(x))
```

`sin(x)/cos(x)`

```python
>>> TR2(cot(x))
```

`cos(x)/sin(x)`

```python
>>> TR2(tan(tan(x) - sin(x)/cos(x)))
```

`0`
sympy.simplify.fu.TR2i(rv, half=False)

Converts ratios involving \( \sin \) and \( \cos \) as follows:
\[
\sin(x)/\cos(x) \rightarrow \tan(x) \\
\sin(x)/(\cos(x) + 1) \rightarrow \tan(x/2) \text{ if half=True}
\]

**Examples**

```python
>>> from sympy.simplify.fu import TR2i
>>> from sympy import sin, cos
>>> TR2i(sin(x)/cos(x))
tan(x)
```

Powers of the numerator and denominator are also recognized

```python
>>> TR2i(sin(x)**2/(cos(x) + 1)**2, half=True)
tan(x/2)**2
```

The transformation does not take place unless assumptions allow (i.e. the base must be positive or the exponent must be an integer for both numerator and denominator)

```python
>>> TR2i(sin(x)**a/(cos(x) + 1)**a)
sin(x)**a/(cos(x) + 1)**a
```

sympy.simplify.fu.TR3(rv)

Induced formula: example \( \sin(-a) = -\sin(a) \)

**Examples**

```python
>>> from sympy.simplify.fu import TR3
>>> from sympy import sin
>>> TR3(sin(-x))
-sin(x)
```

sympy.simplify.fu.TR4(rv)

Identify values of special angles.
\( A = 0 \pi/6 \pi/4 \pi/3 \pi/2 \)

\[
\begin{array}{cccc}
sin(a) & 0 & 1/2 & \sqrt{2}/2 & \sqrt{3}/2 & 1 \\
cos(a) & 1 & \sqrt{3}/2 & \sqrt{2}/2 & 1/2 & 0 \\
tan(a) & 0 & \sqrt{3}/3 & 1 & \sqrt{3} & \infty \\
\end{array}
\]

**Examples**

```python
>>> from sympy import pi
>>> from sympy import cos, sin, tan, cot
>>> for s in (0, pi/6, pi/4, pi/3, pi/2):
...     print(('%s %s %s %s' % (cos(s), sin(s), tan(s), cot(s)))).strip())
...
1 0 0 zoo
sqrt(3)/2 1/2 sqrt(3)/3 sqrt(3)
sqrt(2)/2 sqrt(2)/2 1 1
1/2 sqrt(3)/2 sqrt(3) sqrt(3)/3
0 1 zoo 0
```

_sympy.simplify.fu.TR5(rv, max=4, pow=False)_

Replacement of \( \sin^2 \) with \( 1 - \cos(x)^2 \).

See _TR6 docstring for advanced use of max and pow._

**Examples**

```python
>>> from sympy.simplify.fu import TR5
>>> from sympy import sin
>>> TR5(sin(x)**2)
1 - cos(x)**2
>>> TR5(sin(x)**-2)  # unchanged
sin(x)**(-2)
>>> TR5(sin(x)**4)
(1 - cos(x)**2)**2
```

_sympy.simplify.fu.TR6(rv, max=4, pow=False)_

Replacement of \( \cos^2 \) with \( 1 - \sin(x)^2 \).

See _TR6 docstring for advanced use of max and pow._

**Examples**

```python
>>> from sympy.simplify.fu import TR6
>>> from sympy import cos
>>> TR6(cos(x)**2)
1 - sin(x)**2
>>> TR6(cos(x)**-2)  # unchanged
cos(x)**(-2)
```
(continues on next page)
sympy.simplify.fu.TR7(rv)
Lowering the degree of \( \cos(x)^2 \).

**Examples**

```python
>>> from sympy.simplify.fu import TR7
>>> from sympy import x
>>> TR7(cos(x)**2)
\frac{\cos(2x)}{2} + \frac{1}{2}
```

sympy.simplify.fu.TR8(rv, first=True)
Converting products of \( \cos \) and/or \( \sin \) to a sum or difference of \( \cos \) and or \( \sin \) terms.

**Examples**

```python
>>> from sympy.simplify.fu import TR8
>>> from sympy import cos, sin
>>> TR8(cos(2)*cos(3))
\frac{\cos(5)}{2} + \frac{\cos(1)}{2}
>>> TR8(sin(2)*sin(3))
-\frac{\cos(5)}{2} + \frac{\cos(1)}{2}
```

sympy.simplify.fu.TR9(rv)
Sum of \( \cos \) or \( \sin \) terms as a product of \( \cos \) or \( \sin \).

**Examples**

```python
>>> from sympy.simplify.fu import TR9
>>> from sympy import cos, sin
>>> TR9(cos(1) + cos(2))
2*\cos(1/2)*\cos(3/2)
>>> TR9(cos(1) + 2*sin(1) + 2*sin(2))
\cos(1) + 4*\sin(3/2)*\cos(1/2)
```

If no change is made by TR9, no re-arrangement of the expression will be made. For example, though factoring of common term is attempted, if the factored expression was not changed, the original expression will be returned:

```python
>>> TR9(cos(3) + cos(3)*cos(2))
\cos(3) + \cos(2)*\cos(3)
```
SymPy Documentation, Release 1.12.1

sympy.simplify.fu.TR10(rv, first=True)
Separates sums in $\cos$ and $\sin$.

Examples

```python
>>> from sympy.simplify.fu import TR10
>>> from sympy import cos, sin
>>> TR10(cos(a + b))
-sin(a)*sin(b) + cos(a)*cos(b)
>>> TR10(sin(a + b))
sin(a)*cos(b) + sin(b)*cos(a)
>>> TR10(sin(a + b + c))
(-sin(a)*sin(b) + cos(a)*cos(b))*sin(c) + (sin(a)*cos(b) + sin(b)*cos(a))*cos(c)
```

sympy.simplify.fu.TR10i(rv)
Sum of products to function of sum.

Examples

```python
>>> from sympy.simplify.fu import TR10i
>>> from sympy import cos, sin, sqrt
>>> from sympy.abc import x
>>> TR10i(cos(1)*cos(3) + sin(1)*sin(3))
cos(2)
>>> TR10i(cos(1)*sin(3) + sin(1)*cos(3) + cos(3))
cos(3) + sin(4)
>>> TR10i(sqrt(2)*cos(x)*x + sqrt(6)*sin(x)*x)
2*sqrt(2)*x*sin(x + pi/6)
```

sympy.simplify.fu.TR11(rv, base=None)
Function of double angle to product. The `base` argument can be used to indicate what is the un-doubled argument, e.g. if 3*pi/7 is the base then cosine and sine functions with argument 6*pi/7 will be replaced.

Examples

```python
>>> from sympy.simplify.fu import TR11
>>> from sympy import cos, sin, pi
>>> from sympy.abc import x
>>> TR11(sin(2*x))
2*sin(x)*cos(x)
>>> TR11(cos(2*x))
-2*sin(x)**2 + cos(x)**2
>>> TR11(sin(4*x))
4*(-sin(x)**2 + cos(x)**2)*sin(x)*cos(x)
```
If the arguments are simply integers, no change is made unless a base is provided:

```python
>>> TR11(cos(2))
cos(2)
>>> TR11(cos(4), 2)
-sin(2)**2 + cos(2)**2
```

There is a subtle issue here in that autosimplification will convert some higher angles to lower angles

```python
>>> cos(6*pi/7) + cos(3*pi/7)
-cos(pi/7) + cos(3*pi/7)
```

The 6*pi/7 angle is now pi/7 but can be targeted with TR11 by supplying the 3*pi/7 base:

```python
>>> TR11(_, 3*pi/7)
-sin(3*pi/7)**2 + cos(3*pi/7)**2 + cos(3*pi/7)
```

`sympy.simplify.fu.TR11(rv, first=True)`

Separate sums in tan.

**Examples**

```python
>>> from sympy.abc import x, y
>>> from sympy import tan
>>> from sympy.simplify.fu import TR12
>>> TR12(tan(x + y))
(tan(x) + tan(y))/(-tan(x)*tan(y) + 1)
```

`sympy.simplify.fu.TR12i(rv)`

Combine tan arguments as \((\tan(y) + \tan(x))/(\tan(x)\tan(y) - 1) \rightarrow -\tan(x + y)\).

**Examples**

```python
>>> from sympy.simplify.fu import TR12i
>>> from sympy import tan
>>> from sympy.abc import a, b, c
>>> ta, tb, tc = [tan(i) for i in (a, b, c)]
>>> TR12i((ta + tb)/(ta*tb + 1))
tan(a + b)
>>> TR12i((ta + tb)/(ta*tb - 1))
-tan(a + b)
>>> TR12i((-ta - tb)/(ta*tb - 1))
tan(a + b)
>>> eq = (ta + tb)/(-ta*tb + 1)**2*(-3*ta - 3*tc)/(2*(ta*tc - 1))
>>> TR12i(eq.expand())
-3*tan(a + b)*tan(a + c)/(2*(tan(a) + tan(b) - 1))
```
sympy.simplify.fu.TR13(rv)
    Change products of tan or cot.

Examples

```python
>>> from sympy.simplify.fu import TR13
>>> from sympy import tan, cot
>>> TR13(tan(3)*tan(2))
-tan(2)/tan(5) - tan(3)/tan(5) + 1
>>> TR13(cot(3)*cot(2))
cot(2)*cot(5) + 1 + cot(3)*cot(5)
```

sympy.simplify.fu.TRmorrie(rv)
    Returns \(\cos(x)\cos(2x)\ldots\cos(2^k x)\rightarrow \sin(2^k x)/(2^k \sin(x))\)

Examples

```python
>>> from sympy.simplify.fu import TRmorrie, TR8, TR3
>>> from sympy importMul, cos, pi
>>> TRmorrie(cos(x)*cos(2*pi/9)*cos(3*pi/9)*cos(4*pi/9))
sin(4*x)/(4*sin(x))
>>> TRmorrie(7*Mul(*[cos(x) for x in range(10)]))
7*sin(12)*sin(16)*cos(5)*cos(7)*cos(9)/(64*sin(1)*sin(3))
```

Sometimes autosimplification will cause a power to be not recognized. e.g. in the following, \(\cos(4\pi/7)\) automatically simplifies to \(-\cos(3\pi/7)\) so only 2 of the 3 terms are recognized:

```python
>>> TRmorrie(cos(pi/7)*cos(2*pi/7)*cos(3*pi/7))
-sin(3*pi/7)*cos(3*pi/7)/(4*sin(pi/7))
```

A touch by TR8 resolves the expression to a Rational

```python
>>> TR8(_)
-1/8
```

In this case, if eq is unsimplified, the answer is obtained directly:

```python
>>> eq = cos(pi/9)*cos(2*pi/9)*cos(3*pi/9)*cos(4*pi/9)
>>> TRmorrie(eq)
1/16
```

But if angles are made canonical with TR3 then the answer is not simplified without further work:

```python
>>> TR3(eq)
sin(pi/18)*cos(pi/9)*cos(2*pi/9)/2
>>> TRmorrie(_)
sin(pi/18)*sin(4*pi/9)/(8*sin(pi/9))
>>> TR8(_)
```
(continues on next page)
The original expression would have resolve to 1/16 directly with TR8, however:

```python
>>> TR8(eq)
1/16
```

## References

[R784]

sympy.simplify.fu.TR14(rv, first=True)

Convert factored powers of sin and cos identities into simpler expressions.

### Examples

```python
>>> from sympy.simplify.fu import TR14
>>> from sympy.abc import x, y
>>> from sympy import cos, sin
>>> TR14((cos(x) - 1)*(cos(x) + 1))
-sin(x)**2
>>> TR14((sin(x) - 1)*(sin(x) + 1))
-cos(x)**2
>>> p1 = (cos(x) + 1)*(cos(x) - 1)
>>> p2 = (cos(y) - 1)**2*(cos(y) + 1)
>>> p3 = (3*cos(y) - 1)**2*(3*cos(y) + 1)
>>> TR14(p1*p2*p3*(x - 1))
-18*(x - 1)*sin(x)**2*sin(y)**4
```

sympy.simplify.fu.TR15(rv, max=4, pow=False)

Convert \(\sin(x)^{-2}\) to \(1 + \cot(x)^2\).

See _TR56 docstring for advanced use of max and pow.

### Examples

```python
>>> from sympy.simplify.fu import TR15
>>> from sympy.abc import x
>>> from sympy import sin
>>> TR15(1 - 1/sin(x)**2)
-cot(x)**2
```

sympy.simplify.fu.TR16(rv, max=4, pow=False)

Convert \(\cos(x)^{-2}\) to \(1 + \tan(x)^2\).

See _TR56 docstring for advanced use of max and pow.
Examples

```python
>>> from sympy.simplify.fu import TR16
>>> from sympy.abc import x
>>> from sympy import cos
>>> TR16(1 - 1/cos(x)**2)
-tan(x)**2
```

```
sympy.simplify.fu.TR111(rv)
Convert f(x)**i to g(x)**i where either i is an integer or the base is positive and f, g are: tan, cot; sin, csc; or cos, sec.
```

Examples

```python
>>> from sympy.simplify.fu import TR111
>>> from sympy.abc import x
>>> from sympy import tan
>>> TR111(1 - 1/tan(x)**2)
1 - cot(x)**2
```

```
sympy.simplify.fu.TR22(rv, max=4, pow=False)
Convert tan(x)**2 to sec(x)**2 - 1 and cot(x)**2 to csc(x)**2 - 1.
See _TR56 docstring for advanced use of max and pow.
```

Examples

```python
>>> from sympy.simplify.fu import TR22
>>> from sympy.abc import x
>>> from sympy import cos, sin
>>> TR22(sin(x)**6)
-15*cos(2*x)/32 + 3*cos(4*x)/16 - cos(6*x)/32 + 5/16
>>> TR22(sin(x)**3*cos(2*x)**4)
(3*sin(x)/4 - sin(3*x)/4)*(cos(4*x)/2 + cos(8*x)/8 + 3/8)
```

```
sympy.simplify.fu.TRpower(rv)
Convert sin(x)**n and cos(x)**n with positive n to sums.
```

Examples

```python
>>> from sympy.simplify.fu import TRpower
>>> from sympy.abc import x
>>> from sympy import cos, sin
>>> TRpower(sin(x)**6)
-15*cos(2*x)/32 + 3*cos(4*x)/16 - cos(6*x)/32 + 5/16
>>> TRpower(sin(x)**3*cos(2*x)**4)
(3*sin(x)/4 - sin(3*x)/4)*(cos(4*x)/2 + cos(8*x)/8 + 3/8)
```
References

[R785]
sympy.simplify.fu.fu(rv, measure=<function <lambda>>)

Attempt to simplify expression by using transformation rules given in the algorithm by Fu et al.

fu() (page 768) will try to minimize the objective function measure. By default this first minimizes the number of trig terms and then minimizes the number of total operations.

Examples

>>> from sympy.simplify.fu import fu
>>> from sympy import cos, sin, tan, pi, S, sqrt
>>> from sympy.abc import x, y, a, b

>>> fu(sin(50)**2 + cos(50)**2 + sin(pi/6))
3/2
>>> fu(sqrt(6)*cos(x) + sqrt(2)*sin(x))
2*sqrt(2)*sin(x + pi/3)

CTR1 example

>>> eq = sin(x)**4 - cos(y)**2 + sin(y)**2 + 2*cos(x)**2
>>> fu(eq)
cos(x)**4 - 2*cos(y)**2 + 2

CTR2 example

>>> fu(S.Half - cos(2*x)/2)
sin(x)**2

CTR3 example

>>> fu(sin(a)*(cos(b) - sin(b)) + cos(a)*(sin(b) + cos(b)))
sqrt(2)*sin(a + b + pi/4)

CTR4 example

>>> fu(sqrt(3)*cos(x)/2 + sin(x)/2)
sin(x + pi/3)

Example 1

>>> fu(1-sin(2*x)**2/4-sin(y)**2-cos(x)**4)
-cos(x)**2 + cos(y)**2

Example 2

>>> fu(cos(4*pi/9))
sin(pi/18)
>>> fu(cos(pi/9)*cos(2*pi/9)*cos(3*pi/9)*cos(4*pi/9))
1/16
Example 3

```python
>>> fu(tan(7*pi/18)+tan(5*pi/18)-sqrt(3)*tan(5*pi/18)*tan(7*pi/18)) -sqrt(3)
Objective function example

```n

```python
>>> fu(sin(x)/cos(x))  # default objective function
tan(x)
```

```python
>>> fu(sin(x)/cos(x), measure=lambda x: -x.count_ops())  # maximize op
sin(x)/cos(x)
```

Solvers

This module documentation contains details about the `sympy.solvers` module. functions.

Contents

Diophantine

Note: For a beginner-friendly guide focused on solving Diophantine equations, refer to *Solve a Diophantine Equation Algebraically* (page 181).
Diophantine equations

The word “Diophantine” comes with the name Diophantus, a mathematician lived in the great city of Alexandria sometime around 250 AD. Often referred to as the “father of Algebra”, Diophantus in his famous work “Arithmetica” presented 150 problems that marked the early beginnings of number theory, the field of study about integers and their properties. Diophantine equations play a central and an important part in number theory.

We call a “Diophantine equation” to an equation of the form, \( f(x_1, x_2, \ldots x_n) = 0 \) where \( n \geq 2 \) and \( x_1, x_2, \ldots x_n \) are integer variables. If we can find \( n \) integers \( a_1, a_2, \ldots a_n \) such that \( x_1 = a_1, x_2 = a_2, \ldots x_n = a_n \) satisfies the above equation, we say that the equation is solvable. You can read more about Diophantine equations in\(^1\) and\(^2\).

Currently, following five types of Diophantine equations can be solved using `diophantine()` (page 775) and other helper functions of the Diophantine module.

- Linear Diophantine equations: \( a_1x_1 + a_2x_2 + \ldots + a_nx_n = b \).
- General binary quadratic equation: \( ax^2 + bxy + cy^2 + dx + ey + f = 0 \)
- Homogeneous ternary quadratic equation: \( ax^2 + by^2 + cz^2 + dxy + eyz + fzx = 0 \)
- Extended Pythagorean equation: \( a_1x_1^2 + a_2x_2^2 + \ldots + a_nx_n^2 = a_{n+1}x_{n+1}^2 \)
- General sum of squares: \( x_1^2 + x_2^2 + \ldots + x_n^2 = k \)

Module structure

This module contains `diophantine()` (page 775) and helper functions that are needed to solve certain Diophantine equations. It’s structured in the following manner:

- `diophantine()` (page 775)
  - `diop_solve()` (page 777)
    - `classify_diop()` (page 776)
    - `diop_linear()` (page 777)
    - `diop_quadratic()` (page 779)
    - `diop_ternary_quadratic()` (page 784)
    - `diop_ternary_quadratic_normal()` (page 794)
    - `diop_general_pythagorean()` (page 786)
    - `diop_general_sum_of_squares()` (page 786)
    - `diop_general_sum_of_even_powers()` (page 787)
  - `merge_solution()` (page 791)

When an equation is given to `diophantine()` (page 775), it factors the equation(if possible) and solves the equation given by each factor by calling `diop_solve()` (page 777) separately. Then all the results are combined using `merge_solution()` (page 791).

`diop_solve()` (page 777) internally uses `classify_diop()` (page 776) to find the type of the equation(and some other details) given to it and then calls the appropriate solver function.

---
\(^{1}\) Andreescu, Titu. Andrica, Dorin. Cucurezeanu, Ion. An Introduction to Diophantine Equations
Based on the type returned. For example, if `classify_diop()` (page 776) returned "linear" as the type of the equation, then `diop_solve()` (page 777) calls `diop_linear()` (page 777) to solve the equation.

Each of the functions, `diop_linear()` (page 777), `diop_quadratic()` (page 779), `diop_ternary_quadratic()` (page 784), `diop_general_pythagorean()` (page 786) and `diop_general_sum_of_squares()` (page 786) solves a specific type of equations and the type can be easily guessed by its name.

Apart from these functions, there are a considerable number of other functions in the “Diophantine Module” and all of them are listed under User functions and Internal functions.

**Tutorial**

First, let’s import the highest API of the Diophantine module.

```
>>> from sympy.solvers.diophantine import diophantine
```

Before we start solving the equations, we need to define the variables.

```
>>> from sympy import symbols
>>> x, y, z = symbols("x, y, z", integer=True)
```

Let’s start by solving the easiest type of Diophantine equations, i.e. linear Diophantine equations. Let’s solve $2x + 3y = 5$. Note that although we write the equation in the above form, when we input the equation to any of the functions in Diophantine module, it needs to be in the form $eq = 0$.

```
>>> diophantine(2*x + 3*y - 5)
{(3*t_0 - 5, 5 - 2*t_0)}
```

Note that stepping one more level below the highest API, we can solve the very same equation by calling `diop_solve()` (page 777).

```
>>> from sympy.solvers.diophantine.diophantine import diop_solve
>>> diop_solve(2*x + 3*y - 5)
(3*t_0 - 5, 5 - 2*t_0)
```

Note that it returns a tuple rather than a set. `diophantine()` (page 775) always return a set of tuples. But `diop_solve()` (page 777) may return a single tuple or a set of tuples depending on the type of the equation given.

We can also solve this equation by calling `diop_linear()` (page 777), which is what `diop_solve()` (page 777) calls internally.

```
>>> from sympy.solvers.diophantine.diophantine import diop_linear
>>> diop_linear(2*x + 3*y - 5)
(3*t_0 - 5, 5 - 2*t_0)
```

If the given equation has no solutions then the outputs will look like below.

```
>>> diophantine(2*x + 4*y - 3)
set()
```

```
>>> diop_solve(2*x + 4*y - 3)
(None, None)
```

(continues on next page)
Note that except for the highest level API, in case of no solutions, a tuple of `None` are returned. Size of the tuple is the same as the number of variables. Also, one can specifically set the parameter to be used in the solutions by passing a customized parameter. Consider the following example:

```python
>>> m = symbols("m", integer=True)
>>> diop_solve(2*x + 3*y - 5, m)
(3*m_0 - 5, 5 - 2*m_0)
```

For linear Diophantine equations, the customized parameter is the prefix used for each free variable in the solution. Consider the following example:

```python
>>> diop_solve(2*x + 3*y - 5*z + 7, m)
(m_0, m_0 + 5*m_1 - 14, m_0 + 3*m_1 - 7)
```

In the solution above, `m_0` and `m_1` are independent free variables.

Please note that for the moment, users can set the parameter only for linear Diophantine equations and binary quadratic equations.

Let’s try solving a binary quadratic equation which is an equation with two variables and has a degree of two. Before trying to solve these equations, an idea about various cases associated with the equation would help a lot. Please refer\(^3\) and\(^4\) for detailed analysis of different cases and the nature of the solutions. Let us define \(\Delta = b^2 - 4ac\) w.r.t. the binary quadratic \(ax^2 + bxy + cy^2 + dx + ey + f = 0\).

When \(\Delta < 0\), there are either no solutions or only a finite number of solutions.

```python
>>> diophantine(x**2 - 4*x*y + 8*y**2 - 3*x + 7*y - 5)
{(2, 1), (5, 1)}
```

In the above equation \(\Delta = (-4)^2 - 4 \times 1 \times 8 = -16\) and hence only a finite number of solutions exist.

When \(\Delta = 0\) we might have either no solutions or parameterized solutions.

```python
>>> diophantine(3*x**2 - 6*x*y + 3*y**2 - 3*x + 7*y - 5)
set()
>>> diophantine(x**2 - 4*x*y + 4*y**2 - 3*x + 7*y - 5)
{(-2*t**2 - 7*t + 10, -t**2 - 3*t + 5)}
>>> diophantine(x**2 + 2*x*y + y**2 - 3*x - 3*y)
{(t_0, -t_0), (t_0, 3 - t_0)}
```

The most interesting case is when \(\Delta > 0\) and it is not a perfect square. In this case, the equation has either no solutions or an infinite number of solutions. Consider the below cases where \(\Delta = 8\).

---

\(^3\) Methods to solve \(Ax^2 + Bxy + Cy^2 + Dx + Ey + F = 0\), [online]. Available: https://www.alpertron.com.ar/METHODS.HTM

```python
>>> diophantine(x**2 - 4*x*y + 2*y**2 - 3*x + 7*y - 5)
set()
>>> from sympy import sqrt
>>> n = symbols("n", integer=True)
>>> s = diophantine(x**2 - 2*y**2 - 2*x - 4*y, n)
>>> x_1, y_1 = s.pop()
>>> x_2, y_2 = s.pop()
```

Here \( n \) is an integer. Although \( x_n \) and \( y_n \) may not look like integers, substituting in specific values for \( n \) (and simplifying) shows that they are. For example consider the following example where we set \( n \) equal to 9.

```python
>>> from sympy import simplify
>>> simplify(x_n.subs({n: 9}))
-9369318
```

Any binary quadratic of the form \( ax^2 + bxy + cy^2 + dx + ey + f = 0 \) can be transformed to an equivalent form \( X^2 - D Y^2 = N \).

```python
>>> from sympy.solvers.diophantine import find_DN, diop_DN, transformation_to_DN
>>> find_DN(x**2 - 3*x*y + y**2 - 7*x + 5*y - 3)
(5, 920)
```

So, the above equation is equivalent to the equation \( X^2 - 5Y^2 = 920 \) after a linear transformation. If we want to find the linear transformation, we can use `transformation_to_DN()` (page 782)

```python
>>> A, B = transformation_to_DN(x**2 - 3*x*y + y**2 - 7*x + 5*y - 3)
```

Here \( A \) is a 2 X 2 matrix and \( B \) is a 2 X 1 matrix such that the transformation

\[
\begin{bmatrix}
X \\
Y \\
\end{bmatrix}
= A
\begin{bmatrix}
x \\
y \\
\end{bmatrix}
+ B
\]

gives the equation \( X^2 - 5Y^2 = 920 \). Values of \( A \) and \( B \) are as belows.

```python
>>> A
Matrix([[
1/10, 3/10],
[ 0,  1/5]])
```

```python
>>> B
Matrix([[
  1/5],
[-11/5]])
```

We can solve an equation of the form \( X^2 - D Y^2 = N \) by passing \( D \) and \( N \) to `diop_DN()` (page 780)
```python
>>> diop_DN(5, 920)
[]
```

Unfortunately, our equation has no solution.

Now let’s turn to homogeneous ternary quadratic equations. These equations are of the form
\[ax^2 + by^2 + cz^2 + dxy + eyz + fzx = 0.\] These type of equations either have infinitely many solutions or no solutions (except the obvious solution \((0, 0, 0)\))

```python
>>> diophantine(3*x**2 + 4*y**2 - 5*z**2 + 4*x*y - 7*y*z + 7*z*x)
{(0, 0, 0)}
>>> diophantine(3*x**2 + 4*y**2 - 5*z**2 + 4*x*y - 7*y*z + 7*z*x)
{(-16*p**2 + 28*p*q + 20*q**2, 3*p**2 + 38*p*q - 25*q**2, 4*p**2 - 24*p*q + ... 68*q**2)}
```

If you are only interested in a base solution rather than the parameterized general solution (to be more precise, one of the general solutions), you can use `diop_ternary_quadratic()` (page 784).

```python
>>> from sympy.solvers.diophantine.diophantine import diop_ternary_quadratic
>>> diop_ternary_quadratic(3*x**2 + 4*y**2 - 5*z**2 + 4*x*y - 7*y*z + 7*z*x)
(-4, 5, 1)
```

`diop_ternary_quadratic()` (page 784) first converts the given equation to an equivalent equation of the form \(w^2 = AX^2 + BY^2\) and then it uses `descent()` (page 785) to solve the latter equation. You can refer to the docs of `transformation_to_normal()` (page 785) to find more on this. The equation \(w^2 = AX^2 + BY^2\) can be solved more easily by using the Aforementioned `descent()` (page 785).

```python
>>> from sympy.solvers.diophantine.diophantine import descent
>>> descent(3, 1) # solves the equation w**2 = 3*Y**2 + Z**2
(1, 0, 1)
```

Here the solution tuple is in the order \((w, Y, Z)\)

The extended Pythagorean equation, \(a_1x_1^2 + a_2x_2^2 + \ldots + a_nx_n^2 = a_{n+1}x_{n+1}^2\) and the general sum of squares equation, \(x_1^2 + x_2^2 + \ldots + x_n^2 = k\) can also be solved using the Diophantine module.

```python
>>> from sympy.abc import a, b, c, d, e, f
>>> diophantine(9*a**2 + 16*b**2 + c**2 + 49*d**2 + 4*e**2 - 25*f**2)
{(70*t1**2 + 70*t2**2 + 70*t3**2 + 70*t4**2 - 70*t5**2, 105*t1*t5, 420*t2*t5, ... 60*t3*t5, 210*t4*t5, 42*t1**2 + 42*t2**2 + 42*t3**2 + 42*t4**2 + 42*t5**2)}
```

function `diop_general_pythagorean()` (page 786) can also be called directly to solve the same equation. Either you can call `diop_general_pythagorean()` (page 786) or use the high level API. For the general sum of squares, this is also true, but one advantage of calling `diop_general_sum_of_squares()` (page 786) is that you can control how many solutions are returned.

```python
>>> from sympy.solvers.diophantine.diophantine import diop_general_sum_of_squares
>>> eq = a**2 + b**2 + c**2 + d**2 - 18
>>> diophantine(eq)
{(0, 0, 3, 3), (0, 1, 1, 4), (1, 2, 2, 3)}
```
>>> diop_general_sum_of_squares(eq, 2)
{(0, 0, 3, 3), (1, 2, 2, 3)}

The sum_of_squares() routine will provide an iterator that returns solutions and one may control whether the solutions contain zeros or not (and the solutions not containing zeros are returned first):

```python
>>> from sympy import *
>>> sos = sum_of_squares(18, 4, zeros=True)
>>> next(sos)
(1, 2, 2, 3)
>>> next(sos)
(0, 0, 3, 3)
```

Simple Egyptian fractions can be found with the Diophantine module, too. For example, here are the ways that one might represent 1/2 as a sum of two unit fractions:

```python
>>> from sympy import Eq, S
>>> diophantine(Eq(1/x + 1/y, S(1)/2))
{(-2, 1), (1, -2), (3, 6), (4, 4), (6, 3)}
```

To get a more thorough understanding of the Diophantine module, please refer to the following blog:

https://thilinaatsympy.wordpress.com/

**References**

**User Functions**

This function is imported into the global namespace with from sympy import *:

```python
sympy.solvers.diophantine.diophantine.diophantine(eq, param=t, syms=None, permutate=False)
```

Simplify the solution procedure of diophantine equation eq by converting it into a product of terms which should equal zero.

**Explanation**

For example, when solving, \( x^2 - y^2 = 0 \) this is treated as \((x + y)(x - y) = 0\) and \( x + y = 0 \) and \( x - y = 0 \) are solved independently and combined. Each term is solved by calling diop_solve(). (Although it is possible to call diop_solve() directly, one must be careful to pass an equation in the correct form and to interpret the output correctly; diophantine() is the public-facing function to use in general.)

Output of diophantine() is a set of tuples. The elements of the tuple are the solutions for each variable in the equation and are arranged according to the alphabetic ordering of the variables. e.g. For an equation with two variables, \( a \) and \( b \), the first element of the tuple is the solution for \( a \) and the second for \( b \).
**Usage**

diophantine(eq, t, syms): Solve the diophantine equation eq. t is the optional parameter to be used by diop_solve(). syms is an optional list of symbols which determines the order of the elements in the returned tuple.

By default, only the base solution is returned. If permute is set to True then permutations of the base solution and/or permutations of the signs of the values will be returned when applicable.

**Details**

eq should be an expression which is assumed to be zero. t is the parameter to be used in the solution.

**Examples**

```python
>>> from sympy import diophantine
>>> from sympy.abc import a, b
>>> eq = a**4 + b**4 - (2**4 + 3**4)
>>> diophantine(eq)
{(2, 3)}
>>> diophantine(eq, permute=True)
{(-3, -2), (-3, 2), (-2, -3), (2, -3), (-2, 3), (2, 3), (3, -2), (3, 2)}
```

```python
>>> from sympy.abc import x, y, z
>>> diophantine(x**2 - y**2)
{(t_0, -t_0), (t_0, t_0)}
```

```python
>>> diophantine(x*(2*x + 3*y - z))
{(0, n1, n2), (t_0, t_1, 2*t_0 + 3*t_1)}
>>> diophantine(x**2 + 3*x*y + 4*x)
{(0, n1), (3*t_0 - 4, -t_0)}
```

**See also:**

diop_solve (page 777), sympy.utilities.iterables.permute_signs (page 2160),
sympy.utilities.iterables.signed_permutations (page 2166)

And this function is imported with from sympy.solvers.diophantine import *:
sympy.solvers.diophantine.diophantine.classify_diop(eq, _dict=True)
**Internal Functions**

These functions are intended for internal use in the Diophantine module.

```python
sympy.solvers.diophantine.diophantine.diop_solve(eq, param=t)
```

Solves the diophantine equation `eq`.

**Explanation**

Unlike `diophantine()`, factoring of `eq` is not attempted. Uses `classify_diop()` to determine the type of the equation and calls the appropriate solver function.

Use of `diophantine()` is recommended over other helper functions. `diop_solve()` can return either a set or a tuple depending on the nature of the equation.

**Usage**

`diop_solve(eq, t)`: Solve diophantine equation, `eq` using `t` as a parameter if needed.

**Details**

`eq` should be an expression which is assumed to be zero. `t` is a parameter to be used in the solution.

**Examples**

```python
>>> from sympy.solvers.diophantine import diop_solve
>>> from sympy.abc import x, y, z, w
>>> diop_solve(2*x + 3*y - 5)
(3*t_0 - 5, 5 - 2*t_0)
>>> diop_solve(4*x + 3*y - 4*z + 5)
(t_0, 8*t_0 + 4*t_1 + 5, 7*t_0 + 3*t_1 + 5)
>>> diop_solve(x + 3*y - 4*z + w - 6)
(t_0, t_0 + t_1, 6*t_0 + 5*t_1 + 4*t_2 - 6, 5*t_0 + 4*t_1 + 3*t_2 - 6)
>>> diop_solve(x**2 + y**2 - 5)
{(-2, -1), (-2, 1), (-1, -2), (-1, 2), (1, -2), (1, 2), (2, -1), (2, 1)}
```

**See also:**

`diophantine` (page 775)

```python
sympy.solvers.diophantine.diophantine.diop_linear(eq, param=t)
```

Solves linear diophantine equations.

A linear diophantine equation is an equation of the form $a_1x_1 + a_2x_2 + \ldots + a_nx_n = 0$ where $a_1, a_2, \ldots a_n$ are integer constants and $x_1, x_2, \ldots x_n$ are integer variables.
Usage

diop_linear(eq): Returns a tuple containing solutions to the diophantine equation eq. Values in the tuple is arranged in the same order as the sorted variables.

Details

eq is a linear diophantine equation which is assumed to be zero. param is the parameter to be used in the solution.

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import diop_linear
>>> from sympy.abc import x, y, z

>>> diop_linear(2*x - 3*y - 5)  # solves equation 2*x - 3*y - 5 == 0
(3*t_0 - 5, 2*t_0 - 5)
```

Here x = -3*t_0 - 5 and y = -2*t_0 - 5

```python
>>> diop_linear(2*x - 3*y - 4*z -3)
(t_0, 2*t_0 + 4*t_1 + 3, -t_0 - 3*t_1 - 3)
```

See also:
diop_quadratic (page 779), diop_ternary_quadratic (page 784),
diop_general_pythagorean (page 786), diop_general_sum_of_squares (page 786)

sympy.solvers.diophantine.diophantine.base_solution_linear(c, a, b, t=None)

Return the base solution for the linear equation, \( ax + by = c \).

Explanation

Used by diop_linear() to find the base solution of a linear Diophantine equation. If t is given then the parametrized solution is returned.

Usage

base_solution_linear(c, a, b, t): a, b, c are coefficients in \( ax + by = c \) and t is the parameter to be used in the solution.
Examples

```python
>>> from sympy.solvers.diophantine.diophantine import base_solution_linear
>>> from sympy.abc import t
>>> base_solution_linear(5, 2, 3)  # equation 2*x + 3*y = 5
(-5, 5)
>>> base_solution_linear(0, 5, 7)  # equation 5*x + 7*y = 0
(0, 0)
>>> base_solution_linear(5, 2, 3, t)  # equation 2*x + 3*y = 5
(3*t - 5, 5 - 2*t)
>>> base_solution_linear(0, 5, 7, t)  # equation 5*x + 7*y = 0
(7*t, -5*t)
```

sympy.solvers.diophantine.diophantine.

```python
diop_quadratic(eq, param=t)
```

Solves quadratic diophantine equations.

i.e. equations of the form $Ax^2 + Bxy + Cy^2 + Dx + Ey + F = 0$. Returns a set containing the tuples $(x, y)$ which contains the solutions. If there are no solutions then $(None, None)$ is returned.

Usage

diop_quadratic(eq, param): eq is a quadratic binary diophantine equation. param is used to indicate the parameter to be used in the solution.

Details

eq should be an expression which is assumed to be zero. param is a parameter to be used in the solution.

Examples

```python
>>> from sympy.abc import x, y, t
>>> from sympy.solvers.diophantine.diophantine import diop_quadratic
>>> diop_quadratic(x**2 + y**2 + 2*x + 2*y + 2, t)
{(-1, -1)}
```

References

[R790], [R791]
sympy.solvers.diophantine.diophantine.diop_DN(D, N, t=t)
Solves the equation \( x^2 - Dy^2 = N \).

Explanation

Mainly concerned with the case \( D > 0 \), \( D \) is not a perfect square, which is the same as the generalized Pell equation. The LMM algorithm [R792] is used to solve this equation. Returns one solution tuple, \((x, y)\) for each class of the solutions. Other solutions of the class can be constructed according to the values of \( D \) and \( N \).

Usage

diop_DN(D, N, t): \( D \) and \( N \) are integers as in \( x^2 - Dy^2 = N \) and \( t \) is the parameter to be used in the solutions.

Details

\( D \) and \( N \) correspond to \( D \) and \( N \) in the equation. \( t \) is the parameter to be used in the solutions.

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import diop_DN
>>> diop_DN(13, -4)  # Solves equation x**2 - 13*y**2 = -4
[(3, 1), (393, 109), (36, 10)]
```

The output can be interpreted as follows: There are three fundamental solutions to the equation \( x^2 - 13y^2 = -4 \) given by \((3, 1)\), \((393, 109)\) and \((36, 10)\). Each tuple is in the form \((x, y)\), i.e. solution \((3, 1)\) means that \( x = 3 \) and \( y = 1 \).

```python
>>> diop_DN(986, 1)  # Solves equation x**2 - 986*y**2 = 1
[(49299, 1570)]
```

* find_DN (page 784), diop_bf_DN (page 781)
References

[R792]  

sympy.solvers.diophantine.diophantine.cornacchia \((a, b, m)\)

Solves \(ax^2 + by^2 = m\) where \(\gcd(a, b) = 1 = \gcd(a, m)\) and \(a, b > 0\).

Explanation

Uses the algorithm due to Cornacchia. The method only finds primitive solutions, i.e. ones with \(\gcd(x, y) = 1\). So this method cannot be used to find the solutions of \(x^2 + y^2 = 20\) since the only solution to former is \((x, y) = (4, 2)\) and it is not primitive. When \(a = b\), only the solutions with \(x \leq y\) are found. For more details, see the References.

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import cornacchia

>>> cornacchia(2, 3, 35)  # equation 2x**2 + 3y**2 = 35
{(2, 3), (4, 1)}

>>> cornacchia(1, 1, 25)  # equation x**2 + y**2 = 25
{(4, 3)}
```

sympy.utilities.iterables.signed_permutations (page 2166)

References

[R793], [R794]

sympy.solvers.diophantine.diophantine.diop_bf_DN \((D, N, t=t)\)

Uses brute force to solve the equation, \(x^2 - Dy^2 = N\).

Explanation

Mainly concerned with the generalized Pell equation which is the case when \(D > 0, D\) is not a perfect square. For more information on the case refer [R795]. Let \((t, u)\) be the minimal positive solution of the equation \(x^2 - Dy^2 = 1\). Then this method requires \(\sqrt{\frac{N}{|t \pm 1|}} 2D\) to be small.
Usage

diop_bf_DN(D, N, t): D and N are coefficients in $x^2 - Dy^2 = N$ and t is the parameter to be used in the solutions.

Details

D and N correspond to D and N in the equation. t is the parameter to be used in the solutions.

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import diop_bf_DN
>>> diop_bf_DN(13, -4)
[(3, 1), (-3, 1), (36, 10)]
>>> diop_bf_DN(986, 1)
[(49299, 1570)]
```

See also:

diop_DN (page 780)

References

[R795] sympy.solvers.diophantine.diophantine.transformation_to_DN(eq)
This function transforms general quadratic, $ax^2 + bxy + cy^2 + dx + ey + f = 0$ to more easy to deal with $x^2 - Dy^2 = N$ form.

Explanation

This is used to solve the general quadratic equation by transforming it to the latter form. Refer to [R796] for more detailed information on the transformation. This function returns a tuple (A, B) where A is a 2 X 2 matrix and B is a 2 X 1 matrix such that,

$\text{Transpose([x y]) = A * Transpose([X Y]) + B}$

Usage

transformation_to_DN(eq): where eq is the quadratic to be transformed.
Examples

```python
>>> from sympy.abc import x, y
>>> from sympy.solvers.diophantine.diophantine import transformation_to_DN
>>> A, B = transformation_to_DN(x**2 - 3*x*y - y**2 - 2*y + 1)
>>> A
Matrix([[1/26, 3/26],
        [0, 1/13]])
>>> B
Matrix([[-6/13],
        [-4/13]])
```

A, B returned are such that Transpose((x y)) = A * Transpose((X Y)) + B. Substituting these values for \(x\) and \(y\) and a bit of simplifying work will give an equation of the form \(x^2 - Dy^2 = N\).

```python
>>> from sympy.abc import X, Y
>>> from sympy import Matrix, simplify
>>> u = (A*Matrix([X, Y]) + B)[0] # Transformation for x
>>> u
X/26 + 3*Y/26 - 6/13
>>> v = (A*Matrix([X, Y]) + B)[1] # Transformation for y
>>> v
Y/13 - 4/13
```

Next we will substitute these formulas for \(x\) and \(y\) and do simplify().

```python
>>> eq = simplify((x**2 - 3*x*y - y**2 - 2*y + 1).subs(zip((x, y), (u, v))))
>>> eq
X**2/676 - Y**2/52 + 17/13
```

By multiplying the denominator appropriately, we can get a Pell equation in the standard form.

```python
>>> eq * 676
X**2 - 13*Y**2 + 884
```

If only the final equation is needed, `find_DN()` can be used.

**See also:**

`find_DN` (page 784)
References

[R796]
sympy.solvers.diophantine.diophantine.transformation_to_normal(eq)

Returns the transformation Matrix that converts a general ternary quadratic equation eq
\((ax^2 + by^2 + cz^2 + dxy + eyz + fxz)\) to a form without cross terms: \(ax^2 + by^2 + cz^2 = 0\). This is not
used in solving ternary quadratics; it is only implemented for the sake of completeness.

sympy.solvers.diophantine.diophantine.find_DN(eq)

This function returns a tuple, \((D;N)\) of the simplified form, \(x^2 - Dy^2 = N\), corresponding
to the general quadratic, \(ax^2 + bxy + cy^2 + dx + ey + f = 0\).

Solving the general quadratic is then equivalent to solving the equation \(X^2 - DY^2 = N\) and transforming the solutions by using the transformation matrices returned by
transformation_to_DN().

Usage

find_DN(eq): where eq is the quadratic to be transformed.

Examples

>>> from sympy.abc import x, y
>>> from sympy.solvers.diophantine.diophantine import find_DN
>>> find_DN(x**2 - 3*x*y - y**2 - 2*y + 1)
(13, -884)

Interpretation of the output is that we get \(X^2 - 13Y^2 = -884\) after transforming \(x^2 - 3xy - y^2 - 2y + 1\) using the transformation returned by transformation_to_DN().

See also:

transformation_to_DN (page 782)

References

[R797]
sympy.solvers.diophantine.diophantine.diop_ternary_quadratic(eq, parameterize=False)

Solves the general quadratic ternary form, \(ax^2 + by^2 + cz^2 + fxy + gyz + hzx = 0\).

Returns a tuple \((x, y, z)\) which is a base solution for the above equation. If there are no
solutions, \((None, None, None)\) is returned.
Usage

diop_ternary_quadratic(eq): Return a tuple containing a basic solution to eq.

Details

eq should be an homogeneous expression of degree two in three variables and it is assumed to be zero.

Examples

```python
>>> from sympy.abc import x, y, z
>>> from sympy.solvers.diophantine import diop_ternary_quadratic
>>> diop_ternary_quadratic(x**2 + 3*y**2 - z**2)
(1, 0, 1)
>>> diop_ternary_quadratic(4*x**2 + 5*y**2 - z**2)
(1, 0, 2)
>>> diop_ternary_quadratic(45*x**2 - 7*y**2 - 8*x*y - z**2)
(28, 45, 105)
>>> diop_ternary_quadratic(x**2 - 49*y**2 - z**2 + 13*z*y - 8*x*y)
(9, 1, 5)
```

sympy.solvers.diophantine.diophantine.square_factor(a)

Returns an integer c s.t. $a = c^2k$, $c, k \in \mathbb{Z}$. Here $k$ is square free. $a$ can be given as an integer or a dictionary of factors.

Examples

```python
>>> from sympy.solvers.diophantine import square_factor
>>> square_factor(24)
2
>>> square_factor(-36*3)
6
>>> square_factor(1)
1
>>> square_factor({3: 2, 2: 1, -1: 1})  # -18
3
```

See also:
sympy.ntheory.factor_.core (page 1549)
sympy.solvers.diophantine.diophantine.descent(A, B)

Returns a non-trivial solution, $(x, y, z)$, to $x^2 = A y^2 + B z^2$ using Lagrange’s descent method with lattice-reduction. $A$ and $B$ are assumed to be valid for such a solution to exist.

This is faster than the normal Lagrange’s descent algorithm because the Gaussian reduction is used.
Examples

```python
>>> from sympy.solvers.diophantine.diophantine import descent
>>> descent(3, 1) # x**2 = 3*y**2 + z**2
(1, 0, 1)
```

$(x, y, z) = (1, 0, 1)$ is a solution to the above equation.

```python
>>> descent(41, -113)
(-16, -3, 1)
```

References

[R798] sympy.solvers.diophantine.diophantine.diop_general_pythagorean(eq, param=m)

Solves the general pythagorean equation, $a_1^2 x_1^2 + a_2^2 x_2^2 + \cdots + a_n^2 x_n^2 - a_{n+1}^2 x_{n+1}^2 = 0$.

Returns a tuple which contains a parametrized solution to the equation, sorted in the same order as the input variables.

Usage
diop_general_pythagorean(eq, param): where eq is a general pythagorean equation which is assumed to be zero and param is the base parameter used to construct other parameters by subscripting.

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import diop_general_pythagorean
>>> from sympy.abc import a, b, c, d, e
>>> diop_general_pythagorean(a**2 + b**2 + c**2 - d**2)
(m1**2 + m2**2 - m3**2, 2*m1*m3, 2*m2*m3, m1**2 + m2**2 + m3**2)
>>> diop_general_pythagorean(9*a**2 - 4*b**2 + 16*c**2 + 25*d**2 + e**2)
(10*m1**2 + 10*m2**2 + 10*m3**2 - 10*m4**2, 15*m1**2 + 15*m2**2 + 15*m3**2 + 15*m4**2 + 15*m5**2 + 25*m6**2 + 50*m7**2 + 75*m8**2 + 125*m9**2 + 375*m10**2 + 1250*m11**2 + 3750*m12**2 + 11250*m13**2 + 33750*m14**2 + 100000*m15**2)
```

sympy.solvers.diophantine.diophantine.diop_general_sum_of_squares(eq, limit=1)

Solves the equation $x_1^2 + x_2^2 + \cdots + x_n^2 - k = 0$.

Returns at most limit number of solutions.
Usage

general_sum_of_squares(eq, limit): Here eq is an expression which is assumed to be zero. Also, eq should be in the form, \( x_1^2 + x_2^2 + \ldots + x_n^2 - k = 0 \).

Details

When \( n = 3 \) if \( k = 4^a(8m + 7) \) for some \( a, m \in \mathbb{Z} \) then there will be no solutions. Refer to [R799] for more details.

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import diop_general_sum_of_squares
>>> from sympy.abc import a, b, c, d, e
>>> diop_general_sum_of_squares(a**2 + b**2 + c**2 + d**2 + e**2 - 2345)
{(15, 22, 22, 24, 24)}
```

Reference

sympy.solvers.diophantine.diophantine.diop_general_sum_of_even_powers(eq, limit=1)

Solves the equation \( x_1^e + x_2^e + \ldots + x_n^e - k = 0 \) where \( e \) is an even, integer power.

Returns at most limit number of solutions.

Usage

general_sum_of_even_powers(eq, limit): Here eq is an expression which is assumed to be zero. Also, eq should be in the form, \( x_1^e + x_2^e + \ldots + x_n^e - k = 0 \).

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import diop_general_sum_of_even_powers
>>> from sympy.abc import a, b
>>> diop_general_sum_of_even_powers(a**4 + b**4 - (2**4 + 3**4))
{(2, 3)}
```

See also:

power_representation (page 787)

sympy.solvers.diophantine.diophantine.power_representation(n, p, k, zeros=False)

Returns a generator for finding k-tuples of integers, \( (n_1, n_2, \ldots, n_k) \), such that \( n = n_1^p + n_2^p + \ldots + n_k^p \).
Usage

power_representation(n, p, k, zeros): Represent non-negative number n as a sum of k pth powers. If zeros is true, then the solutions is allowed to contain zeros.

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import power_representation

Represent 1729 as a sum of two cubes:
```
```python
>>> f = power_representation(1729, 3, 2)
>>> next(f)
(9, 10)
>>> next(f)
(1, 12)
```

If the flag zeros is True, the solution may contain tuples with zeros; any such solutions will be generated after the solutions without zeros:
```
>>> list(power_representation(125, 2, 3, zeros=True))
[(5, 6, 8), (3, 4, 10), (0, 5, 10), (0, 2, 11)]
```

For even p the permute_signs function can be used to get all signed values:
```
>>> from sympy.utilities.iterables import permute_signs
>>> list(permute_signs((1, 12)))
[(1, 12), (-1, 12), (1, -12), (-1, -12)]
```

All possible signed permutations can also be obtained:
```
>>> from sympy.utilities.iterables import signed_permutations
>>> list(signed_permutations((1, 12)))
[(1, 12), (-1, 12), (1, -12), (-1, -12), (12, 1), (-12, 1), (12, -1), (-12, -1)]
```

sympy.solvers.diophantine.diophantine.partition(n, k=None, zeros=False)
Returns a generator that can be used to generate partitions of an integer n.

Explanation

A partition of n is a set of positive integers which add up to n. For example, partitions of 3 are 3, 1 + 2, 1 + 1 + 1. A partition is returned as a tuple. If k equals None, then all possible partitions are returned irrespective of their size, otherwise only the partitions of size k are returned. If the zero parameter is set to True then a suitable number of zeros are added at the end of every partition of size less than k.

zero parameter is considered only if k is not None. When the partitions are over, the last next() call throws the StopIteration exception, so this function should always be used inside a try-except block.
Details

partition(n, k): Here n is a positive integer and k is the size of the partition which is also positive integer.

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import partition
>>> f = partition(5)
>>> next(f)
(1, 1, 1, 1, 1)
>>> next(f)
(1, 1, 1, 2)
>>> g = partition(5, 3)
>>> next(g)
(1, 1, 3)
>>> next(g)
(1, 2, 2)
>>> g = partition(5, 3, zeros=True)
>>> next(g)
(0, 0, 5)
```

sympy.solvers.diophantine.diophantine.sum_of_three_squares(n)

Returns a 3-tuple \((a, b, c)\) such that \(a^2 + b^2 + c^2 = n\) and \(a, b, c \geq 0\).

Returns None if \(n = 4^a(8m + 7)\) for some \(a, m \in \mathbb{Z}\). See [R800] for more details.

Usage

sum_of_three_squares(n): Here n is a non-negative integer.

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import sum_of_three_squares
>>> sum_of_three_squares(44542)
(18, 37, 207)
```

See also:

sum_of_squares (page 791)
**References**

[R800]
sympy.solvers.diophantine.diophantine.\texttt{sum\_of\_four\_squares}(n)  
Returns a 4-tuple \((a, b, c, d)\) such that \(a^2 + b^2 + c^2 + d^2 = n\).  
Here \(a, b, c, d \geq 0\).

**Usage**

\texttt{sum\_of\_four\_squares}(n): Here \(n\) is a non-negative integer.

**Examples**

```python  
>>> from sympy.solvers.diophantine.diophantine import sum_of_four_squares  
>>> sum_of_four_squares(3456)  
(8, 8, 32, 48)  
>>> sum_of_four_squares(1294585930293)  
(0, 1234, 2161, 1137796)  
```

See also:  
\texttt{sum\_of\_squares} (page 791)

**References**

[R801]
sympy.solvers.diophantine.diophantine.\texttt{sum\_of\_powers}(n, p, k, zeros=False)  
Returns a generator for finding \(k\)-tuples of integers, \((n_1, n_2, \ldots n_k)\), such that \(n = n_1^p + n_2^p + \ldots n_k^p\).

**Usage**

\texttt{power\_representation}(n, p, k, zeros): Represent non-negative number \(n\) as a sum of \(k\) \(p\)th powers. If \(zeros\) is true, then the solutions is allowed to contain zeros.

**Examples**

```python  
>>> from sympy.solvers.diophantine.diophantine import power_representation  
Represent 1729 as a sum of two cubes:  
>>> f = power_representation(1729, 3, 2)  
>>> next(f)  
(9, 10)  
>>> next(f)  
(1, 12)  
```
If the flag `zeros` is True, the solution may contain tuples with zeros; any such solutions will be generated after the solutions without zeros:

```python
>>> list(power_representation(125, 2, 3, zeros=True))
[(5, 6, 8), (3, 4, 10), (0, 5, 10), (0, 2, 11)]
```

For even $p$ the `permute_sign` function can be used to get all signed values:

```python
>>> from sympy.utilities.iterables import permute_signs
>>> list(permute_signs((1, 12)))
[(1, 12), (-1, 12), (1, -12), (-1, -12)]
```

All possible signed permutations can also be obtained:

```python
>>> from sympy.utilities.iterables import signed_permutations
>>> list(signed_permutations((1, 12)))
[(1, 12), (-1, 12), (1, -12), (-1, -12), (12, 1), (-12, 1), (12, -1), (-12, -1)]
```

`syrpy.solvers.diophantine.diophantine.sum_of_squares(n, k, zeros=False)`

Return a generator that yields the $k$-tuples of nonnegative values, the squares of which sum to $n$. If zeros is False (default) then the solution will not contain zeros. The nonnegative elements of a tuple are sorted.

- If $k == 1$ and $n$ is square, $(n,)$ is returned.
- If $k == 2$ then $n$ can only be written as a sum of squares if every prime in the factorization of $n$ that has the form $4*k + 3$ has an even multiplicity. If $n$ is prime then it can only be written as a sum of two squares if it is in the form $4*k + 1$.
- If $k == 3$ then $n$ can be written as a sum of squares if it does not have the form $4**m*(8*k + 7)$.
- All integers can be written as the sum of 4 squares.
- If $k > 4$ then $n$ can be partitioned and each partition can be written as a sum of 4 squares; if $n$ is not evenly divisible by 4 then $n$ can be written as a sum of squares only if the an additional partition can be written as sum of squares. For example, if $k = 6$ then $n$ is partitioned into two parts, the first being written as a sum of 4 squares and the second being written as a sum of 2 squares – which can only be done if the condition above for $k = 2$ can be met, so this will automatically reject certain partitions of $n$.

**Examples**

```python
>>> from sympy.solvers.diophantine.diophantine import sum_of_squares
>>> list(sum_of_squares(25, 2))
[[3, 4]]
>>> list(sum_of_squares(25, 2, True))
[[3, 4], [0, 5]]
>>> list(sum_of_squares(25, 4))
[[1, 2, 2, 4]]
```

**See also:**

`syrpy.utilities.iterables.signed_permutations` (page 2166)

5.8. Topics 791
**Explanation**

For example when solving the equation \((x - y)(x^2 + y^2 - z^2) = 0\), solutions for each of the equations \(x - y = 0\) and \(x^2 + y^2 - z^2\) are found independently. Solutions for \(x - y = 0\) are \((x, y) = (t, t)\). But we should introduce a value for \(z\) when we output the solution for the original equation. This function converts \((t, t)\) into \((t, t, n_1)\) where \(n_1\) is an integer parameter.

**Explanation**

There are six sequences of integers defined related to the continued fraction representation of \(\frac{P_0}{Q_0} + \sqrt{D}Q_0\), namely \(\{P_i\}, \{Q_i\}, \{a_i\}, \{A_i\}, \{B_i\}, \{G_i\}\). \(\text{PQa}()\) Returns these values as a 6-tuple in the same order as mentioned above. Refer [R802] for more detailed information.

**Usage**

\(\text{PQa}(P_0, Q_0, D)\): \(P_0, Q_0\) and \(D\) are integers corresponding to \(P_0, Q_0\) and \(D\) in the continued fraction \(\frac{P_0}{Q_0} + \sqrt{D}Q_0\). Also it’s assumed that \(P_0^2 = D mod(|Q_0|)\) and \(D\) is square free.

**Examples**

```python
>>> from sympy.solvers.diophantine.diophantine import PQa
>>> pqa = PQa(13, 4, 5) # (13 + sqrt(5))/4
>>> next(pqa) # (P_0, Q_0, a_0, A_0, B_0, G_0)
(13, 4, 3, 3, 1, -1)
>>> next(pqa) # (P_1, Q_1, a_1, A_1, B_1, G_1)
(-1, 1, 1, 4, 1, 3)
```
References

[R802]
sympy.solvers.diophantine.diophantine.equivalent(u, v, r, s, D, N)
Returns True if two solutions (u, v) and (r, s) of \(x^2 - Dy^2 = N\) belongs to the same equivalence class and False otherwise.

Explanation

Two solutions (u, v) and (r, s) to the above equation fall to the same equivalence class iff both \((ur - Dvs)\) and \((us - vr)\) are divisible by \(N\). See reference [R803]. No test is performed to test whether (u, v) and (r, s) are actually solutions to the equation. User should take care of this.

Usage

equivalent(u, v, r, s, D, N): (u, v) and (r, s) are two solutions of the equation \(x^2 - Dy^2 = N\) and all parameters involved are integers.

Examples

```python
>>> from sympy import equivalent
>>> equivalent(18, 5, -18, -5, 13, -1)
True
>>> equivalent(3, 1, -18, 393, 109, -4)
False
```

References

[R803]
sympy.solvers.diophantine.diophantine.parametrize_ternary_quadratic(eq)
Returns the parametrized general solution for the ternary quadratic equation eq which has the form \(ax^2 + by^2 + cz^2 + fxy + gyz + hzx = 0\).

Examples

```python
>>> from sympy import Tuple, ordered
>>> from sympy import x, y, z
>>> from sympy import parametrize_ternary_quadratic

The parametrized solution may be returned with three parameters:

```
There might also be only two parameters:

```python
>>> parametrize_ternary_quadratic(4*x**2 + 2*y**2 - 3*z**2)
(2*p**2 - 3*q**2, -4*p**2 + 12*p*q - 6*q**2, 4*p**2 - 8*p*q + 6*q**2)
```

**Notes**

Consider \( p \) and \( q \) in the previous 2-parameter solution and observe that more than one solution can be represented by a given pair of parameters. If \( p \) and \( q \) are not coprime, this is trivially true since the common factor will also be a common factor of the solution values. But it may also be true even when \( p \) and \( q \) are coprime:

```python
>>> sol = Tuple(*_)
>>> p, q = ordered(sol.free_symbols)
>>> sol.subs([(p, 3), (q, 2)]))
(6, 12, 12)
>>> sol.subs([(q, 1), (p, 1)])
(-1, 2, 2)
>>> sol.subs([(q, 0), (p, 1)])
(2, -4, 4)
>>> sol.subs([(q, 1), (p, 0)])
(-3, -6, 6)
```

Except for sign and a common factor, these are equivalent to the solution of \( (1, 2, 2) \).

**References**

[R804] sympy.solvers.diophantine.diophantine.diopternaryquadraticnormal(eq, parameterize=False)

Solves the quadratic ternary diophantine equation, \( ax^2 + by^2 + cz^2 = 0 \).

**Explanation**

Here the coefficients \( a, b, \) and \( c \) should be non zero. Otherwise the equation will be a quadratic binary or univariate equation. If solvable, returns a tuple \( (x, y, z) \) that satisfies the given equation. If the equation does not have integer solutions, \( (None, None, None) \) is returned.
Usage

diop_ternary_quadratic_normal(eq): where eq is an equation of the form $ax^2 + by^2 + cz^2 = 0$.

Examples

```python
>>> from sympy.abc import x, y, z
>>> from sympy.solvers.diophantine import diop_ternary_quadratic_normal
>>> diop_ternary_quadratic_normal(x**2 + 3*y**2 - z**2)
(1, 0, 1)
>>> diop_ternary_quadratic_normal(4*x**2 + 5*y**2 - z**2)
(1, 0, 2)
>>> diop_ternary_quadratic_normal(34*x**2 - 3*y**2 - 301*z**2)
(4, 9, 1)
```

symy.solvers.diophantine.ldescent($A, B$)

Return a non-trivial solution to $w^2 = Ax^2 + By^2$ using Lagrange’s method; return None if there is no such solution.

Here, $A \neq 0$ and $B \neq 0$ and $A$ and $B$ are square free. Output a tuple $(w_0, x_0, y_0)$ which is a solution to the above equation.

Examples

```python
>>> from sympy.solvers.diophantine import ldescent
>>> ldescent(1, 1)  # $w^2 = x^2 + y^2$
(1, 1, 0)
>>> ldescent(4, -7)  # $w^2 = 4x^2 - 7y^2$
(2, -1, 0)
```

This means that $x = -1, y = 0$ and $w = 2$ is a solution to the equation $w^2 = 4x^2 - 7y^2$

```python
>>> ldescent(5, -1)  # $w^2 = 5x^2 - y^2$
(2, 1, -1)
```

References

[R805], [R806]

symy.solvers.diophantine.gaussian_reduce($w, a, b$)

Returns a reduced solution $(x, z)$ to the congruence $X^2 - aZ^2 \equiv 0 \pmod{b}$ so that $x^2 + |a|z^2$ is minimal.
Details

Here \( w \) is a solution of the congruence \( x^2 \equiv a \pmod{b} \)

References

[R807], [R808]

**sympy.solvers.diophantine.diophantine.holzer**\( (x, y, z, a, b, c) \)

Simplify the solution \((x, y, z)\) of the equation \( ax^2 + by^2 = cz^2 \) with \( a, b, c > 0 \) and \( z^2 \geq |ab| \) to a new reduced solution \((x', y', z')\) such that \( z'^2 \leq |ab| \).

The algorithm is an interpretation of Mordell’s reduction as described on page 8 of Cremona and Rusin’s paper [R809] and the work of Mordell in reference [R810].

References

[R809], [R810]

**sympy.solvers.diophantine.diophantine.prime_as_sum_of_two_squares**\( (p) \)

Represent a prime \( p \) as a unique sum of two squares; this can only be done if the prime is congruent to 1 mod 4.

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import prime_as_sum_of_two_squares
>>> prime_as_sum_of_two_squares(7)  # can't be done
>>> prime_as_sum_of_two_squares(5)
(1, 2)
```

Reference

See also:

*sum_of_squares* (page 791)

**sympy.solvers.diophantine.diophantine.sqf_normal**\( (a, b, c, steps=False) \)

Return \( a', b', c' \), the coefficients of the square-free normal form of \( ax^2 + by^2 + cz^2 = 0 \), where \( a', b', c' \) are pairwise prime. If \( steps \) is True then also return three tuples: \( sq, sqf, \) and \( (a', b', c') \) where \( sq \) contains the square factors of \( a, b \) and \( c \) after removing the \( \gcd(a, b, c) \); \( sqf \) contains the values of \( a, b \) and \( c \) after removing both the \( \gcd(a, b, c) \) and the square factors.

The solutions for \( ax^2 + by^2 + cz^2 = 0 \) can be recovered from the solutions of \( a'x'^2 + b'y'^2 + c'z'^2 = 0 \).
Examples

```python
>>> from sympy.solvers.diophantine.diophantine import sqf_normal
>>> sqf_normal(2 * 3**2 * 5, 2 * 5 * 11, 2 * 7**2 * 11)
(11, 1, 5)
>>> sqf_normal(2 * 3**2 * 5, 2 * 5 * 11, 2 * 7**2 * 11, True)
((3, 1, 7), (5, 55, 11), (11, 1, 5))
```

See also:

`reconstruct` (page 797)

References

[R812]

sympy.solvers.diophantine.diophantine.\(\text{reconstruct}(A, B, z)\)

Reconstruct the \(z\) value of an equivalent solution of \(ax^2 + by^2 + cz^2\) from the \(z\) value of a
solution of the square-free normal form of the equation, \(a'x^2 + b'y^2 + c'z^2\), where \(a'\),
\(b'\) and \(c'\) are square free and \(gcd(a', b', c') == 1\).

Internal Classes

These classes are intended for internal use in the Diophantine module.

```python
class sympy.solvers.diophantine.diophantine.\(\text{DiophantineSolutionSet}\)(symbols_seq, parameters)
```

Container for a set of solutions to a particular diophantine equation.

The base representation is a set of tuples representing each of the solutions.

Parameters

symbols : list

List of free symbols in the original equation.

parameters: list

List of parameters to be used in the solution.

Examples

Adding solutions:

```python
>>> from sympy.solvers.diophantine.diophantine import DiophantineSolutionSet
>>> from sympy.abc import x, y, t, u
>>> s1 = DiophantineSolutionSet([x, y], [t, u])
>>> s1
set()
>>> s1.add((2, 3))
>>> s1.add((-1, u))
>>> s1
```

(continues on next page)
>>> s2 = DiophantineSolutionSet([x, y], [t, u])
>>> s2.add((3, 4))
>>> s1.update(s2)
>>> s1
{(-1, u), (2, 3), (3, 4)}

Conversion of solutions into dicts:

>>> list(s1.dict_iterator())
[{x: -1, y: u}, {x: 2, y: 3}, {x: 3, y: 4}]

Substituting values:

>>> s3 = DiophantineSolutionSet([x, y], [t, u])
>>> s3.add((t**2, t + u))
>>> s3
{(t**2, t + u)}
>>> s3.subs({t: 2, u: 3})
{(4, 5)}
>>> s3.subs(t, -1)
{(1, u - 1)}
>>> s3.subs(t, 3)
{(9, u + 3)}

Evaluation at specific values. Positional arguments are given in the same order as the parameters:

>>> s3(-2, 3)
{(4, 1)}
>>> s3(5)
{(25, u + 5)}
>>> s3(None, 2)
{(t**2, t + 2)}

class sympy.solvers.diophantine.diophantine.DiophantineEquationType(equation, free_symbols=None)

Internal representation of a particular diophantine equation type.

**Parameters**

- **equation**: The diophantine equation that is being solved.
- **free_symbols**: list (optional)
  The symbols being solved for.
Attributes

<table>

matches()

Determine whether the given equation can be matched to the particular equation type.

class sympy.solvers.diophantine.diophantine.Univariate(equation, free_symbols=None)

Representation of a univariate diophantine equation.

A univariate diophantine equation is an equation of the form \(a_0 + a_1 x + a_2 x^2 + \ldots + a_n x^n = 0\) where \(a_1, a_2, \ldots, a_n\) are integer constants and \(x\) is an integer variable.

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import Univariate
>>> from sympy.abc import x
>>> Univariate((x - 2)*(x - 3)**2).solve() # solves equation (x - 2)*(x - 3)**2 == 0
{(2,), (3,)}
```

class sympy.solvers.diophantine.diophantine.Linear(equation, free_symbols=None)

Representation of a linear diophantine equation.

A linear diophantine equation is an equation of the form \(a_1 x_1 + a_2 x_2 + \ldots + a_n x_n = 0\) where \(a_1, a_2, \ldots, a_n\) are integer constants and \(x_1, x_2, \ldots, x_n\) are integer variables.

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import Linear
>>> from sympy.abc import x, y, z
>>> l1 = Linear(2*x - 3*y - 5)
>>> l1.matches() # is this equation linear
True
>>> l1.solve() # solves equation 2*x - 3*y - 5 == 0
{(3*t_0 - 5, 2*t_0 - 5)}
```

Here \(x = -3t_0 - 5\) and \(y = -2t_0 - 5\)

```python
>>> Linear(2*x - 3*y - 4*z - 3).solve()
{(t_0, 2*t_0 + 4*t_1 + 3, -t_0 - 3*t_1 - 3)}
```
class sympy.solvers.diophantine.diophantine.BinaryQuadratic(equation, free_symbols=None)

Representation of a binary quadratic diophantine equation.

A binary quadratic diophantine equation is an equation of the form $Ax^2 + Bxy + Cy^2 + Dx + Ey + F = 0$, where $A, B, C, D, E, F$ are integer constants and $x$ and $y$ are integer variables.

Examples

```python
>>> from sympy.abc import x, y
>>> from sympy.solvers.diophantine.diophantine import BinaryQuadratic
>>> b1 = BinaryQuadratic(x**3 + y**2 + 1)
>>> b1.matches()
False
>>> b2 = BinaryQuadratic(x**2 + y**2 + 2*x + 2*y + 2)
>>> b2.matches()
True
>>> b2.solve()
{(-1, -1)}
```

References

[R813], [R814]

class sympy.solvers.diophantine.diophantine.InhomogeneousTernaryQuadratic(equation, free_symbols=None)

Representation of an inhomogeneous ternary quadratic.

No solver is currently implemented for this equation type.

class sympy.solvers.diophantine.diophantine.HomogeneousTernaryQuadraticNormal(equation, free_symbols=None)

Representation of a homogeneous ternary quadratic normal diophantine equation.

Examples

```python
>>> from sympy.abc import x, y, z
>>> from sympy.solvers.diophantine.diophantine import HomogeneousTernaryQuadraticNormal
>>> HomogeneousTernaryQuadraticNormal(4*x**2 - 5*y**2 + z**2).solve()
{(1, 2, 4)}
```

class sympy.solvers.diophantine.diophantine.HomogeneousTernaryQuadratic(equation, free_symbols=None)

Representation of a homogeneous ternary quadratic diophantine equation.
Examples

```python
>>> from sympy.abc import x, y, z
>>> from sympy.solvers.diophantine.diophantine import
t
HomogeneousTernaryQuadratic
>>> HomogeneousTernaryQuadratic(x**2 + y**2 - 3*z**2 + x*y).solve()
{(-1, 2, 1)}
>>> HomogeneousTernaryQuadratic(3*x**2 + y**2 - 3*z**2 + 5*x*y + y*z).
solve()
{(3, 12, 13)}
```

class sympy.solvers.diophantine.diophantine.InhomogeneousGeneralQuadratic(equation, free_symbols=None)

Representation of an inhomogeneous general quadratic.

No solver is currently implemented for this equation type.

class sympy.solvers.diophantine.diophantine.HomogeneousGeneralQuadratic(equation, free_symbols=None)

Representation of a homogeneous general quadratic.

No solver is currently implemented for this equation type.

class sympy.solvers.diophantine.diophantine.GeneralSumOfSquares(equation, free_symbols=None)

Representation of the diophantine equation

\[ x_1^2 + x_2^2 + \ldots + x_n^2 - k = 0. \]

Details

When \( n = 3 \) if \( k = 4^a(8m + 7) \) for some \( a, m \in \mathbb{Z} \) then there will be no solutions. Refer [R815] for more details.

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import GeneralSumOfSquares
>>> from sympy.abc import a, b, c, d, e
>>> GeneralSumOfSquares(a**2 + b**2 + c**2 + d**2 + e**2 - 2345).solve()
{(15, 22, 22, 24, 24)}
```

By default only 1 solution is returned. Use the `limit` keyword for more:

```python
>>> sorted(GeneralSumOfSquares(a**2 + b**2 + c**2 + d**2 + e**2 - 2345).solve(limit=3))
[(15, 22, 22, 24, 24), (16, 19, 24, 24, 24), (16, 20, 22, 23, 26)]
```
References

[R815]

class sympy.solvers.diophantine.diophantine.GeneralPythagorean(equation, free_symbols=None)

Representation of the general pythagorean equation, \( a_1^2 x_1^2 + a_2^2 x_2^2 + \cdots + a_n^2 x_n^2 - a_{n+1} x_{n+1}^2 = 0 \).

Examples

```python
>>> from sympy.solvers.diophantine.diophantine import GeneralPythagorean
>>> from sympy import a, b, c, d, e, x, y, z, t

>>> GeneralPythagorean(a**2 + b**2 + c**2 - d**2).solve()
{(z_0**2 + t_1**2 - t_2**2, 2*z_0*t_2, 2*t_1*t_2, t_0**2 + t_1**2 + t_2**2)}

>>> GeneralPythagorean(9*a**2 - 4*b**2 + 16*c**2 + 25*d**2 + e**2).solve(parameters=[x, y, z, t])
{(-10**2 + 10*x**2 + 10*y**2 + 10*z**2, 15*t**2 + 15*x**2 + 15*y**2 + 15*z**2, 15*t*x, 12*t*y, 60*t*z)}
```

class sympy.solvers.diophantine.diophantine.CubicThue(equation, free_symbols=None)

Representation of a cubic Thue diophantine equation.

A cubic Thue diophantine equation is a polynomial of the form \( f(x, y) = r \) of degree 3, where \( x \) and \( y \) are integers and \( r \) is a rational number.

No solver is currently implemented for this equation type.

Examples

```python
>>> from sympy.abc import x, y

>>> from sympy.solvers.diophantine.diophantine import CubicThue

>>> c1 = CubicThue(x**3 + y**2 + 1)

>>> c1.matches()
True
```

class sympy.solvers.diophantine.diophantine.GeneralSumOfEvenPowers(equation, free_symbols=None)

Representation of the diophantine equation

\( x_1^e + x_2^e + \cdots + x_n^e - k = 0 \)

where \( e \) is an even, integer power.
Examples

```python
>>> from sympy.solvers.diophantine.diophantine import
| GeneralSumOfEvenPowers
>>> from sympy.abc import a, b
>>> GeneralSumOfEvenPowers(a**4 + b**4 - (2**4 + 3**4)).solve()
{(2, 3)}
```

Inequality Solvers

For general cases `reduce_inequalities()` (page 805) should be used. Other functions are
the subcategories useful for special dedicated operations, and will be called internally as
needed by `reduce_inequalities`.

Note: For a beginner-friendly guide focused on solving inequalities, refer to *Reduce One or
a System of Inequalities for a Single Variable Algebraically* (page 177).

Note: Some of the examples below use `poly()` (page 2435), which simply transforms an
expression into a polynomial; it does not change the mathematical meaning of the expression.

```python
sympy.solvers.inequalities.solve_rational_inequalities(eqs)
Solve a system of rational inequalities with rational coefficients.

Examples

```python
>>> from sympy.abc import x
>>> from sympy import solve_rational_inequalities, Poly

```python
>>> solve_rational_inequalities([[... (Poly(-x + 1), Poly(1, x)), '>='),
... (Poly(-x + 1), Poly(1, x)), '<=')]]
{1}

```python
>>> solve_rational_inequalities([[... (Poly(x), Poly(1, x)), '!='),
... (Poly(-x + 1), Poly(1, x)), '>'])
Union(Interval.open(-oo, 0), Interval.Lopen(0, 1))
```

See also:

`solve_poly_inequality` (page 803)

sympy.solvers.inequalities.solve_poly_inequality(poly, rel)
Solve a polynomial inequality with rational coefficients.
Examples

```python
>>> from sympy import solve_poly_inequality, Poly
>>> from sympy.abc import x
```

```python
>>> solve_poly_inequality(Poly(x, x, domain='ZZ'), '==')
[[{0}]]
```

```python
>>> solve_poly_inequality(Poly(x**2 - 1, x, domain='ZZ'), '!=')
[Interval.open(-oo, -1), Interval.open(-1, 1), Interval.open(1, oo)]
```

```python
>>> solve_poly_inequality(Poly(x**2 - 1, x, domain='ZZ'), '==')
[{-1}, {1}]
```

See also:

`solve_poly_inequalities` (page 804)

sympy.solvers.inequalities.solve_poly_inequalities(polys)

Solve polynomial inequalities with rational coefficients.

Examples

```python
>>> from sympy import Poly
>>> from sympy.solvers.inequalities import solve_poly_inequalities
>>> from sympy.abc import x
```

```python
>>> solve_poly_inequalities(((...Poly(x**2 - 3),">"), (...Poly(-x**2 + 1),"">")))
Union(Interval.open(-oo, -sqrt(3)), Interval.open(-1, 1), Interval.open(sqrt(3), oo))
```

sympy.solvers.inequalities.reduce_rational_inequalities(exprs, gen, relational=True)

Reduce a system of rational inequalities with rational coefficients.

Examples

```python
>>> from sympy import Symbol
>>> from sympy.solvers.inequalities import reduce_rational_inequalities
```

```python
>>> x = Symbol('x', real=True)
>>> reduce_rational_inequalities([[x**2 <= 0]], x)
Eq(x, 0)
```

```python
>>> reduce_rational_inequalities([[x + 2 > 0]], x)
-2 < x
```

(continues on next page)
-2 < x
>>> reduce_rational_inequalities([[x + 2]], x)
Eq(x, -2)

This function find the non-infinite solution set so if the unknown symbol is declared as extended real rather than real then the result may include finiteness conditions:

>>> y = Symbol('y', extended_real=True)
>>> reduce_rational_inequalities([[y + 2 > 0]], y)
(-2 < y) & (y < oo)

sympy.solvers.inequalities.reduce_abs_inequality(expr, rel, gen)
Reduce an inequality with nested absolute values.

Examples

>>> from sympy import reduce_abs_inequality, Abs, Symbol
>>> x = Symbol('x', real=True)

>>> reduce_abs_inequality(Abs(x - 5) - 3, '<', x)
(2 < x) & (x < 8)

>>> reduce_abs_inequality(Abs(x + 2)*3 - 13, '<', x)
(-19/3 < x) & (x < 7/3)

See also:
reduce_abs_inequality (page 805)

sympy.solvers.inequalities.reduce_abs_inequalities(exprs, gen)
Reduce a system of inequalities with nested absolute values.

Examples

>>> from sympy import reduce_abs_inequalities, Abs, Symbol

>>> reduce_abs_inequalities([[Abs(3*x - 5) - 7, '<'],
... (Abs(x + 25) - 13, '>')], x)
((-2/3 < x) & (x < 4) & (((-oo < x) & (x < -38)) | ((-12 < x) & (x < oo))))

>>> reduce_abs_inequalities([[Abs(x - 4) + Abs(3*x - 5) - 7, '<']], x)
(1/2 < x) & (x < 4)

See also:
reduce_abs_inequality (page 805)

sympy.solvers.inequalities.reduce_inequalities(inequalities, symbols=[]) Reduce a system of inequalities with rational coefficients.
Examples

```python
>>> from sympy.abc import x, y
>>> from sympy import reduce_inequalities

>>> reduce_inequalities(0 <= x + 3, [])
(-3 <= x) & (x < oo)

>>> reduce_inequalities(0 <= x + y**2 - 1, [x])
(x < oo) & (x >= 1 - 2*y)
```

`sympy.solvers.inequalities.solve_univariate_inequality(expr, gen, relational=True, domain=Reals, continuous=False)`

Solves a real univariate inequality.

**Parameters**
- `expr` : Relational
  The target inequality
- `gen` : Symbol
  The variable for which the inequality is solved
- `relational` : bool
  A Relational type output is expected or not
- `domain` : Set
  The domain over which the equation is solved
- `continuous` : bool
  True if expr is known to be continuous over the given domain (and so `continuous_domain()` does not need to be called on it)

**Raises**
- `NotImplementedError`
  The solution of the inequality cannot be determined due to limitation in `sympy.solvers.solve_set.solveify()` (page 917).

**Notes**
Currently, we cannot solve all the inequalities due to limitations in `sympy.solvers.solve_set.solveify()` (page 917). Also, the solution returned for trigonometric inequalities are restricted in its periodic interval.
Examples

```python
>>> from sympy import solve_univariate_inequality, Symbol, sin, Interval, S
>>> x = Symbol('x')

>>> solve_univariate_inequality(x**2 >= 4, x)
((2 <= x) & (x < oo)) | ((-oo < x) & (x <= -2))

>>> solve_univariate_inequality(x**2 >= 4, x, relational=False)
Union(Interval(-oo, -2), Interval(2, oo))

>>> domain = Interval(0, S.Infinity)
>>> solve_univariate_inequality(x**2 >= 4, x, False, domain)
Interval(2, oo)

>>> solve_univariate_inequality(sin(x) > 0, x, relational=False)
Interval.open(0, pi)
```

solver returning solveset solutions with solve's output API

ODE

Note: For a beginner-friendly guide focused on solving ODEs, refer to *Solve an Ordinary Differential Equation (ODE) Algebraically* (page 150).

User Functions

These are functions that are imported into the global namespace with `from sympy import *`. These functions (unlike *Hint Functions* (page 818), below) are intended for use by ordinary users of SymPy.

```python
sympy.solvers.ode.dsolve(eq, func=None, hint='default', simplify=True, ics=None, xi=None, eta=None, x0=0, n=6, **kwargs)
```

Solves any (supported) kind of ordinary differential equation and system of ordinary differential equations.
For Single Ordinary Differential Equation

It is classified under this when number of equation in eq is one. **Usage**

\[ \text{dsolve(eq, f(x), hint)} \rightarrow \text{Solve ordinary differential equation eq for function f(x), using method hint.} \]

**Details**

- **eq can be any supported ordinary differential equation (see the ode (page 807) docstring for supported methods).** This can either be an Equality (page 1071), or an expression, which is assumed to be equal to 0.
- **f(x) is a function of one variable whose derivatives in that variable make up the ordinary differential equation eq.** In many cases it is not necessary to provide this; it will be autodetected (and an error raised if it could not be detected).
- **hint is the solving method that you want dsolve to use. Use classify_ode(eq, f(x)) to get all of the possible hints for an ODE. The default hint, default, will use whatever hint is returned first by classify_ode() (page 812). See Hints below for more options that you can use for hint.**
- **simplify enables simplification by odesimp() (page 819).** See its docstring for more information. Turn this off, for example, to disable solving of solutions for func or simplification of arbitrary constants. It will still integrate with this hint. Note that the solution may contain more arbitrary constants than the order of the ODE with this option enabled.
- **xi and eta are the infinitesimal functions of an ordinary differential equation.** They are the infinitesimals of the Lie group of point transformations for which the differential equation is invariant. The user can specify values for the infinitesimals. If nothing is specified, xi and eta are calculated using infinitesimals() (page 816) with the help of various heuristics.
- **ics is the set of initial/boundary conditions for the differential equation.** It should be given in the form of \{f(x0): x1, f(x).diff(x).subs(x, x2): x3\} and so on. For power series solutions, if no initial conditions are specified f(0) is assumed to be C0 and the power series solution is calculated about 0.
- **x0 is the point about which the power series solution of a differential equation is to be evaluated.**
- **n gives the exponent of the dependent variable up to which the power series solution of a differential equation is to be evaluated.**

**Hints**

Aside from the various solving methods, there are also some meta-hints that you can pass to **dsolve()** (page 807):

- **default:** This uses whatever hint is returned first by classify_ode() (page 812). This is the default argument to dsolve() (page 807).
**all:**
To make *dsolve()* (page 807) apply all relevant classification hints, use *dsolve*(ODE, func, hint="all"). This will return a dictionary of hint:solution terms. If a hint causes *dsolve* to raise the *NotImplementedError*, value of that hint’s key will be the exception object raised. The dictionary will also include some special keys:

- **order**: The order of the ODE. See also *ode_order()* (page 899) in *deutils.py*.
- **best**: The simplest hint; what would be returned by best below.
- **best_hint**: The hint that would produce the solution given by best. If more than one hint produces the best solution, the first one in the tuple returned by *classify_ode()* (page 812) is chosen.
- **default**: The solution that would be returned by default. This is the one produced by the hint that appears first in the tuple returned by *classify_ode()* (page 812).

**all_Integral**:  
This is the same as all, except if a hint also has a corresponding _Integral hint, it only returns the _Integral hint. This is useful if all causes *dsolve()* (page 807) to hang because of a difficult or impossible integral. This meta-hint will also be much faster than all, because *integrate()* (page 1016) is an expensive routine.

**best**:  
To have *dsolve()* (page 807) try all methods and return the simplest one. This takes into account whether the solution is solvable in the function, whether it contains any Integral classes (i.e. unevaluatable integrals), and which one is the shortest in size.

See also the *classify_ode()* (page 812) docstring for more info on hints, and the *ode* (page 807) docstring for a list of all supported hints.

**Tips**

- You can declare the derivative of an unknown function this way:

```python
>>> from sympy import Function, Derivative
>>> from sympy.abc import x  # x is the independent variable
>>> f = Function("f") (x)  # f is a function of x
>>> # f_ will be the derivative of f with respect to x
>>> f_ = Derivative(f, x)
```

- See *test_ode.py* for many tests, which serves also as a set of examples for how to use *dsolve()* (page 807).

- *dsolve()* (page 807) always returns an *Equality* (page 1071) class (except for the case when the hint is all or all_Integral). If possible, it solves the solution explicitly for the function being solved for. Otherwise, it returns an implicit solution.

- Arbitrary constants are symbols named C1, C2, and so on.

- Because all solutions should be mathematically equivalent, some hints may return the exact same result for an ODE. Often, though, two different hints will return the same solution formatted differently. The two should be equivalent. Also note that sometimes the values of the arbitrary constants in two different solutions may not be the same, because one constant may have “absorbed” other constants into it.
• Do `help(ode.ode_<hintname>)` to get help more information on a specific hint, where `<hintname>` is the name of a hint without `_Integral`.

**For System Of Ordinary Differential Equations**

**Usage**

```plaintext
dsolve(eq, func) -> Solve a system of ordinary differential equations `eq` for `func` being list of functions including `x(t)`, `y(t)`, `z(t)` where number of functions in the list depends upon the number of equations provided in `eq`.
```

**Details**

- `eq` can be any supported system of ordinary differential equations. This can either be an `Equality` (page 1071), or an expression, which is assumed to be equal to 0.
- `func` holds `x(t)` and `y(t)` being functions of one variable which together with some of their derivatives make up the system of ordinary differential equation `eq`. It is not necessary to provide this; it will be autodetected (and an error raised if it could not be detected).

**Hints**

The hints are formed by parameters returned by `classify_sysode`, combining them give hints name used later for forming method name.

**Examples**

```python
>>> from sympy import Function, dsolve, Eq, Derivative, sin, cos, symbols
>>> from sympy.abc import x
>>> f = Function('f')
>>> dsolve(Derivative(f(x), x, x) + 9*f(x), f(x))
Eq(f(x), C1*sin(3*x) + C2*cos(3*x))

>>> eq = sin(x)*cos(f(x)) + cos(x)*sin(f(x))*f(x).diff(x)
>>> dsolve(eq, hint='1st_exact')
[Eq(f(x), -acos(C1/cos(x)) + 2*pi), Eq(f(x), acos(C1/cos(x)))]

>>> t = symbols('t')
>>> x, y = symbols(x, y, cls=Function)
>>> eq = (Eq(Derivative(x(t),t), 12*t*x(t) + 8*y(t)), Eq(Derivative(y(t),t), 21*x(t) + 7*t*y(t)))
>>> dsolve(eq)
{Eq(x(t), -exp(C1)/(C2*exp(C1) - cos(t))), Eq(y(t), -1/(C1 - cos(t)))}
```
Solves any(supported) system of Ordinary Differential Equations

**Parameters**

- **eqs**: List
  - system of ODEs to be solved
- **funcs**: List or None
  - List of dependent variables that make up the system of ODEs
- **t**: Symbol or None
  - Independent variable in the system of ODEs
- **ics**: Dict or None
  - Set of initial boundary/conditions for the system of ODEs
- **doit**: Boolean
  - Evaluate the solutions if True. Default value is True. Can be set to false if the integral evaluation takes too much time and/or is not required.
- **simplify**: Boolean
  - Simplify the solutions for the systems. Default value is True. Can be set to false if simplification takes too much time and/or is not required.

**Returns**

List of List of Equations

**Raises**

- **NotImplementedError**
  - When the system of ODEs is not solvable by this function.
- **ValueError**
  - When the parameters passed are not in the required form.

**Explanation**

This function takes a system of ODEs as an input, determines if the it is solvable by this function, and returns the solution if found any.

This function can handle:
1. Linear, First Order, Constant coefficient homogeneous system of ODEs
2. Linear, First Order, Constant coefficient non-homogeneous system of ODEs
3. Linear, First Order, non-constant coefficient homogeneous system of ODEs
4. Linear, First Order, non-constant coefficient non-homogeneous system of ODEs
5. Any implicit system which can be divided into system of ODEs which is of the above 4 forms
6. Any higher order linear system of ODEs that can be reduced to one of the 5 forms of systems described above.

The types of systems described above are not limited by the number of equations, i.e. this function can solve the above types irrespective of the number of equations in the system passed. But, the bigger the system, the more time it will take to solve the system.
This function returns a list of solutions. Each solution is a list of equations where LHS is the dependent variable and RHS is an expression in terms of the independent variable.

Among the non constant coefficient types, not all the systems are solvable by this function. Only those which have either a coefficient matrix with a commutative antiderivative or those systems which may be divided further so that the divided systems may have coefficient matrix with commutative antiderivative.

**Examples**

```python
>>> from sympy import symbols, Eq, Function
>>> from sympy.solvers.ode.systems import dsolve_system
>>> f, g = symbols("f g", cls=Function)
>>> x = symbols("x")

>>> eqs = [Eq(f(x).diff(x), g(x)), Eq(g(x).diff(x), f(x))]
>>> dsolve_system(eqs)
[[Eq(f(x), -C1*exp(-x) + C2*exp(x)), Eq(g(x), C1*exp(-x) + C2*exp(x))]]
```

You can also pass the initial conditions for the system of ODEs:

```python
>>> dsolve_system(eqs, ics={f(0): 1, g(0): 0})
[[Eq(f(x), exp(x)/2 + exp(-x)/2), Eq(g(x), exp(x)/2 - exp(-x)/2)]]
```

Optionally, you can pass the dependent variables and the independent variable for which the system is to be solved:

```python
>>> funcs = [f(x), g(x)]
>>> dsolve_system(eqs, funcs=funcs, t=x)
[[Eq(f(x), -C1*exp(-x) + C2*exp(x)), Eq(g(x), C1*exp(-x) + C2*exp(x))]]
```

Let's look at an implicit system of ODEs:

```python
>>> eqs = [Eq(f(x).diff(x)**2, g(x)**2), Eq(g(x).diff(x), g(x))]
>>> dsolve_system(eqs)
[[Eq(f(x), C1 - C2*exp(x)), Eq(g(x), C2*exp(x))], [Eq(f(x), C1 +
    -C2*exp(x)), Eq(g(x), C2*exp(x))]]
```

**sympy.solvers.odeclassify_ode(eq, func=None, dict=False, ics=None, *, prep=True, xi=None, eta=None, n=None, **kwargs)**

Returns a tuple of possible `dsolve()` (page 807) classifications for an ODE.

The tuple is ordered so that first item is the classification that `dsolve()` (page 807) uses to solve the ODE by default. In general, classifications at the near the beginning of the list will produce better solutions faster than those near the end, thought there are always exceptions. To make `dsolve()` (page 807) use a different classification, use `dsolve(ODE, func, hint=<classification>).` See also the `dsolve()` (page 807) docstring for different meta-hints you can use.

If `dict` is true, `classify_ode()` (page 812) will return a dictionary of hint:match expression terms. This is intended for internal use by `dsolve()` (page 807). Note that because dictionaries are ordered arbitrarily, this will most likely not be in the same order as the tuple.
You can get help on different hints by executing `help(ode.ode_hintname)`, where `hintname` is the name of the hint without `_Integral`.

See `allhints` (page 818) or the `ode` (page 807) docstring for a list of all supported hints that can be returned from `classify_ode()` (page 812).

**Notes**

These are remarks on hint names.

_Integral

If a classification has _Integral at the end, it will return the expression with an unevaluated `Integral` (page 660) class in it. Note that a hint may do this anyway if `integrate()` (page 1016) cannot do the integral, though just using an _Integral will do so much faster. Indeed, an _Integral hint will always be faster than its corresponding hint without _Integral because `integrate()` (page 1016) is an expensive routine. If `dsolve()` (page 807) hangs, it is probably because `integrate()` (page 1016) is hanging on a tough or impossible integral. Try using an _Integral hint or all _Integral to get it return something.

Note that some hints do not have _Integral counterparts. This is because `integrate()` (page 657) is not used in solving the ODE for those method. For example, nth order linear homogeneous ODEs with constant coefficients do not require integration to solve, so there is no nth_linear_homogeneous_constant_coeff_Integrate hint. You can easily evaluate any unevaluated `Integral` (page 660) in an expression by doing expr. doit().

Ordinals

Some hints contain an ordinal such as 1st_linear. This is to help differentiate them from other hints, as well as from other methods that may not be implemented yet. If a hint has nth in it, such as the nth_linear hints, this means that the method used to applies to ODEs of any order.

indep and dep

Some hints contain the words indep or dep. These reference the independent variable and the dependent function, respectively. For example, if an ODE is in terms of $f(x)$, then indep will refer to $x$ and dep will refer to $f$.

subs

If a hints has the word subs in it, it means that the ODE is solved by substituting the expression given after the word subs for a single dummy variable. This is usually in terms of indep and dep as above. The substituted expression will be written only in characters allowed for names of Python objects, meaning operators will be spelled out. For example, indep/dep will be written as indep_div_dep.

coeff

The word coeff in a hint refers to the coefficients of something in the ODE, usually of the derivative terms. See the docstring for the individual methods for more info (help(ode)). This is contrast to coefficients, as in undetermined_coefficients, which refers to the common name of a method.
Methods that have more than one fundamental way to solve will have a hint for each sub-method and a _best meta-classification. This will evaluate all hints and return the best, using the same considerations as the normal best meta-hint.

Examples

```python
>>> from sympy import Function, classify_ode, Eq
>>> from sympy.abc import x
>>> f = Function('f')
>>> classify_ode(Eq(f(x).diff(x), 0), f(x))
```

```python
sympy.solvers.ode.checkodesol(ode, sol, func=None, order='auto', solve_for_func=True)
```

Substitutes sol into ode and checks that the result is 0.

This works when func is one function, like \( f(x) \) or a list of functions like \([f(x), g(x)]\) when ode is a system of ODEs. sol can be a single solution or a list of solutions. Each solution may be an Equality (page 1071) that the solution satisfies, e.g. Eq(f(x), C1), Eq(f(x) + C1, 0); or simply an Expr (page 999), e.g. f(x) - C1. In most cases it will not be necessary to explicitly identify the function, but if the function cannot be inferred from the original equation it can be supplied through the func argument.

If a sequence of solutions is passed, the same sort of container will be used to return the result for each solution.

It tries the following methods, in order, until it finds zero equivalence:

1. Substitute the solution for \( f \) in the original equation. This only works if ode is solved for \( f \). It will attempt to solve it first unless solve_for_func == False.

2. Take \( n \) derivatives of the solution, where \( n \) is the order of ode, and check to see if that is equal to the solution. This only works on exact ODEs.

3. Take the 1st, 2nd, ..., \( n \)th derivatives of the solution, each time solving for the derivative of \( f \) of that order (this will always be possible because \( f \) is a linear operator). Then back substitute each derivative into ode in reverse order.
This function returns a tuple. The first item in the tuple is True if the substitution results in 0, and False otherwise. The second item in the tuple is what the substitution results in. It should always be 0 if the first item is True. Sometimes this function will return False even when an expression is identically equal to 0. This happens when simplify() (page 719) does not reduce the expression to 0. If an expression returned by this function vanishes identically, then sol really is a solution to the ode.

If this function seems to hang, it is probably because of a hard simplification.

To use this function to test, test the first item of the tuple.

**Examples**

```python
>>> from sympy import (Eq, Function, checkodesol, symbols,
                      ...                      Derivative, exp)
>>> x, C1, C2 = symbols('x,C1,C2')
>>> f, g = symbols('f g', cls=Function)
>>> checkodesol(f(x).diff(x), Eq(f(x), C1))
(True, 0)
>>> assert checkodesol(f(x).diff(x), C1)[0]
>>> assert not checkodesol(f(x).diff(x), x)[0]
>>> checkodesol(f(x).diff(x, 2), x**2)
(False, 2)
```

```python
>>> eqs = [Eq(Derivative(f(x), x), f(x)), Eq(Derivative(g(x), x), g(x))]
>>> sol = [Eq(f(x), C1*exp(x)), Eq(g(x), C2*exp(x))]
>>> checkodesol(eqs, sol)
(True, [0, 0])
```

`sympy.solvers.ode.homogeneous_order(eq, *symbols)`

Returns the order n if g is homogeneous and None if it is not homogeneous.

Determines if a function is homogeneous and if so of what order. A function \( f(x, y, \cdots) \) is homogeneous of order \( n \) if \( f(tx, ty, \cdots) = t^n f(x, y, \cdots) \).

If the function is of two variables, \( F(x, y) \), then \( f \) being homogeneous of any order is equivalent to being able to rewrite \( F(x, y) \) as \( G(x/y) \) or \( H(y/x) \). This fact is used to solve 1st order ordinary differential equations whose coefficients are homogeneous of the same order (see the docstrings of `HomogeneousCoeffSubsDepDivIndep` (page 824) and `HomogeneousCoeffSubsIndepDivDep` (page 825)).

Symbols can be functions, but every argument of the function must be a symbol, and the arguments of the function that appear in the expression must match those given in the list of symbols. If a declared function appears with different arguments than given in the list of symbols, None is returned.
Examples

```python
>>> from sympy import Function, homogeneous_order, sqrt
>>> from sympy.abc import x, y

>>> f = Function('f')
>>> homogeneous_order(f(x), f(x)) is None
True
>>> homogeneous_order(f(x, y), f(y, x), x, y) is None
True
>>> homogeneous_order(f(x), f(x), x)
1
>>> homogeneous_order(x**2*f(x)/sqrt(x**2+f(x)**2), x, f(x))
2
>>> homogeneous_order(x**2+f(x), x, f(x)) is None
True
```

`sympy.solvers.ode.infinitesimals(eq, func=None, order=None, hint='default', match=None)`

The infinitesimal functions of an ordinary differential equation, \( \xi(x, y) \) and \( \eta(x, y) \), are the infinitesimals of the Lie group of point transformations for which the differential equation is invariant. So, the ODE \( y' = f(x, y) \) would admit a Lie group \( x^* = X(x, y; \epsilon) = x + \epsilon \xi(x, y), y^* = Y(x, y; \epsilon) = y + \epsilon \eta(x, y) \) such that \( (y'^*) = f(x^*, y^*) \). A change of coordinates, to \( r(x, y) \) and \( s(x, y) \), can be performed so this Lie group becomes the translation group, \( r^* = r \) and \( s^* = s + \epsilon \). They are tangents to the coordinate curves of the new system.

Consider the transformation \((x, y) \to (X, Y)\) such that the differential equation remains invariant. \( \xi \) and \( \eta \) are the tangents to the transformed coordinates \( X \) and \( Y \), at \( \epsilon = 0 \).

\[
\left( \frac{\partial X(x, y; \epsilon)}{\partial \epsilon} \right) |_{\epsilon=0} = \xi, \left( \frac{\partial Y(x, y; \epsilon)}{\partial \epsilon} \right) |_{\epsilon=0} = \eta.
\]

The infinitesimals can be found by solving the following PDE:

```python
>>> from sympy import Function, Eq, pprint
>>> from sympy.abc import x, y

>>> xi, eta, h = map(Function, ['xi', 'eta', 'h'])
>>> h = h(x, y) # dy/dx = h
>>> eta = eta(x, y)
>>> xi = xi(x, y)

>>> genform = Eq(eta.diff(x) + (eta.diff(y) - xi.diff(x))*h
... - (xi.diff(y))*h**2 - xi*(h.diff(x)) - eta*(h.diff(y)), 0)
>>> pprint(genform)
```

Solving the above mentioned PDE is not trivial, and can be solved only by making intelligent assumptions for \( \xi \) and \( \eta \) (heuristics). Once an infinitesimal is found, the attempt
to find more heuristics stops. This is done to optimise the speed of solving the differential equation. If a list of all the infinitesimals is needed, hint should be flagged as all, which gives the complete list of infinitesimals. If the infinitesimals for a particular heuristic needs to be found, it can be passed as a flag to hint.

**Examples**

```python
>>> from sympy import Function
>>> from sympy.solvers.ode.lie_group import infinitesimals
>>> from sympy.abc import x

>>> f = Function('f')
>>> eq = f(x).diff(x) - x**2*f(x)
>>> infinitesimals(eq)
[{eta(x, f(x)): exp(x**3/3), xi(x, f(x)): 0}]
```

**References**

- Solving differential equations by Symmetry Groups, John Starrett, pp. 1 - pp. 14

```python
sympy.solvers.ode.checkinfsol(eq, infinitesimals, func=None, order=None)
```

This function is used to check if the given infinitesimals are the actual infinitesimals of the given first order differential equation. This method is specific to the Lie Group Solver of ODEs.

As of now, it simply checks, by substituting the infinitesimals in the partial differential equation.

$$\frac{\partial \eta}{\partial x} + \left(\frac{\partial \eta}{\partial y} - \frac{\partial \xi}{\partial x}\right) * h - \frac{\partial \xi}{\partial y} * h^2 - \xi \frac{\partial h}{\partial x} - \eta \frac{\partial h}{\partial y} = 0$$

where \(\eta\) and \(\xi\) are the infinitesimals and \(h(x, y) = \frac{\partial u}{\partial x}\)

The infinitesimals should be given in the form of a list of dicts [{\(\xi(x, y): \inf\), \(\eta(x, y): \inf\)], corresponding to the output of the function infinitesimals. It returns a list of values of the form [{(True/False, sol)}] where sol is the value obtained after substituting the infinitesimals in the PDE. If it is True, then sol would be 0.

```python
sympy.solvers.ode.constantsimp(expr, constants)
```

Simplifies an expression with arbitrary constants in it.

This function is written specifically to work with `dsolve()` (page 807), and is not intended for general use.

Simplification is done by “absorbing” the arbitrary constants into other arbitrary constants, numbers, and symbols that they are not independent of.

The symbols must all have the same name with numbers after it, for example, \(C1, C2, C3\). The symbol name here would be ‘C’, the start number would be 1, and the end number would be 3. If the arbitrary constants are independent of the variable \(x\), then the independent symbol would be \(x\). There is no need to specify the dependent function, such as \(f(x)\), because it already has the independent symbol, \(x\), in it.

Because terms are “absorbed” into arbitrary constants and because constants are renumbered after simplifying, the arbitrary constants in expr are not necessarily equal to the ones of the same name in the returned result.

5.8. Topics
If two or more arbitrary constants are added, multiplied, or raised to the power of each other, they are first absorbed together into a single arbitrary constant. Then the new constant is combined into other terms if necessary.

Absorption of constants is done with limited assistance:

1. terms of Add (page 1062)s are collected to try join constants so $e^x(C_1 \cos(x) + C_2 \cos(x))$ will simplify to $e^xC_1 \cos(x)$;
2. powers with exponents that are Add (page 1062)s are expanded so $e^{C_1 + x}$ will be simplified to $C_1 e^x$.

Use constant_renumber() (page 820) to renumber constants after simplification or else arbitrary numbers on constants may appear, e.g. $C_1 + C_3 x$.

In rare cases, a single constant can be “simplified” into two constants. Every differential equation solution should have as many arbitrary constants as the order of the differential equation. The result here will be technically correct, but it may, for example, have $C_1$ and $C_2$ in an expression, when $C_1$ is actually equal to $C_2$. Use your discretion in such situations, and also take advantage of the ability to use hints in dsolve() (page 807).

**Examples**

```python
>>> from sympy import symbols
>>> from sympy.solvers.ode.ode import constantsimp
>>> C1, C2, C3, x, y = symbols('C1, C2, C3, x, y')
>>> constantsimp(2*C1*x, {C1, C2, C3})
C1*x
>>> constantsimp(C1 + 2 + x, {C1, C2, C3})
C1 + x
>>> constantsimp(C1*C2 + 2 + C2 + C3*x, {C1, C2, C3})
C1 + C3*x
```

**Hint Functions**

These functions are intended for internal use by dsolve() (page 807) and others. Unlike User Functions (page 807), above, these are not intended for every-day use by ordinary SymPy users. Instead, functions such as dsolve() (page 807) should be used. Nonetheless, these functions contain useful information in their docstrings on the various ODE solving methods. For this reason, they are documented here.

'2nd_nonlinear_autonomous_conserved_Integral')

Built-in immutable sequence.

If no argument is given, the constructor returns an empty tuple. If iterable is specified
the tuple is initialized from iterable’s items.

If the argument is a tuple, the return value is the same object.

sympy.solvers.ode.odesimp(ode, eq, func, hint)
Simplifies solutions of ODEs, including trying to solve for func and running
constantsimp() (page 817).

It may use knowledge of the type of solution that the hint returns to apply additional
simplifications.

It also attempts to integrate any Integral (page 660)s in the expression, if the hint is not an _Integral hint.

This function should have no effect on expressions returned by dsolve() (page 807), as
dsolve() (page 807) already calls odesimp() (page 819), but the individual hint functions do not call odesimp() (page 819) (because the dsolve() (page 807) wrapper does). Therefore, this function is designed for mainly internal use.

Examples

```python
>>> from sympy import sin, symbols, dsolve, pprint, Function
>>> from sympy.solvers.ode.ode import odesimp
>>> x, u2, C1 = symbols('x,u2,C1')
>>> f = Function('f')

>>> eq = dsolve(x*f(x).diff(x) - f(x) - x*sin(f(x)/x), f(x),
... hint='1st_homogeneous_coeff_subs_indep_div_dep_integral',
```

(continues on next page)
\[ \log(f(x)) = \log(C1) + \frac{d(u1)}{2u1} \]

>>>

\[
\begin{align*}
\text{sympy.solvers.ode.ode.constant_renumber}(expr, \text{variables}=\text{None}, \text{newconstants}=\text{None})
\end{align*}
\]

Renumber arbitrary constants in expr to use the symbol names as given in newconstants. In the process, this reorders expression terms in a standard way.

If newconstants is not provided then the new constant names will be C1, C2 etc. Otherwise newconstants should be an iterable giving the new symbols to use for the constants in order.

The variables argument is a list of non-constant symbols. All other free symbols found in expr are assumed to be constants and will be renumbered. If variables is not given then any numbered symbol beginning with C (e.g. C1) is assumed to be a constant.

Symbols are renumbered based on .sort_key(), so they should be numbered roughly in the order that they appear in the final, printed expression. Note that this ordering is based in part on hashes, so it can produce different results on different machines.

The structure of this function is very similar to that of constantsimp() (page 817).
**Examples**

```python
>>> from sympy import symbols
>>> from sympy.solvers.ode import constant_renumber
>>> x, C1, C2, C3 = symbols('x,C1:4')
>>> expr = C3 + C2*x + C1*x**2
>>> expr
C1*x**2 + C2*x + C3
>>> constant_renumber(expr)
C1 + C2*x + C3*x**2
```

The `variables` argument specifies which are constants so that the other symbols will not be renumbered:

```python
>>> constant_renumber(expr, [C1, x])
C1*x**2 + C2 + C3*x
```

The `newconstants` argument is used to specify what symbols to use when replacing the constants:

```python
>>> constant_renumber(expr, [x], newconstants=symbols('E1:4'))
E1 + E2*x + E3*x**2
```

`sympy.solvers.ode.ode.ode_sol_simplicity(sol, func, try-solving=True)`

Returns an extended integer representing how simple a solution to an ODE is.

The following things are considered, in order from most simple to least:

- `sol` is solved for `func`.
- `sol` is not solved for `func`, but can be if passed to solve (e.g., a solution returned by `dsolve(ode, func, simplify=False)`).
- If `sol` is not solved for `func`, then base the result on the length of `sol`, as computed by `len(str(sol))`.
- If `sol` has any unevaluated `Integral` (page 660)s, this will automatically be considered less simple than any of the above.

This function returns an integer such that if solution A is simpler than solution B by above metric, then `ode_sol_simplicity(sol_a, func) < ode_sol_simplicity(sol_b, func)`.

Currently, the following are the numbers returned, but if the heuristic is ever improved, this may change. Only the ordering is guaranteed.

<table>
<thead>
<tr>
<th>Simplicity</th>
<th>Return</th>
</tr>
</thead>
<tbody>
<tr>
<td>sol solved for func</td>
<td>-2</td>
</tr>
<tr>
<td>sol not solved for func but can be</td>
<td>-1</td>
</tr>
<tr>
<td>sol is not solved nor solvable for func</td>
<td><code>len(str(sol))</code></td>
</tr>
<tr>
<td>sol contains an <code>Integral</code> (page 660)</td>
<td><code>oo</code></td>
</tr>
</tbody>
</table>

`oo` here means the SymPy infinity, which should compare greater than any integer.
If you already know `solve()` (page 882) cannot solve sol, you can use `trysolving=False` to skip that step, which is the only potentially slow step. For example, `dsolve()` (page 807) with the `simplify=False` flag should do this.

If sol is a list of solutions, if the worst solution in the list returns `oo` it returns that, otherwise it returns `len(str(sol))`, that is, the length of the string representation of the whole list.

**Examples**

This function is designed to be passed to `min` as the key argument, such as `min(listofsolutions, key=lambda i: ode_sol_simplicity(i, f(x)))`.

```python
>>> from sympy import symbols, Function, Eq, tan, Integral
>>> x, C1, C2 = symbols('x, C1, C2')
>>> f = Function('f')

>>> ode_sol_simplicity(Eq(f(x), C1*x**2), f(x))
-2
>>> ode_sol_simplicity(Eq(x**2 + f(x), C1), f(x))
-1
>>> ode_sol_simplicity(Eq(f(x), C1*Integral(2*x, x)), f(x))
oo
>>> eq1 = Eq(f(x)/tan(f(x)/(2*x)), C1)
>>> eq2 = Eq(f(x)/tan(f(x)/(2*x) + f(x)), C2)
>>> [ode_sol_simplicity(eq, f(x)) for eq in [eq1, eq2]]
[28, 35]
>>> min([eq1, eq2], key=lambda i: ode_sol_simplicity(i, f(x)))
Eq(f(x)/tan(f(x)/(2*x)), C1)
```

**class** `sympy.solvers.ode.single.Factorable(ode_problem)`

Solves equations having a solvable factor.

This function is used to solve the equation having factors. Factors may be of type algebraic or ode. It will try to solve each factor independently. Factors will be solved by calling `dsolve`. We will return the list of solutions.

**Examples**

```python
>>> from sympy import Function, dsolve, pprint
>>> from sympy.abc import x
>>> f = Function('f')
>>> eq = (f(x)**2-4)*(f(x).diff(x)+f(x))
>>> pprint(dsolve(eq, f(x)))
-f
[f(x) = 2, f(x) = -2, f(x) = C1*e]
```

**class** `sympy.solvers.ode.single.FirstExact(ode_problem)`

Solves 1st order exact ordinary differential equations.
A 1st order differential equation is called exact if it is the total differential of a function. That is, the differential equation

\[ P(x, y) \frac{\partial}{\partial x} + Q(x, y) \frac{\partial}{\partial y} = 0 \]

is exact if there is some function \( F(x, y) \) such that \( P(x, y) = \frac{\partial F}{\partial x} \) and \( Q(x, y) = \frac{\partial F}{\partial y} \). It can be shown that a necessary and sufficient condition for a first order ODE to be exact is that \( \frac{\partial P}{\partial y} = \frac{\partial Q}{\partial x} \). Then, the solution will be as given below:

```python
>>> from sympy import Function, Eq, Integral, symbols, pprint
>>> x, y, t, x0, y0, C1 = symbols('x, y, t, x0, y0, C1')
>>> P, Q, F = map(Function, ['P', 'Q', 'F'])
>>> pprint(Eq(Eq(F(x, y), Integral(P(t, y), (t, x0, x)) + Integral(Q(x0, t), (t, y0, y))), C1))
\[
\begin{align*}
F(x, y) = &\int P(t, y) \, dt + \int Q(x0, t) \, dt = C1 \\
&x0 \quad y0
\end{align*}
\]
```

Where the first partials of \( P \) and \( Q \) exist and are continuous in a simply connected region.

A note: SymPy currently has no way to represent inert substitution on an expression, so the hint `1st_exact_Integral` will return an integral with \( dy \). This is supposed to represent the function that you are solving for.

**Examples**

```python
>>> from sympy import Function, dsolve, cos, sin
>>> from sympy.abc import x
>>> f = Function('f')
>>> dsolve(cos(f(x)) - (x*sin(f(x)) - f(x)**2)*f(x).diff(x), ... f(x), hint='1st_exact')
Eq(x*cos(f(x)) + f(x)**3/3, C1)
```

**References**

- https://en.wikipedia.org/wiki/Exact_differential_equation

# indirect doctest
class sympy.solvers.ode.single.HomogeneousCoeffBest(ode_problem)
Returns the best solution to an ODE from the two hints `1st_homogeneous_coeff_subs_dep_div_indep` and `1st_homogeneous_coeff_subs_indep_div_dep`. This is as determined by `ode_sol_simplicity()` (page 821).

See the `HomogeneousCoeffSubsIndepDivDep` (page 825) and `HomogeneousCoeffSubsDepDivIndep` (page 824) docstrings for more information on these hints. Note that there is no `ode_1st_homogeneous_coeff_best_Integral` hint.
Examples

```python
>>> from sympy import Function, dsolve, pprint
>>> from sympy.abc import x
>>> f = Function('f')
>>> pprint(dsolve(2*x*f(x) + (x**2 + f(x)**2)*f(x).diff(x), f(x),
... hint='1st_homogeneous_coeff_best', simplify=False))
```

```
/  2 \   
| 3*x |
\ \f (x) /
|----- + 1|
| 2 |
log|----- + 1|
\ \f (x) /
log(f(x)) = log(C1) - -----------
\ 3 /
```

References

```python
# indirect doctest
class sympy.solvers.ode.single.HomogeneousCoeffSubsDepDivIndep(ode_problem)
Solves a 1st order differential equation with homogeneous coefficients using the substitution $u_1 = \frac{<dependent variable>}{<independent variable>}$. 
This is a differential equation

$$P(x, y) + Q(x, y)\frac{dy}{dx} = 0$$

such that $P$ and $Q$ are homogeneous and of the same order. A function $F(x, y)$ is homogeneous of order $n$ if $F(xt, yt) = t^n F(x, y)$. Equivalently, $F(x, y)$ can be rewritten as $G(y/x)$ or $H(x/y)$. See also the docstring of homogeneous_order() (page 815).

If the coefficients $P$ and $Q$ in the differential equation above are homogeneous functions of the same order, then it can be shown that the substitution $y = u_1 x$ (i.e. $u_1 = y/x$) will turn the differential equation into an equation separable in the variables $x$ and $u$. If $h(u_1)$ is the function that results from making the substitution $u_1 = f(x)/x$ on $P(x, f(x))$ and $g(u_2)$ is the function that results from the substitution on $Q(x, f(x))$ in the differential equation $P(x, f(x)) + Q(x, f(x))f'(x) = 0$, then the general solution is:

```python
>>> from sympy import Function, dsolve, pprint
>>> from sympy.abc import x
>>> f, g, h = map(Function, ['f', 'g', 'h'])
>>> genform = g(f(x)/x) + h(f(x)/x)*f(x).diff(x)
>>> pprint(genform)
```

```
g|-----| + h|-----|*--(f(x))
\ x / \ x / dx
```

```python
>>> pprint(dsolve(genform, f(x),
... hint='1st_homogeneous_coeff_subs_dep_div_indep_Integral'))
f(x)
```

(continues on next page)
Where \( u_1 h(u_1) + g(u_1) \neq 0 \) and \( x \neq 0 \).

See also the docstrings of \texttt{HomogeneousCoeffBest} (page 823) and \texttt{HomogeneousCoeffSubsIndepDivDep} (page 825).

\section*{Examples}

\begin{Verbatim}
>>> from sympy import Function, dsolve
>>> from sympy.abc import x
>>> f = Function('f')
>>> pprint(dsolve(2*x*f(x) + (x**2 + f(x)**2)*f(x).diff(x), f(x),
... hint='1st_homogeneous_coeff_subs_dep_div_indep', simplify=False))

\[
\frac{3}{3 - \frac{3f(x)}{f(x)}} \log\left|\frac{3f(x)}{f(x)}\right| + \log\left|\frac{x}{f(x)}\right| + \log(C1)
\]

\[
\log(x) = \log(C1) - \frac{3}{x}
\]
\end{Verbatim}

\section*{References}

\# indirect doctest
class sympy.solvers.ode.single.HomogeneousCoeffSubsIndepDivDep(ode_problem)
Solves a 1st order differential equation with homogeneous coefficients using the substitution \( u_2 = \frac{x}{y} \).

This is a differential equation

\[
P(x, y) + Q(x, y) dy/dx = 0
\]
such that \( P \) and \( Q \) are homogeneous and of the same order. A function \( F(x, y) \) is homogeneous of order \( n \) if \( F(tx, ty) = t^n F(x, y) \). Equivalently, \( F(x, y) \) can be rewritten as \( G(y/x) \) or \( H(x/y) \). See also the docstring of \texttt{homogeneous_order()} (page 815).

If the coefficients \( P \) and \( Q \) in the differential equation above are homogeneous functions of the same order, then it can be shown that the substitution \( x = u_2 y \) (i.e. \( u_2 = x/y \)) will
turn the differential equation into an equation separable in the variables $y$ and $u_2$. If $h(u_2)$ is the function that results from making the substitution $u_2 = x/f(x)$ on $P(x, f(x))$ and $g(u_2)$ is the function that results from the substitution on $Q(x, f(x))$ in the differential equation $P(x, f(x)) + Q(x, f(x))f'(x) = 0$, then the general solution is:

```python
>>> from sympy import Function, dsolve, pprint
>>> from sympy.abc import x
>>> f, g, h = map(Function, ['f', 'g', 'h'])
>>> genform = g(x/f(x)) + h(x/f(x))*f(x).diff(x)
>>> pprint(genform)
\frac{g}{f} + \frac{h}{f} \cdot f'\(x)\n
|\frac{u1 \cdot g(u1) + h(u1)}{f(x)} = C1*e
```

Where $u1g(u1) + h(u1) \neq 0$ and $f(x) \neq 0$.

See also the docstrings of `HomogeneousCoeffBest` (page 823) and `HomogeneousCoeffSubsDepDivIndep` (page 824).

**Examples**

```python
>>> from sympy import Function, pprint, dsolve
>>> from sympy.abc import x
>>> f = Function('f')
>>> pprint(dsolve(2*x*f(x) + (x**2 + f(x)**2)*f(x).diff(x), f(x),
... hint='1st_homogeneous_coeff_subs_indep_div_dep',
... simplify=False))
| \log{f(x)} = \log{C1} - \frac{1}{3}
```

```python
>>> from sympy import Function, pprint, dsolve
>>> from sympy.abc import x
>>> f = Function('f')
>>> pprint(dsolve(2*x*f(x) + (x**2 + f(x)**2)*f(x).diff(x), f(x),
... hint='1st_homogeneous_coeff_subs_indep_div_dep',
... simplify=False))
| \log{f(x)} = \log{C1} - \frac{1}{3}
```

```python
# indirect doctest
class sympy.solvers.ode.single.FirstLinear(ode_problem)
Solves 1st order linear differential equations.
These are differential equations of the form

\[ \frac{dy}{dx} + P(x)y = Q(x). \]

These kinds of differential equations can be solved in a general way. The integrating
factor \( e^{\int P(x) \, dx} \) will turn the equation into a separable equation. The general solution is:

```python
>>> from sympy import Function, dsolve, Eq, pprint, diff, sin
>>> from sympy.abc import x
>>> f, P, Q = map(Function, ['f', 'P', 'Q'])
>>> genform = Eq(f(x).diff(x) + P(x)*f(x), Q(x))
>>> pprint(genform)
\[
dP(x)f(x) + \frac{df(x)}{dx} = Q(x)
\]
>>> pprint(dsolve(genform, f(x), hint='1st_linear_Integral'))
\[
\begin{align*}
| & C1 + Q(x)\int e^{\int P(x) \, dx} dx | P(x) \int e^{\int P(x) \, dx} dx \\
| & \int & Q(x)\int e^{\int P(x) \, dx} dx & - P(x) \int e^{\int P(x) \, dx} dx \\
f(x) = & C1 + Q(x)\int e^{\int P(x) \, dx} dx \\
\end{align*}
\]
```

Examples

```python
>>> f = Function('f')
>>> pprint(dsolve(Eq(x*diff(f(x), x) - f(x), x**2*sin(x)), ...
... f(x), '1st_linear'))
f(x) = x*(C1 - cos(x))
```
References

- [https://en.wikipedia.org/wiki/Linear_differential_equation#First-order_equation_with_variable_coefficients](https://en.wikipedia.org/wiki/Linear_differential_equation#First-order_equation_with_variable_coefficients)

```python
class sympy.solvers.ode.single.RationalRiccati(ode_problem)
```

Gives general solutions to the first order Riccati differential equations that have at least one rational particular solution.

\[
y' = b_0(x) + b_1(x)y + b_2(x)y^2
\]

where \(b_0\), \(b_1\) and \(b_2\) are rational functions of \(x\) with \(b_2 \neq 0\) (\(b_2 = 0\) would make it a Bernoulli equation).

Examples

```python
>>> from sympy import Symbol, Function, dsolve, checkodesol
>>> f = Function('f')
>>> x = Symbol('x')

>>> eq = -x**4*f(x)**2 + x**3*f(x).diff(x) + x**2*f(x) + 20
>>> sol = dsolve(eq, hint="1st_rational_riccati")
>>> sol
Eq(f(x), (4*C1 - 5*x**9 - 4)/(x**2*(C1 + x**9 - 1)))
```

```python
>>> checkodesol(eq, sol)
(True, 0)
```

References

```python
class sympy.solvers.ode.single.SecondLinearAiry(ode_problem)
```

Gives solution of the Airy differential equation

\[
\frac{d^2y}{dx^2} + (a + bx)y(x) = 0
\]

in terms of Airy special functions airyai and airybi.
Examples

```python
>>> from sympy import dsolve, Function
>>> from sympy.abc import x
>>> f = Function("f")
>>> eq = f(x).diff(x, 2) - x*f(x)
>>> dsolve(eq)
Eq(f(x), C1*airyai(x) + C2*airybi(x))
```

class sympy.solvers.ode.single.SecondLinearBessel(ode_problem)

Gives solution of the Bessel differential equation

\[ x^2 \frac{d^2 y}{dx^2} + x \frac{dy}{dx}(x) + (x^2 - n^2)y(x) \]

if \( n \) is integer then the solution is of the form \( Eq(f(x), C0 \text{ besselj}(n, x) + C1 \text{ bessely}(n, x)) \) as both the solutions are linearly independent else if \( n \) is a fraction then the solution is of the form \( Eq(f(x), C0 \text{ besselj}(n, x) + C1 \text{ besselj}(-n, x)) \) which can also transform into \( Eq(f(x), C0 \text{ besselj}(n, x) + C1 \text{ bessely}(n, x)) \).

Examples

```python
>>> from sympy.abc import x
>>> from sympy import Symbol
>>> v = Symbol('v', positive=True)
>>> from sympy import dsolve, Function
>>> f = Function('f')
>>> y = f(x)
>>> genform = x**2*y.diff(x, 2) + x*y.diff(x) + (x**2 - v**2)*y
>>> dsolve(genform)
Eq(f(x), C1*besselj(v, x) + C2*bessely(v, x))
```

References

https://math24.net/bessel-differential-equation.html

class sympy.solvers.ode.single.Bernoulli(ode_problem)

Solves Bernoulli differential equations.

These are equations of the form

\[ \frac{dy}{dx} + P(x)y = Q(x)y^n, n \neq 1. \]

The substitution \( w = 1/y^{1-n} \) will transform an equation of this form into one that is linear (see the docstring of FirstLinear (page 827)). The general solution is:

```python
>>> from sympy import Function, dsolve, Eq, pprint
>>> from sympy.abc import x, n
>>> f, P, Q = map(Function, ['f', 'P', 'Q'])
>>> genform = Eq(f(x).diff(x) + P(x)*f(x), Q(x)*f(x)**n)
>>> pprint(genform)
```

(continues on next page)
\[
\frac{d}{dx} P(x)f(x) + (-f(x)) = Q(x)f(x)
\]

Here is a solution using SymPy:

```python
>>> pprint(dsolve(genform, f(x), hint='Bernoulli_Integral'), num_columns=110)
-1
n - 1
// \\ / \\
|| \ || \\
||| || |
||| || /
||| || |
||| || |
\| | | |
-(n - 1)* \(P(x) \ dx \) | -(n - 1)* \(P(x) \ dx\)
\| | | |
\| | | |
\| | | |
\| | | |
\| | | |
f(x) = \[C1 - n* \(Q(x)*e^{-dy} \) \] dx + \(Q(x)*e^{-dy}\)
```

Note that the equation is separable when \(n = 1\) (see the docstring of `Separable` (page 839)).

```python
>>> pprint(dsolve(Eq(f(x).diff(x) + P(x)*f(x), Q(x)*f(x)), f(x),
... hint='separable_Integral'))
f(x)
/ \\
| 1
| - dy = C1 + \(-P(x) + Q(x)\) dx
| y
| /
/```
Examples

```python
>>> from sympy import Function, dsolve, Eq, pprint, log
>>> from sympy.abc import x
>>> f = Function('f')

>>> pprint(dsolve(Eq(x*f(x).diff(x) + f(x), log(x)*f(x)**2),
... f(x), hint='Bernoulli'))
\frac{f(x)}{C1*x + \log(x) + 1}
```

References

```
# indirect doctest
class sympy.solvers.ode.single.Liouville(ode_problem)
Solves 2nd order Liouville differential equations.
The general form of a Liouville ODE is
\[
\frac{d^2y}{dx^2} + g(y)\left(\frac{dy}{dx}\right)^2 + h(x)\frac{dy}{dx}.
\]
The general solution is:
```
Examples

```python
>>> from sympy import Function, dsolve, Eq, pprint
>>> from sympy.abc import x

>>> f = Function('f')
>>> pprint(dsolve(diff(f(x), x, x) + diff(f(x), x)**2/f(x) + ...
... diff(f(x), x)/x, f(x), hint='Liouville'))
[f(x) = -\sqrt{C1 + C2*\log(x)} , f(x) = \sqrt{C1 + C2*\log(x)} ]
```

References

```python
# indirect doctest
class sympy.solvers.ode.single.RiccatiSpecial(ode_problem)
The general Riccati equation has the form
\[ dy/dx = f(x)y^2 + g(x)y + h(x). \]

While it does not have a general solution [1], the “special” form, \( dy/dx = ay^2 - bx^c \), does have solutions in many cases [2]. This routine returns a solution for \( a(dy/dx) = by^2 + cy/x^d \) that is obtained by using a suitable change of variables to reduce it to the special form and is valid when neither \( a \) nor \( b \) are zero and either \( c \) or \( d \) is zero.

```python
>>> from sympy.abc import x, a, b, c, d

>>> y = f(x)

>>> genform = a*y.diff(x) - (b*y**2 + c*y/x + d/x**2)

>>> sol = dsolve(genform, y, hint="Riccati_special_minus2")
>>> pprint(sol, wrap_line=False)
\[
\begin{align*}
\frac{-a + c \sqrt{4b^2d - (a + c)^2} \tan^{-1} \left( \sqrt{\frac{2a}{4b^2d - (a + c)^2}} \right) \log(x)}{2b^2x} & \quad \text{or} \\
\frac{-a + c \sqrt{4b^2d - (a + c)^2} \tan^{-1} \left( \sqrt{\frac{2a}{4b^2d - (a + c)^2}} \right) \log(x)}{2b^2x} & \quad \text{or} \\
\frac{-a + c \sqrt{4b^2d - (a + c)^2} \tan^{-1} \left( \sqrt{\frac{2a}{4b^2d - (a + c)^2}} \right) \log(x)}{2b^2x}
\end{align*}
\]
```

```python
>>> checkodesol(genform, sol, order=1)[0]
True
```
References

class sympy.solvers.ode.single.NthLinearConstantCoeffHomogeneous(ode_problem)
Solves an \( n \)th order linear homogeneous differential equation with constant coefficients.

This is an equation of the form

\[ a_n f^{(n)}(x) + a_{n-1} f^{(n-1)}(x) + \cdots + a_1 f'(x) + a_0 f(x) = 0. \]

These equations can be solved in a general manner, by taking the roots of the characteristic equation \( a_n m^n + a_{n-1} m^{n-1} + \cdots + a_1 m + a_0 = 0 \). The solution will then be the sum of \( C_n x^r e^{rx} \) terms, for each where \( C_n \) is an arbitrary constant, \( r \) is a root of the characteristic equation and \( i \) is one of each from 0 to the multiplicity of the root - 1 (for example, a root 3 of multiplicity 2 would create the terms \( C_1 e^{3x} + C_2 xe^{3x} \)). The exponential is usually expanded for complex roots using Euler’s equation \( e^{ix} = \cos(x) + i\sin(x) \). Complex roots always come in conjugate pairs in polynomials with real coefficients, so the two roots will be represented (after simplifying the constants) as \( e^{ax} (C_1 \cos(bx) + C_2 \sin(bx)) \).

If SymPy cannot find exact roots to the characteristic equation, a \( \text{ComplexRootOf} \) (page 2507) instance will be return instead.

```python
>>> from sympy import Function, dsolve
>>> from sympy.abc import x
>>> f = Function('f')
>>> dsolve(f(x).diff(x, 5) + 10*f(x).diff(x) - 2*f(x), f(x),
... hint='nth_linear_constant_coeff_homogeneous')
... Eq(f(x), C5*exp(x*CRootOf(_x**5 + 10*_x - 2, 0))
+ (C1*sin(x*im(CRootOf(_x**5 + 10*_x - 2, 1))))*exp(x*re(CRootOf(_x**5 +
-10* x - 2, 1))))
+ (C2*cos(x*im(CRootOf(_x**5 + 10*_x - 2, 1))))*exp(x*re(CRootOf(_x**5 +
-10* x - 2, 1))))
+ (C3*sin(x*im(CRootOf(_x**5 + 10*_x - 2, 3))))
+ (C4*cos(x*im(CRootOf(_x**5 + 10*_x - 2, 3))))*exp(x*re(CRootOf(_x**5 +
-10* x - 2, 3))))
```

Note that because this method does not involve integration, there is no \( \text{nth_linear_constant_coeff_homogeneous} \) \( \text{Integral} \) hint.

Examples

```python
>>> from sympy import Function, dsolve, pprint
>>> from sympy.abc import x
>>> f = Function('f')
>>> pprint(dsolve(f(x).diff(x, 4) + 2*f(x).diff(x, 2) - 6*f(x).diff(x) + 5*f(x), f(x),
... hint='nth_linear_constant_coeff_homogeneous'))
\[
\begin{align*}
x -2^x f(x) &= (C1 + C2*x)*e + (C3*\sin(x) + C4*\cos(x))*e
\end{align*}
```

```python
# indirect doctest
class syppy.solvers.ode.single.NthLinearConstantCoeffUndeterminedCoefficients(ode_problem)

Solves an n\text{th} order linear differential equation with constant coefficients using the method of undetermined coefficients.

This method works on differential equations of the form

\[ a_n f^{(n)}(x) + a_{n-1} f^{(n-1)}(x) + \cdots + a_1 f'(x) + a_0 f(x) = P(x), \]

where \( P(x) \) is a function that has a finite number of linearly independent derivatives.

Functions that fit this requirement are finite sums functions of the form \( a x^i e^{bx} \sin(cx + d) \) or \( a x^i e^{bx} \cos(cx + d) \), where \( i \) is a non-negative integer and \( a, b, c, \) and \( d \) are constants. For example any polynomial in \( x \), functions like \( x^2 e^{2x}, x \sin(x), \) and \( e^x \cos(x) \) can all be used. Products of \( \sin \)'s and \( \cos \)'s have a finite number of derivatives, because they can be expanded into \( \sin(ax) \) and \( \cos(bx) \) terms. However, SymPy currently cannot do that expansion, so you will need to manually rewrite the expression in terms of the above to use this method. So, for example, you will need to manually convert \( \sin^2(x) \) into \( (1 + \cos(2x))/2 \) to properly apply the method of undetermined coefficients on it.

This method works by creating a trial function from the expression and all of its linear independent derivatives and substituting them into the original ODE. The coefficients for each term will be a system of linear equations, which are be solved for and substituted, giving the solution. If any of the trial functions are linearly dependent on the solution to the homogeneous equation, they are multiplied by sufficient \( x \) to make them linearly independent.

**Examples**

```python
>>> from sympy import Function, dsolve, pprint, exp, cos
>>> from sympy.abc import x
>>> f = Function('f')
>>> pprint(dsolve(f(x).diff(x, 2) + 2*f(x).diff(x) + f(x) -
... 4*exp(-x)*x**2 + cos(2*x), f(x),
... hint='nth_linear_constant_coeff_undetermined_coefficients'))
\[ f(x) = C1 + x \left| C2 + -\frac{x}{3} \right| + \frac{-4\sin(2\times) + 3\cos(2\times)}{25} \]
```

References

class sympy.solvers.ode.single.NthLinearConstantCoeffVariationOfParameters(ode_problem)

Solves an $n$th order linear differential equation with constant coefficients using the method of variation of parameters.

This method works on any differential equations of the form

$$f^{(n)}(x) + a_{n-1}f^{(n-1)}(x) + \cdots + a_1 f'(x) + a_0 f(x) = P(x).$$

This method works by assuming that the particular solution takes the form

$$\sum_{i=1}^{n} c_i(x)y_i(x),$$

where $y_i$ is the $i$th solution to the homogeneous equation. The solution is then solved using Wronskian’s and Cramer’s Rule. The particular solution is given by

$$\sum_{i=1}^{n} \left( \int \frac{W_i(x)}{W(x)} \, dx \right) y_i(x),$$

where $W(x)$ is the Wronskian of the fundamental system (the system of $n$ linearly independent solutions to the homogeneous equation), and $W_i(x)$ is the Wronskian of the fundamental system with the $i$th column replaced with $[0, 0, \ldots, 0, P(x)]$.

This method is general enough to solve any $n$th order inhomogeneous linear differential equation with constant coefficients, but sometimes SymPy cannot simplify the Wronskian well enough to integrate it. If this method hangs, try using the `nth_linear_constant_coeff_variation_of_parameters_Integral` hint and simplifying the integrals manually. Also, prefer using `nth_linear_constant_coeff_undetermined_coefficients` when it applies, because it does not use integration, making it faster and more reliable.

Warning, using `simplify=False` with `nth_linear_constant_coeff_variation_of_parameters` in `dsolve()` (page 807) may cause it to hang, because it will not attempt to simplify the Wronskian before integrating. It is recommended that you only use `simplify=False` with `nth_linear_constant_coeff_variation_of_parameters_Integral` for this method, especially if the solution to the homogeneous equation has trigonometric functions in it.

Examples

```python
>>> from sympy import Function, dsolve, pprint, exp, log
>>> from sympy.abc import x
>>> f = Function('f')
>>> pprint(dsolve(f(x).diff(x, 3) - 3*f(x).diff(x, 2) + 3*f(x).diff(x) - f(x) - exp(x)*log(x), f(x), hint='nth_linear_constant_coeff_variation_of_parameters'))
\[f(x) = \left(\frac{C1}{x} + \frac{C2}{x^2} + \frac{C3}{x^3}\right) + \frac{\ln(x)}{x^6} + \left(\frac{\ln(x) - 11x}{x^6}\right) \cdot e^{\frac{x}{x^2}}\]
```

5.8. Topics
References

- https://planetmath.org/VariationOfParameters

```python
>>> from sympy import Function, dsolve
>>> from sympy.abc import x
>>> f = Function('f')
>>> dsolve(4*x**2*f(x).diff(x, 2) + f(x), f(x),
        hint='nth_linear_euler_eq_homogeneous')
...   Eq(f(x), sqrt(x)*(C1 + C2*log(x))
```

Note that because this method does not involve integration, there is no `nth_linear_euler_eq_homogeneous_Integral` hint.

The following is for internal use:

- `returns = 'sol'` returns the solution to the ODE.
- `returns = 'list'` returns a list of linearly independent solutions, corresponding to the fundamental solution set, for use with non homogeneous solution methods like variation of parameters and undetermined coefficients. Note that, though the solutions should be linearly independent, this function does not explicitly check that. You can do `assert simplify(wronskian(sollist)) != 0` to check for linear independence. Also, `assert len(sollist) == order` will need to pass.
- `returns = 'both'`, return a dictionary `{'sol': <solution to ODE>, 'list': <list of linearly independent solutions>}.`
Examples

```python
>>> from sympy import Function, dsolve, pprint
>>> from sympy.abc import x
>>> f = Function('f')
>>> eq = f(x).diff(x, 2)*x**2 - 4*f(x).diff(x)*x + 6*f(x)
>>> pprint(dsolve(eq, f(x),
...     hint='nth_linear_euler_eq_homogeneous'))
2
f(x) = x *(C1 + C2*x)
```

# indirect doctest
class sympy.solvers.ode.single.NthLinearEulerEqNonhomogeneousVariationOfParameters(ode_problem)

Solves an \( n \)th order linear non homogeneous Cauchy-Euler equidimensional ordinary differential equation using variation of parameters.

This is an equation with form \( g(x) = a_0 f(x) + a_1 x f'(x) + a_2 x^2 f''(x) \cdots \).

This method works by assuming that the particular solution takes the form

\[
\sum_{x=1}^{n} c_i(x) y_i(x) a_n x^n,
\]

where \( y_i \) is the \( i \)th solution to the homogeneous equation. The solution is then solved using Wronskian’s and Cramer’s Rule. The particular solution is given by multiplying \( \sum \) given below with \( a_n x^n \)

\[
\sum_{x=1}^{n} \left( \int W_i(x) \frac{1}{W(x)} \, dx \right) y_i(x),
\]

where \( W(x) \) is the Wronskian of the fundamental system (the system of \( n \) linearly independent solutions to the homogeneous equation), and \( W_i(x) \) is the Wronskian of the fundamental system with the \( i \)th column replaced with \([0,0,\ldots,0,\frac{x^n}{a_n}g(x)]\).

This method is general enough to solve any \( n \)th order inhomogeneous linear differential equation, but sometimes SymPy cannot simplify the Wronskian well enough to integrate it. If this method hangs, try using the `nth_linear_constant_coeff_variation_of_parameters_Integral` hint and simplifying the integrals manually. Also, prefer using `nth_linear_constant_coeff_undetermined_coefficients` when it applies, because it does not use integration, making it faster and more reliable.

Warning, using simplify=False with 'nth_linear_constant_coeff_variation_of_parameters' in `dsolve()` (page 807) may cause it to hang, because it will not attempt to simplify the Wronskian before integrating. It is recommended that you only use simplify=False with 'nth_linear_constant_coeff_variation_of_parameters_Integral' for this method, especially if the solution to the homogeneous equation has trigonometric functions in it.
Examples

```python
>>> from sympy import Function, dsolve, Derivative
>>> f = Function('f')
>>> eq = x**2*Derivative(f(x), x, x) - 2*x*Derivative(f(x), x) + 2*f(x) - x**4
>>> dsolve(eq, f(x), hint='nth_linear_euler_eq_nonhomogeneous_variation_of_parameters').expand()
Eq(f(x), C1*x + C2*x**2 + x**4/6)
```

```python
class sympy.solvers.ode.single.NthLinearEulerEqNonhomogeneousUndeterminedCoefficients(ode_problem)
Solves an nth order linear non homogeneous Cauchy-Euler equidimensional ordinary differential equation using undetermined coefficients.

This is an equation with form \( g(x) = a_0 f(x) + a_1 x f'(x) + a_2 x^2 f''(x) \cdots \).

These equations can be solved in a general manner, by substituting solutions of the form \( x = \exp(t) \), and deriving a characteristic equation of form \( g(\exp(t)) = b_0 f(t) + b_1 f'(t) + b_2 f''(t) \cdots \) which can be then solved by nth_linear_constant_coeff_undetermined_coefficients if \( g(\exp(t)) \) has finite number of linearly independent derivatives.

Functions that fit this requirement are finite sums functions of the form \( ax^i e^{bx} \sin(cx + d) \) or \( ax^i e^{bx} \cos(cx + d) \), where \( i \) is a non-negative integer and \( a, b, c, \) and \( d \) are constants. For example any polynomial in \( x \), functions like \( x^2 e^{2x}, x \sin(x), \) and \( e^x \cos(x) \) can all be used. Products of sin's and cos's have a finite number of derivatives, because they can be expanded into \( \sin(ax) \) and \( \cos(bx) \) terms. However, SymPy currently cannot do that expansion, so you will need to manually rewrite the expression in terms of the above to use this method. So, for example, you will need to manually convert \( \sin^2(x) \) into \( (1 + \cos(2x))/2 \) to properly apply the method of undetermined coefficients on it.

After replacement of \( x \) by \( \exp(t) \), this method works by creating a trial function from the expression and all of its linear independent derivatives and substituting them into the original ODE. The coefficients for each term will be a system of linear equations, which are be solved for and substituted, giving the solution. If any of the trial functions are linearly dependent on the solution to the homogeneous equation, they are multiplied by sufficient \( x \) to make them linearly independent.

Examples

```python
>>> from sympy import dsolve, Function, Derivative, log
>>> f = Function('f')
>>> eq = x**2*Derivative(f(x), x, x) - 2*x*Derivative(f(x), x) + 2*f(x) - log(x)
>>> dsolve(eq, f(x), hint='nth_linear_euler_eq_nonhomogeneous_undetermined_coefficients').expand()
Eq(f(x), C1*x + C2*x**2 + log(x)/2 + 3/4)
```

class sympy.solvers.ode.single.NthAlgebraic(ode_problem)
Solves an nth order ordinary differential equation using algebra and integrals.
There is no general form for the kind of equation that this can solve. The equation is solved algebraically treating differentiation as an invertible algebraic function.

Examples

```python
>>> from sympy import Function, dsolve, Eq
>>> from sympy.abc import x
>>> f = Function('f')
>>> eq = Eq(f(x) * (f(x).diff(x)**2 - 1), 0)
>>> dsolve(eq, f(x), hint='nth_algebraic')
[Eq(f(x), 0), Eq(f(x), C1 - x), Eq(f(x), C1 + x)]
```

Note that this solver can return algebraic solutions that do not have any integration constants (f(x) = 0 in the above example).

class sympy.solvers.ode.single.NthOrderReducible(ode_problem)
Solves ODEs that only involve derivatives of the dependent variable using a substitution of the form \( f^n(x) = g(x) \).

For example any second order ODE of the form \( f''(x) = h(f'(x), x) \) can be transformed into a pair of 1st order ODEs \( g'(x) = h(g(x), x) \) and \( f'(x) = g(x) \). Usually the 1st order ODE for \( g \) is easier to solve. If that gives an explicit solution for \( g \) then \( f \) is found simply by integration.

Examples

```python
>>> from sympy import Function, dsolve, Eq, pprint
>>> from sympy.abc import x
>>> a, b, c, d, f = map(Function, ['a', 'b', 'c', 'd', 'f'])
>>> genform = Eq(a(x)*b(f(x))*f(x).diff(x), c(x)*d(f(x)))
>>> pprint(genform)
```

5.8. Topics
\[ a(x) \cdot b(f(x)) \cdot \frac{d}{dx}(f(x)) = c(x) \cdot d(f(x)) \]

```python
>>> pprint(dsolve(genform, f(x), hint='separable_Integral'))
\[ f(x) \]
```

```latex
\begin{align*}
\left| \begin{array}{c}
\frac{b(y)}{c(x)} - \frac{d(y)}{a(x)}
\end{array} \right| dy = \frac{C1}{dx}
\end{align*}
```

**Examples**

```python
>>> from sympy import Function, dsolve, Eq
>>> from sympy.abc import x
>>> f = Function('f')
>>> pprint(dsolve(Eq(f(x)*f(x).diff(x) + x, 3*x*f(x)**2), f(x),
... hint='separable', simplify=False))
\begin{align*}
\frac{log\left(3 f(x)\right) - 1}{x} - \frac{\frac{C1}{6}}{-2} = \frac{1}{2}
\end{align*}
```

**References**

```python
# indirect doctest
class sympy.solvers.ode.single.AlmostLinear(ode_problem)
Solves an almost-linear differential equation.

The general form of an almost linear differential equation is

\[ a(x)g'(f(x))f'(x) + b(x)g(f(x)) + c(x) \]

Here \( f(x) \) is the function to be solved for (the dependent variable). The substitution \( g(f(x)) = u(x) \) leads to a linear differential equation for \( u(x) \) of the form \( a(x)u' + b(x)u + c(x) = 0 \). This can be solved for \( u(x) \) by the firstlinear hint and then \( f(x) \) is found by solving \( g(f(x)) = u(x) \).
Examples

```python
>>> from sympy import dsolve, Function, pprint, sin, cos
>>> from sympy.abc import x
>>> f = Function('f')
>>> d = f(x).diff(x)
>>> eq = x*d + x*f(x) + 1
>>> dsolve(eq, f(x), hint='almost_linear')
>>> pprint(dsolve(eq, f(x), hint='almost_linear'))
Eq(f(x), (C1 - Ei(x))*exp(-x))
```

```python
>>> example = cos(f(x))*f(x).diff(x) + sin(f(x)) + 1
>>> pprint(example)
- x
d sin(f(x)) + cos(f(x))*--(f(x)) + 1
dx
>>> pprint(dsolve(example, f(x), hint='almost_linear'))
\[
[f(x) = \pi - \arcsin\left(C1*e \right) - 1/, f(x) = \arcsin\left(C1*e \right) - 1/]
```

References

**class sympy.solvers.ode.single.LinearCoefficients(ode_problem)**

Solves a differential equation with linear coefficients.

The general form of a differential equation with linear coefficients is

\[ y' + F \left( \frac{a_1 x + b_1 y + c_1}{a_2 x + b_2 y + c_2} \right) = 0, \]

where \(a_1, b_1, c_1, a_2, b_2, c_2\) are constants and \(a_1 b_2 - a_2 b_1 \neq 0\).

This can be solved by substituting:

\[
x = x' + \frac{b_2 c_1 - b_1 c_2}{a_2 b_1 - a_1 b_2},
\]

\[
y = y' + \frac{a_1 c_2 - a_2 c_1}{a_2 b_1 - a_1 b_2}.
\]

This substitution reduces the equation to a homogeneous differential equation.
Examples

```python
from sympy import dsolve, Function, pprint
from sympy.abc import x
f = Function('f')
df = f(x).diff(x)
eq = (x + f(x) + 1)*df + (f(x) - 6*x + 1)
dsolve(eq, hint='linear_coefficients')
[Eq(f(x), -x - sqrt(C1 + 7*x**2) - 1), Eq(f(x), -x + sqrt(C1 + 7*x**2) - 1)]
pprint(dsolve(eq, hint='linear_coefficients'))

[f(x) = -x - \sqrt{C1 + 7*x^2} - 1, f(x) = -x + \sqrt{C1 + 7*x^2} - 1]
```

References

class sympy.solvers.ode.single.SeparableReduced(ode_problem)
Solves a differential equation that can be reduced to the separable form.

The general form of this equation is

\[ y' + \left(\frac{y}{x}\right)H(x^n y) = 0. \]

This can be solved by substituting \( u(y) = x^n y \). The equation then reduces to the separable form

\[ \frac{u'}{u^{\text{power} - H(u)}} - \frac{1}{x} = 0. \]

The general solution is:

```python
from sympy import Function, dsolve, pprint
from sympy.abc import x, n
f, g = map(Function, ['f', 'g'])
genform = f(x).diff(x) + (f(x)/x)*g(x)**n*f(x)
pprint(genform)

/ n \
\[ d \]
\[ f(x)*g\x *f(x)/ \]
\[ -(f(x)) + \text{-------------} \]
\[ dx \]
\[ x \]
```

```python
pprint(dsolve(genform, hint='separable_reduced'))
```

(continues on next page)
| ------------ dy = C1 + log(x)  |
| y*(n - g(y)) |
| / |

Examples

```python
>>> from sympy import dsolve, Function, pprint
>>> from sympy.abc import x
>>> f = Function('f')
>>> d = f(x).diff(x)
>>> eq = (x - x**2*f(x))*d - f(x)
>>> dsolve(eq, hint='separable_reduced')
[Eq(f(x), (1 - sqrt(C1*x**2 + 1))/x), Eq(f(x), (sqrt(C1*x**2 + 1) + 1)/x)]
>>> pprint(dsolve(eq, hint='separable_reduced'))
___________ ___________
/ 2 / 2
1 - / C1*x + 1 / C1*x + 1 + 1
[f(x) = ------------------, f(x) = ------------------]
    x             x
```

sympy.solvers.ode.single.Separable (page 839)

References

class sympy.solvers.ode.single.LieGroup(ode_problem)

This hint implements the Lie group method of solving first order differential equations. The aim is to convert the given differential equation from the given coordinate system into another coordinate system where it becomes invariant under the one-parameter Lie group of translations. The converted ODE can be easily solved by quadrature. It makes use of the sympy.solvers.ode.infinitesimals() (page 816) function which returns the infinitesimals of the transformation.

The coordinates $r$ and $s$ can be found by solving the following Partial Differential Equations:

$$
\frac{\xi}{\partial x} + \eta \frac{\partial}{\partial y} = 0
$$

$$
\frac{\xi}{\partial x} + \eta \frac{\partial}{\partial y} = 1
$$

The differential equation becomes separable in the new coordinate system

$$
\frac{ds}{dr} = \frac{\partial s}{\partial r} + h(x,y)\frac{\partial s}{\partial y}
$$

$$
\frac{dr}{dr} = \frac{\partial r}{\partial r} + h(x,y)\frac{\partial r}{\partial y}
$$

5.8. Topics 843
After finding the solution by integration, it is then converted back to the original coordinate system by substituting $r$ and $s$ in terms of $x$ and $y$ again.

### Examples

```python
>>> from sympy import Function, dsolve, exp, pprint
>>> from sympy.abc import x
>>> f = Function('f')
>>> pprint(dsolve(f(x).diff(x) + 2*x*f(x) - x*exp(-x**2), f(x),
... hint='lie_group'))
/ 2\  2
| x | -x
f(x) = |C1 + --|*e
\ 2 /
```

#### class sympy.solvers.ode.single.SecondHypergeometric(ode_problem)

Solves 2nd order linear differential equations.

It computes special function solutions which can be expressed using the 2F1, 1F1 or 0F1 hypergeometric functions.

$$y'' + A(x)y' + B(x)y = 0,$$

where $A$ and $B$ are rational functions.

These kinds of differential equations have solution of non-Liouvillean form.

Given linear ODE can be obtained from 2F1 given by

$$(x^2 - x)y'' + ((a + b + 1)x - c)y' + bay = 0,$$

where {a, b, c} are arbitrary constants.

### Notes

The algorithm should find any solution of the form

$$y = P(x)p_Fq(..., \frac{\alpha x^k + \beta}{\gamma x^k + \delta}),$$

where $p_Fq$ is any of 2F1, 1F1 or 0F1 and $P$ is an “arbitrary function”. Currently only the 2F1 case is implemented in SymPy but the other cases are described in the paper and could be implemented in future (contributions welcome!).

- “Non-Liouvillian solutions for second order linear ODEs” by L. Chan, E.S. Cheb-Terrab

`singhpy.solvers.ode.ode.ode_1st_power_series(eq, func, order, match)`

The power series solution is a method which gives the Taylor series expansion to the solution of a differential equation.

For a first order differential equation \( \frac{dy}{dx} = h(x, y) \), a power series solution exists at a point \( x = x_0 \) if \( h(x, y) \) is analytic at \( x_0 \). The solution is given by

\[
y(x) = y(x_0) + \sum_{n=1}^{\infty} \frac{F_n(x_0, b)(x - x_0)^n}{n!},
\]

where \( y(x_0) = b \) is the value of \( y \) at the initial value of \( x_0 \). To compute the values of the \( F_n(x_0, b) \) the following algorithm is followed, until the required number of terms are generated.

1. \( F_1 = h(x_0, b) \)
2. \( F_{n+1} = \frac{\partial F_n}{\partial x} + h(x_0, b) F_1 \)

Examples

```python
>>> from sympy import Function, pprint, exp, dsolve
>>> from sympy.abc import x
>>> f = Function('f')
>>> eq = exp(x)**(f(x).diff(x)) - f(x)
>>> pprint(dsolve(eq, hint='1st_power_series'))
\[
f(x) = C1 + C1*x - \frac{\frac{1}{6}}{24} + \frac{\frac{1}{60}}{1} + 0\times/6
\]
```
References

sympy.solvers.ode.ode.ode_2nd_power_series_ordinary(eq, func, order, match)

Gives a power series solution to a second order homogeneous differential equation with polynomial coefficients at an ordinary point. A homogeneous differential equation is of the form

\[ P(x) \frac{d^2 y}{dx^2} + Q(x) \frac{dy}{dx} + R(x)y(x) = 0 \]

For simplicity it is assumed that \( P(x), Q(x) \) and \( R(x) \) are polynomials, it is sufficient that \( \frac{Q(x)}{P(x)} \) and \( \frac{R(x)}{P(x)} \) exists at \( x_0 \). A recurrence relation is obtained by substituting \( y \) as \( \sum_{n=0}^{\infty} a_n x^n \), in the differential equation, and equating the \( n \)th term. Using this relation various terms can be generated.

Examples

```python
>>> from sympy import dsolve, Function, pprint
>>> from sympy.abc import x
>>> f = Function("f")
>>> eq = f(x).diff(x, 2) + f(x)
>>> pprint(dsolve(eq, hint='2nd_power_series_ordinary'))
  | 4  \ 2\    / 2\   \
/  x \   \ /   \ /   \ /   \ /
| x \  x | x |   6 \  /
\ 24  2  \   \ 6 /
f(x) = C2*|--- - -- + 1| + C1*x*|1 - --| + 0 \x /
          \ 24  2      6 /
```

sympy.solvers.ode.ode.ode_2nd_power_series_regular(eq, func, order, match)

Gives a power series solution to a second order homogeneous differential equation with polynomial coefficients at a regular point. A second order homogeneous differential equation is of the form

\[ P(x) \frac{d^2 y}{dx^2} + Q(x) \frac{dy}{dx} + R(x)y(x) = 0 \]

A point is said to regular singular at \( x_0 \) if \( x - x_0 \frac{Q(x)}{P(x)} \) and \( (x - x_0)^2 \frac{R(x)}{P(x)} \) are analytic at \( x_0 \). For simplicity \( P(x), Q(x) \) and \( R(x) \) are assumed to be polynomials. The algorithm for finding the power series solutions is:

1. Try expressing \((x - x_0)P(x)\) and \((x - x_0)^2Q(x)\) as power series solutions about \( x_0 \).
   Find \( p_0 \) and \( q_0 \) which are the constants of the power series expansions.
2. Solve the indicial equation \( f(m) = m(m - 1) + m * p0 + q0 \), to obtain the roots \( m1 \) and \( m2 \) of the indicial equation.

3. If \( m1 - m2 \) is a non integer there exists two series solutions. If \( m1 = m2 \), there exists only one solution. If \( m1 - m2 \) is an integer, then the existence of one solution is confirmed. The other solution may or may not exist.

The power series solution is of the form \( x^m \sum_{n=0}^\infty a_n x^n \). The coefficients are determined by the following recurrence relation. \( a_n = \frac{\sum_{k=0}^{n-1} q_{n-k} \cdot (m+k) \cdot p_{n-k}}{f(m+n)} \). For the case in which \( m1 - m2 \) is an integer, it can be seen from the recurrence relation that for the lower root \( m \), when \( n \) equals the difference of both the roots, the denominator becomes zero. So if the numerator is not equal to zero, a second series solution exists.

**Examples**

```python
>>> from sympy import dsolve, Function, pprint
>>> from sympy.abc import x
>>> f = Function("f")
>>> eq = x*(f(x).diff(x, 2)) + 2*(f(x).diff(x)) + x*f(x)
>>> pprint(dsolve(eq, hint='2nd_power_series_regular'))
 / 6  4  2 \   / 4  2 \  \ C1*| - ---- + -- - -- + 1| \ 720 24 2 /  / 6\n| x  x  x |   | x  x  |  \ 120  6 / + --------------- + 0\x / \x \
```

**References**

**Lie heuristics**

These functions are intended for internal use of the Lie Group Solver. Nonetheless, they contain useful information in their docstrings on the algorithms implemented for the various heuristics.

```python
sympy.solvers.ode.lie_group.lie_heuristic_abaco1_simple(match, comp=False)
```

The first heuristic uses the following four sets of assumptions on \( \xi \) and \( \eta \)

\[
\begin{align*}
\xi &= 0, \eta = f(x) \\
\xi &= 0, \eta = f(y) \\
\xi &= f(x), \eta = 0 \\
\xi &= f(y), \eta = 0
\end{align*}
\]

The success of this heuristic is determined by algebraic factorisation. For the first assumption \( \xi = 0 \) and \( \eta \) to be a function of \( x \), the PDE

\[
\frac{\partial \eta}{\partial x} + (\frac{\partial \eta}{\partial y} - \frac{\partial \xi}{\partial x}) * h - \frac{\partial \xi}{\partial y} * h^2 - \xi * \frac{\partial h}{\partial x} - \eta * \frac{\partial h}{\partial y} = 0
\]
reduces to \( f'(x) - f \frac{\partial h}{\partial y} = 0 \) if \( \frac{\partial h}{\partial y} \) is a function of \( x \), then this can usually be integrated easily. A similar idea is applied to the other 3 assumptions as well.

\[
f' = \partial h \partial y = 0
\]

If \( \partial h \partial y \) is a function of \( x \), then this can usually be integrated easily.

A similar idea is applied to the other 3 assumptions as well.

References

- E.S. Cheb-Terrab, L.G.S Duarte and L.A.C.P da Mota, Computer Algebra Solving of First Order ODEs Using Symmetry Methods, pp. 8

\[\text{sympy.solvers.ode.lie_group.lie_heuristic_abaco1_product} (\text{match}, \text{comp}=\text{False})\]

The second heuristic uses the following two assumptions on \( \xi \) and \( \eta \)

\[
\eta = 0, \xi = f(x) \ast g(y)
\]

\[
\eta = f(x) \ast g(y), \xi = 0
\]

The first assumption of this heuristic holds good if \( \frac{1}{\eta^2} \frac{\partial^2}{\partial x \partial y} \log(h) \) is separable in \( x \) and \( y \), then the separated factors containing \( x \) is \( f(x) \), and \( g(y) \) is obtained by

\[
e^f \int f \frac{\partial}{\partial x} \left( \frac{1}{\eta^2} \right) dy
\]

provided \( f \frac{\partial}{\partial x} \left( \frac{1}{\eta^2} \right) \) is a function of \( y \) only.

The second assumption holds good if \( \frac{\partial}{\partial x} = h(x,y) \) is rewritten as \( \frac{\partial}{\partial x} = \frac{1}{h(y,x)} \) and the same properties of the first assumption satisfies. After obtaining \( f(x) \) and \( g(y) \), the coordinates are again interchanged, to get \( \eta \) as \( f(x) \ast g(y) \)

References

- E.S. Cheb-Terrab, A.D. Roche, Symmetries and First Order ODE Patterns, pp. 7 - pp. 8

\[\text{sympy.solvers.ode.lie_group.lie_heuristic_bivariate} (\text{match}, \text{comp}=\text{False})\]

The third heuristic assumes the infinitesimals \( \xi \) and \( \eta \) to be bi-variate polynomials in \( x \) and \( y \). The assumption made here for the logic below is that \( h \) is a rational function in \( x \) and \( y \) though that may not be necessary for the infinitesimals to be bivariate polynomials. The coefficients of the infinitesimals are found out by substituting them in the PDE and grouping similar terms that are polynomials and since they form a linear system, solve and check for non trivial solutions. The degree of the assumed bivariates are increased till a certain maximum value.

References

- Lie Groups and Differential Equations pp. 327 - pp. 329

\[\text{sympy.solvers.ode.lie_group.lie_heuristic_ch} (\text{match}, \text{comp}=\text{False})\]

The aim of the fourth heuristic is to find the function \( \chi(x,y) \) that satisfies the PDE \( \frac{\partial \chi}{\partial x} + h \frac{\partial \chi}{\partial x} - \frac{\partial h}{\partial y} \chi = 0 \).

This assumes \( \chi \) to be a bivariate polynomial in \( x \) and \( y \). By intuition, \( h \) should be a rational function in \( x \) and \( y \). The method used here is to substitute a general binomial for \( \chi \) up to a
certain maximum degree is reached. The coefficients of the polynomials, are calculated by collecting terms of the same order in \( x \) and \( y \).

After finding \( \chi \), the next step is to use \( \eta = \xi + \chi \), to determine \( \xi \) and \( \eta \). This can be done by dividing \( \chi \) by \( h \) which would give \( -\xi \) as the quotient and \( \eta \) as the remainder.

**References**

- E.S Cheb-Terrab, L.G.S Duarte and L.A.C.P da Mota, Computer Algebra Solving of First Order ODEs Using Symmetry Methods, pp. 8

```python
sympy.solvers.ode.lie_group.lie_heuristic_abaco2_similar(match, comp=False)
```

This heuristic uses the following two assumptions on \( \xi \) and \( \eta \)

\[
\eta = g(x), \xi = f(x)
\]

\[
\eta = f(y), \xi = g(y)
\]

For the first assumption,

1. First \( \frac{\partial \eta}{\partial y} \) is calculated. Let us say this value is A

2. If this is constant, then \( h \) is matched to the form \( A(x) + B(x)e^h \) then, \( e^{\int A(x) \, dx} \) gives \( f(x) \) and \( A(x) \cdot f(x) \) gives \( g(x) \)

3. Otherwise \( \frac{\partial A}{\partial x} = \gamma \) is calculated. If

   a) \( \gamma \) is a function of \( x \) alone

   b) \( \frac{\gamma \frac{\partial A}{\partial x} - \gamma(x) \frac{\partial A}{\partial x}}{h + \gamma} = G \) is a function of \( x \) alone. then, \( e^{\int G \, dx} \) gives \( f(x) \) and \( -\gamma \cdot f(x) \) gives \( g(x) \)

The second assumption holds good if \( \frac{du}{dx} = h(x,y) \) is rewritten as \( \frac{du}{dx} = \frac{1}{h(y,x)} \) and the same properties of the first assumption satisfies. After obtaining \( f(x) \) and \( g(x) \), the coordinates are again interchanged, to get \( \xi \) as \( f(x^*) \) and \( \eta \) as \( g(y^*) \)

**References**

- E.S. Cheb-Terrab, A.D. Roche, Symmetries and First Order ODE Patterns, pp. 10 - pp. 12

```python
sympy.solvers.ode.lie_group.lie_heuristic_function_sum(match, comp=False)
```

This heuristic uses the following two assumptions on \( \xi \) and \( \eta \)

\[
\eta = 0; \xi = f(x) + g(y)
\]

\[
\eta = f(x) + g(y); \xi = 0
\]

The first assumption of this heuristic holds good if

\[
\frac{\partial}{\partial y} [h \left( \frac{\partial^2}{\partial x^2} (h^{-1}) \right)^{-1}]
\]

is separable in \( x \) and \( y \),

5.8. Topics 849
1. The separated factors containing $y$ is $\frac{\partial g}{\partial y}$. From this $g(y)$ can be determined.

2. The separated factors containing $x$ is $f''(x)$.

3. $h \frac{\partial^2}{\partial x^2}(h^{-1})$ equals $\frac{f''(x)}{f(x)+g(y)}$. From this $f(x)$ can be determined.

The second assumption holds good if $\frac{dy}{dx} = h(x, y)$ is rewritten as $\frac{dy}{dx} = \frac{1}{h(y, x)}$ and the same properties of the first assumption satisfies. After obtaining $f(x)$ and $g(y)$, the coordinates are again interchanged, to get $\eta$ as $f(x) + g(y)$.

For both assumptions, the constant factors are separated among $g(y)$ and $f''(x)$, such that $f''(x)$ obtained from 3] is the same as that obtained from 2]. If not possible, then this heuristic fails.

References

- E.S. Cheb-Terrab, A.D. Roche, Symmetries and First Order ODE Patterns, pp. 7 - pp. 8

```
sympy.solvers.ode.lie_group.lie_heuristic_abaco2_unique_unknown(match, comp=False)
```

This heuristic assumes the presence of unknown functions or known functions with non-integer powers.

1. A list of all functions and non-integer powers containing $x$ and $y$

2. Loop over each element $f$ in the list, find $\frac{\partial f}{\partial x} = R$

   If it is separable in $x$ and $y$, let $X$ be the factors containing $x$. Then

   a] Check if $\xi = X$ and $\eta = -\frac{X}{R}$ satisfy the PDE. If yes, then return $\xi$ and $\eta$ 

   b] Check if $\xi = -\frac{R}{X}$ and $\eta = -\frac{1}{X}$ satisfy the PDE.

   If yes, then return $\xi$ and $\eta$.

   If not, then check if

   a] $\xi = -R, \eta = 1$

   b] $\xi = 1, \eta = -\frac{1}{R}$

   are solutions.

References

- E.S. Cheb-Terrab, A.D. Roche, Symmetries and First Order ODE Patterns, pp. 10 - pp. 12

```
sympy.solvers.ode.lie_group.lie_heuristic_abaco2_unique_general(match, comp=False)
```

This heuristic finds if infinitesimals of the form $\eta = f(x), \xi = g(y)$ without making any assumptions on $h$.

The complete sequence of steps is given in the paper mentioned below.
References

- E.S. Cheb-Terrab, A.D. Roche, Symmetries and First Order ODE Patterns, pp. 10 - pp. 12

sympy.solvers.ode.lie_group.lie_heuristic_linear(match, comp=False)

This heuristic assumes

1. $\xi = ax + by + c$ and
2. $\eta = fx + gy + h$

After substituting the following assumptions in the determining PDE, it reduces to

$$f + (g - a)h - bh^2 - (ax + by + c) \frac{\partial h}{\partial x} - (fx + gy + c) \frac{\partial h}{\partial y}$$

Solving the reduced PDE obtained, using the method of characteristics, becomes impractical. The method followed is grouping similar terms and solving the system of linear equations obtained. The difference between the bivariate heuristic is that $h$ need not be a rational function in this case.

Rational Riccati Solver

These functions are intended for internal use to solve a first order Riccati differential equation with atleast one rational particular solution.

sympy.solvers.ode.riccati.riccati_normal(w, x, b1, b2)

Given a solution $w(x)$ to the equation

$$w'(x) = b_0(x) + b_1(x) * w(x) + b_2(x) * w(x)^2$$

and rational function coefficients $b_1(x)$ and $b_2(x)$, this function transforms the solution to give a solution $y(x)$ for its corresponding normal Riccati ODE

$$y'(x) + y(x)^2 = a(x)$$

using the transformation

$$y(x) = -b_2(x) * w(x) - b'_2(x)/(2 * b_2(x)) - b_1(x)/2$$

sympy.solvers.ode.riccati.riccati_inverse_normal(y, x, b1, b2, bp=None)

Inverse transforming the solution to the normal Riccati ODE to get the solution to the Riccati ODE.

sympy.solvers.ode.riccati.riccati_reduced(eq, f, x)

Convert a Riccati ODE into its corresponding normal Riccati ODE.
sympy.solvers.ode.riccati.construct_c(num, den, x, poles, muls)
Helper function to calculate the coefficients in the c-vector for each pole.

sympy.solvers.ode.riccati.construct_d(num, den, x, val_inf)
Helper function to calculate the coefficients in the d-vector based on the valuation of the function at oo.

sympy.solvers.ode.riccati.rational_laurent_series(num, den, x, r, m, n)
The function computes the Laurent series coefficients of a rational function.

Parameters
num: A Poly object that is the numerator of \( f(x) \).
den: A Poly object that is the denominator of \( f(x) \).
x: The variable of expansion of the series.
r: The point of expansion of the series.
m: Multiplicity of \( r \) if \( r \) is a pole of \( f(x) \). Should be zero otherwise.
n: Order of the term upto which the series is expanded.

Returns
series: A dictionary that has power of the term as key and coefficient of that term as value.

Below is a basic outline of how the Laurent series of a rational function \( f(x) \) about \( x_0 \) is being calculated -
1. Substitute \( x + x_0 \) in place of \( x \). If \( x_0 \) is a pole of \( f(x) \), multiply the expression by \( x^m \) where \( m \) is the multiplicity of \( x_0 \). Denote the resulting expression as \( g(x) \). We do this substitution so that we can now find the Laurent series of \( g(x) \) about \( x = 0 \).
2. We can then assume that the Laurent series of \( g(x) \) takes the following form -

\[
g(x) = \frac{\text{num}(x)}{\text{den}(x)} = \sum_{m=0}^{\infty} a_m x^m
\]

where \( a_m \) denotes the Laurent series coefficients.
3. Multiply the denominator to the RHS of the equation and form a recurrence relation for the coefficients \( a_m \).

sympy.solvers.ode.riccati.compute_m_ybar(x, poles, choice, N)
Helper function to calculate -
1. \( m \) - The degree bound for the polynomial solution that must be found for the auxiliary differential equation.
2. ybar - Part of the solution which can be computed using the poles, c and d vectors.
sympy.solvers.ode.riccati.solve_aux_eq(numa, dena, numy, deny, x, m)
Helper function to find a polynomial solution of degree m for the auxiliary differential equation.

sympy.solvers.ode.riccati.remove_redundant_sols(sol1, sol2, x)
Helper function to remove redundant solutions to the differential equation.

sympy.solvers.ode.riccati.get_gen_sol_from_part_sol(part_sols, a, x)
" Helper function which computes the general solution for a Riccati ODE from its particular solutions.

There are 3 cases to find the general solution from the particular solutions for a Riccati ODE depending on the number of particular solution(s) we have - 1, 2 or 3.

For more information, see Section 6 of "Methods of Solution of the Riccati Differential Equation" by D. R. Haaheim and F. M. Stein

sympy.solvers.ode.riccati.solve_riccati(fx, x, b0, b1, b2, gensol=False)
The main function that gives particular/general solutions to Riccati ODEs that have atleast 1 rational particular solution.

System of ODEs

These functions are intended for internal use by dsolve() (page 807) for system of differential equations.

sympy.solvers.ode.ode._linear_2eq_order1_type6(x, y, t, r, eq)
The equations of this type of ode are:

\[ x' = f(t)x + g(t)y \]
\[ y' = a[f(t) + ah(t)]x + a[g(t) - h(t)]y \]

This is solved by first multiplying the first equation by \(-a\) and adding it to the second equation to obtain

\[ y' - ax' = -ah(t)(y - ax) \]

Setting \( U = y - ax \) and integrating the equation we arrive at

\[ y - ax = C_1e^{-\int h(t) dt} \]

and on substituting the value of \( y \) in first equation give rise to first order ODEs. After solving for \( x \), we can obtain \( y \) by substituting the value of \( x \) in second equation.

sympy.solvers.ode.ode._linear_2eq_order1_type7(x, y, t, r, eq)
The equations of this type of ode are:

\[ x' = f(t)x + g(t)y \]
\[ y' = h(t)x + p(t)y \]

Differentiating the first equation and substituting the value of \( y \) from second equation will give a second-order linear equation

\[ gx'' - (fg + gp + g')x' + (fgp - g^2h + fg' - f'g)x = 0 \]

This above equation can be easily integrated if following conditions are satisfied.
1. \( fgp - g^2h + fg' - f'g = 0 \)
2. \( fgp - g^2h + fg' - f'g = ag, f + g + gp + g' = bg \)

If first condition is satisfied then it is solved by current dsolve solver and in second case it becomes a constant coefficient differential equation which is also solved by current solver.

Otherwise if the above condition fails then, a particular solution is assumed as \( x = x_0(t) \) and \( y = y_0(t) \) Then the general solution is expressed as

\[
x = C_1x_0(t) + C_2x_0(t) \int \frac{g(t)F(t)P(t)}{x_0^2(t)} \, dt
\]

\[
y = C_1y_0(t) + C_2\left[ \frac{F(t)P(t)}{x_0(t)} + y_0(t) \int \frac{g(t)F(t)P(t)}{x_0^2(t)} \, dt \right]
\]

where \( C_1 \) and \( C_2 \) are arbitrary constants and

\[
F(t) = e^{\int f(t) \, dt}, \quad P(t) = e^{\int p(t) \, dt}
\]

sympy.solvers.ode.systems.linear_ode_to_matrix(eqs, funcs, t, order)

Convert a linear system of ODEs to matrix form

**Parameters**
- **eqs**: list of SymPy expressions or equalities
  - The equations as expressions (assumed equal to zero).
- **funcs**: list of applied functions
  - The dependent variables of the system of ODEs.
- **t**: symbol
  - The independent variable.
- **order**: int
  - The order of the system of ODEs.

**Returns**
- The tuple \((A, B)\) where \(A\) is a tuple of matrices and \(B\) is the the matrix representing the rhs of the matrix equation.

**Raises**
- **ODEOrderError**
  - When the system of ODEs have an order greater than what was specified
- **ODENonlinearError**
  - When the system of ODEs is nonlinear
Explanation

Express a system of linear ordinary differential equations as a single matrix differential equation [1]. For example the system \( x' = x + y + 1 \) and \( y' = x - y \) can be represented as

\[
A_1 X' = A_0 X + b
\]

where \( A_1 \) and \( A_0 \) are \( 2 \times 2 \) matrices and \( b, X \) and \( X' \) are \( 2 \times 1 \) matrices with \( X = [x, y]^T \).

Higher-order systems are represented with additional matrices e.g. a second-order system would look like

\[
A_2 X'' = A_1 X' + A_0 X + b
\]

Examples

```python
>>> from sympy import Function, Symbol, Matrix, Eq
>>> from sympy.solvers.ode.systems import linear_ode_to_matrix
>>> t = Symbol('t')
>>> x = Function('x')
>>> y = Function('y')
```

We can create a system of linear ODEs like

```python
>>> eqs = [
...     Eq(x(t).diff(t), x(t) + y(t) + 1),
...     Eq(y(t).diff(t), x(t) - y(t)),
... ]
>>> funcs = [x(t), y(t)]
>>> order = 1 # 1st order system
```

Now `linear_ode_to_matrix` can represent this as a matrix differential equation.

```python
>>> (A1, A0), b = linear_ode_to_matrix(eqs, funcs, t, order)
>>> A1
Matrix([[1, 0],
        [0, 1]])
>>> A0
Matrix([[1, 1],
        [1, -1]])
>>> b
Matrix([[1],
        [0]])
```

The original equations can be recovered from these matrices:

```python
>>> eqs_mat = Matrix([eq.lhs - eq.rhs for eq in eqs])
>>> X = Matrix(funcs)
>>> A1 * X.diff(t) - A0 * X - b == eqs_mat
True
```
If the system of equations has a maximum order greater than the order of the system specified, a ODEOrderError exception is raised.

```python
>>> eqs = [Eq(x(t).diff(t, 2), x(t).diff(t) + x(t)), Eq(y(t).diff(t), y(t) + x(t))]
>>> linear_ode_to_matrix(eqs, funcs, t, 1)
Traceback (most recent call last):
  ... ODEOrderError: Cannot represent system in 1-order form
```

If the system of equations is nonlinear, then ODENonlinearError is raised.

```python
>>> eqs = [Eq(x(t).diff(t), x(t) + y(t)), Eq(y(t).diff(t), y(t)**2 + x(t))]
>>> linear_ode_to_matrix(eqs, funcs, t, 1)
Traceback (most recent call last):
  ... ODENonlinearError: The system of ODEs is nonlinear.
```

See also:

linear_eq_to_matrix (page 917)
for systems of linear algebraic equations.

**References**

[R816]
sympy.solvers.ode.systems.canonical_odes(eqs, funcs, t)
Function that solves for highest order derivatives in a system

**Parameters**

- **eqs**: List
  - List of the ODEs
- **funcs**: List
  - List of dependent variables
- **t**: Symbol
  - Independent variable

**Returns**

List
**Explanation**

This function inputs a system of ODEs and based on the system, the dependent variables and their highest order, returns the system in the following form:

\[ X'(t) = A(t)X(t) + b(t) \]

Here, \( X(t) \) is the vector of dependent variables of lower order, \( A(t) \) is the coefficient matrix, \( b(t) \) is the non-homogeneous term and \( X'(t) \) is the vector of dependent variables in their respective highest order. We use the term canonical form to imply the system of ODEs which is of the above form.

If the system passed has a non-linear term with multiple solutions, then a list of systems is returned in its canonical form.

**Examples**

```python
>>> from sympy import symbols, Function, Eq, Derivative
>>> from sympy.solvers.ode.systems import canonical_odes
>>> f, g = symbols("f g", cls=Function)
>>> x, y = symbols("x y")
>>> funcs = [f(x), g(x)]
>>> eqs = [Eq(f(x).diff(x) - 7*f(x), 12*g(x)), Eq(g(x).diff(x) + g(x), -20*f(x))]

>>> canonical_eqs = canonical_odes(eqs, funcs, x)
>>> canonical_eqs
[[Eq(Derivative(f(x), x), 7*f(x) + 12*g(x)), Eq(Derivative(g(x), x), -20*f(x) - g(x))]]

>>> system = [Eq(Derivative(f(x), x)**2 - 2*Derivative(f(x), x) + 1, 4), Eq(-y*f(x) + Derivative(g(x), x), 0)]

>>> canonical_system = canonical_odes(system, funcs, x)
>>> canonical_system
[[Eq(Derivative(f(x), x), -1), Eq(Derivative(g(x), x), y*f(x))], Eq(Derivative(f(x), x), 3), Eq(Derivative(g(x), x), y*f(x))]]
```

**sympy.solvers.ode.systems.linodesolve_type(A, t, b=None)**

Helper function that determines the type of the system of ODEs for solving with `sympy.solvers.ode.systems.linodesolve()` (page 861)

**Parameters**

- **A**: Matrix
  
  Coefficient matrix of the system of ODEs

- **b**: Matrix or None
  
  Non-homogeneous term of the system. The default value is None. If this argument is None, then the system is assumed to be homogeneous.

**Returns**

- **Dict**
**Raises**

NotImplementedError

When the coefficient matrix does not have a commutative antiderivative

**Explanation**

This function takes in the coefficient matrix and/or the non-homogeneous term and returns the type of the equation that can be solved by `sympy.solvers.ode.systems.linodesolve()` (page 861).

If the system is constant coefficient homogeneous, then “type1” is returned

If the system is constant coefficient non-homogeneous, then “type2” is returned

If the system is non-constant coefficient homogeneous, then “type3” is returned

If the system is non-constant coefficient non-homogeneous, then “type4” is returned

If the system has a non-constant coefficient matrix which can be factorized into constant coefficient matrix, then “type5” or “type6” is returned for when the system is homogeneous or non-homogeneous respectively.

Note that, if the system of ODEs is of “type3” or “type4”, then along with the type, the commutative antiderivative of the coefficient matrix is also returned.

If the system cannot be solved by `sympy.solvers.ode.systems.linodesolve()` (page 861), then NotImplementedError is raised.

**Examples**

```python
>>> from sympy import symbols, Matrix
>>> from sympy.solvers.ode.systems import linodesolve_type
>>> t = symbols("t")
>>> A = Matrix([[1, 1], [2, 3]])
>>> b = Matrix([t, 1])

>>> linodesolve_type(A, t)
{'antiderivative': None, 'type_of_equation': 'type1'}

>>> linodesolve_type(A, t, b=b)
{'antiderivative': None, 'type_of_equation': 'type2'}

>>> A_t = Matrix([[1, t], [-t, 1]])

>>> linodesolve_type(A_t, t)
{'antiderivative': Matrix([[t, t**2/2], [-t**2/2, t]]), 'type_of_equation': 'type3'}
```
```python
>>> linodesolve_type(A_t, t, b=b)
{'antiderivative': Matrix([[t, t**2/2],
[-t**2/2, t]]), 'type_of_equation': 'type4'}
```

```python
>>> A_non_commutative = Matrix([[1, t], [t, -1]])
>>> linodesolve_type(A_non_commutative, t)
Traceback (most recent call last):
...
NotImplementedError:
The system does not have a commutative antiderivative, it cannot be solved by linodesolve.
```

See also:

- **linodesolve** (page 861)
  Function for which linodesolve_type gets the information

```python
sympy.solvers.ode.systems.matrix_exp_jordan_form(A, t)
```
Matrix exponential \(\exp(A \cdot t)\) for the matrix \(A\) and scalar \(t\).

**Parameters**

- **A**: Matrix
  
  The matrix \(A\) in the expression \(\exp(A \cdot t)\)

- **t**: Symbol
  
  The independent variable

**Explanation**

Returns the Jordan form of the \(\exp(A \cdot t)\) along with the matrix \(P\) such that:

\[
\exp(A \cdot t) = P \cdot \exp(J) \cdot P^{-1}
\]

**Examples**

```python
>>> from sympy import Matrix, Symbol
```  
```python
>>> from sympy.solvers.ode.systems import matrix_exp, matrix_exp_jordan_form
```  
```python
>>> t = Symbol('t')
```  
We will consider a 2x2 defective matrix. This shows that our method works even for defective matrices.

```python
>>> A = Matrix([[1, 1], [0, 1]])
```  
It can be observed that this function gives us the Jordan normal form and the required invertible matrix \(P\).

```python
>>> P, expJ = matrix_exp_jordan_form(A, t)
```
Here, it is shown that $P$ and $\exp J$ returned by this function is correct as they satisfy the formula: $P \cdot \exp J \cdot P^{-1} = \exp(A \cdot t)$.

```python
>>> P * expJ * P.inv() == matrix_exp(A, t)
True
```

**References**

[R817], [R818], [R819]

sympy.solvers.ode.systems.matrix_exp($A$, $t$)

Matrix exponential $\exp(A \cdot t)$ for the matrix $A$ and scalar $t$.

**Parameters**

- $A$ : Matrix
  - The matrix $A$ in the expression $\exp(A \cdot t)$
- $t$ : Symbol
  - The independent variable

**Explanation**

This function returns the $\exp(A \cdot t)$ by doing a simple matrix multiplication:

$$\exp(A \cdot t) = P \cdot \exp J \cdot P^{-1}$$

where $\exp J$ is $\exp(J \cdot t)$. $J$ is the Jordan normal form of $A$ and $P$ is matrix such that:

$$A = P \cdot J \cdot P^{-1}$$

The matrix exponential $\exp(A \cdot t)$ appears in the solution of linear differential equations. For example if $x$ is a vector and $A$ is a matrix then the initial value problem

$$\frac{dx(t)}{dt} = A \times x(t), x(0) = x0$$

has the unique solution

$$x(t) = \exp(At)x0$$

**Examples**

```python
>>> from sympy import Symbol, Matrix, pprint
>>> from sympy.solvers.ode.systems import matrix_exp
>>> t = Symbol('t')
```

We will consider a 2x2 matrix for computing the exponential

```python
>>> A = Matrix([[2, -5], [2, -4]])
>>> pprint(A)
[2  -5]
[2  -4]
```
Now, \( \exp(A \cdot t) \) is given as follows:

```python
>>> pprint(matrix_exp(A, t))
[ -t    -t    ]
[ 3*e   *sin(t) + e   *cos(t)  -5*e   *sin(t)  ]
[ ]
[ -t    -t    -t    ]
[ 2*e   *sin(t)    -3*e   *sin(t) + e   *cos(t) ]
```

See also:

* `matrix_exp_jordan_form` (page 859)
  For exponential of Jordan normal form

References

[R820], [R821]

```python
sympy.solvers.ode.systems.linodesolve(A, t, b=None, B=None, type='auto',
                                          doit=False, tau=None)
```

System of n equations linear first-order differential equations

**Parameters**

- **A**: Matrix
  Coefficient matrix of the system of linear first order ODEs.

- **t**: Symbol
  Independent variable in the system of ODEs.

- **b**: Matrix or None
  Non-homogeneous term in the system of ODEs. If None is passed, a homogeneous system of ODEs is assumed.

- **B**: Matrix or None
  Antiderivative of the coefficient matrix. If the antiderivative is not passed and the solution requires the term, then the solver would compute it internally.

- **type**: String
  Type of the system of ODEs passed. Depending on the type, the solution is evaluated. The type values allowed and the corresponding system it solves are: “type1” for constant coefficient homogeneous “type2” for constant coefficient non-homogeneous, “type3” for non-constant coefficient homogeneous, “type4” for non-constant coefficient non-homogeneous, “type5” and “type6” for non-constant coefficient homogeneous and non-homogeneous systems respectively where the coefficient matrix can be factorized to a constant coefficient matrix. The default value is “auto” which will let the solver decide the correct type of the system passed.

- **doit**: Boolean
  Evaluate the solution if True, default value is False

- **tau**: Expression
Used to substitute for the value of $t$ after we get the solution of the system.

**Returns**
List

**Raises**

**ValueError**
This error is raised when the coefficient matrix, non-homogeneous term or the antiderivative, if passed, are not a matrix or do not have correct dimensions

**NonSquareMatrixError**
When the coefficient matrix or its antiderivative, if passed is not a square matrix

**NotImplementedError**
If the coefficient matrix does not have a commutative antiderivative

**Explanation**

This solver solves the system of ODEs of the following form:

$$X'(t) = A(t)X(t) + b(t)$$

Here, $A(t)$ is the coefficient matrix, $X(t)$ is the vector of $n$ independent variables, $b(t)$ is the non-homogeneous term and $X'(t)$ is the derivative of $X(t)$

Depending on the properties of $A(t)$ and $b(t)$, this solver evaluates the solution differently.

When $A(t)$ is constant coefficient matrix and $b(t)$ is zero vector i.e. system is homogeneous, the system is “type1”. The solution is:

$$X(t) = \exp(At)C$$

Here, $C$ is a vector of constants and $A$ is the constant coefficient matrix.

When $A(t)$ is constant coefficient matrix and $b(t)$ is non-zero i.e. system is non-homogeneous, the system is “type2”. The solution is:

$$X(t) = e^{At}\left(\int e^{-At}b\,dt + C\right)$$

When $A(t)$ is coefficient matrix such that its commutative with its antiderivative $B(t)$ and $b(t)$ is a zero vector i.e. system is homogeneous, the system is “type3”. The solution is:

$$X(t) = \exp(B(t))C$$

When $A(t)$ is commutative with its antiderivative $B(t)$ and $b(t)$ is non-zero i.e. system is non-homogeneous, the system is “type4”. The solution is:

$$X(t) = e^{B(t)}\left(\int e^{-B(t)}b(t)\,dt + C\right)$$

When $A(t)$ is a coefficient matrix such that it can be factorized into a scalar and a constant coefficient matrix:

$$A(t) = f(t) \ast A$$
Where $f(t)$ is a scalar expression in the independent variable $t$ and $A$ is a constant matrix, then we can do the following substitutions:

$$
\tau = \int f(t) dt, \quad X(t) = Y(\tau), \quad b(t) = b(f^{-1}(\tau))
$$

Here, the substitution for the non-homogeneous term is done only when its non-zero. Using these substitutions, our original system becomes:

$$
Y'(\tau) = A \cdot Y(\tau) + b(\tau)/f(\tau)
$$

The above system can be easily solved using the solution for “type1” or “type2” depending on the homogeneity of the system. After we get the solution for $Y(\tau)$, we substitute the solution for $\tau$ as $t$ to get back $X(t)$

$$
X(t) = Y(\tau)
$$

Systems of “type5” and “type6” have a commutative antiderivative but we use this solution because its faster to compute.

The final solution is the general solution for all the four equations since a constant coefficient matrix is always commutative with its antiderivative.

An additional feature of this function is, if someone wants to substitute for value of the independent variable, they can pass the substitution $\tau$ and the solution will have the independent variable substituted with the passed expression($\tau$).

**Examples**

To solve the system of ODEs using this function directly, several things must be done in the right order. Wrong inputs to the function will lead to incorrect results.

```python
>>> from sympy import symbols, Function, Eq
>>> from sympy.solvers.ode.systems import canonical_odes, linear_ode_to_matrix, linodesolve, linodesolve_type
>>> from sympy.solvers.ode.subscheck import checkodesol
>>> f, g = symbols("f, g", cls=Function)
>>> x, a = symbols("x, a")
>>> funcs = [f(x), g(x)]
>>> eqs = [Eq(f(x).diff(x) - f(x), a*g(x) + 1), Eq(g(x).diff(x) + g(x), -a*f(x))]
```

Here, it is important to note that before we derive the coefficient matrix, it is important to get the system of ODEs into the desired form. For that we will use `sympy.solvers.ode.systems.canonical_odes()` (page 856).

```python
>>> eqs = canonical_odes(eqs, funcs, x)
>>> eqs
[[Eq(Derivative(f(x), x), a*g(x) + f(x) + 1), Eq(Derivative(g(x), x), -a*f(x) - g(x))]]
```

Now, we will use `sympy.solvers.ode.systems.linear_ode_to_matrix()` (page 854) to get the coefficient matrix and the non-homogeneous term if it is there.
We have the coefficient matrices and the non-homogeneous term ready. Now, we can use `sympy.solvers.ode.systems.linodesolve_type()` (page 857) to get the information for the system of ODEs to finally pass it to the solver.

```python
>>> system_info = linodesolve_type(A, x, b=b)
>>> sol_vector = linodesolve(A, x, b=b, B=system_info['antiderivative'], type=system_info['type_of_equation'])
```

Now, we can prove if the solution is correct or not by using `sympy.solvers.ode.checkodesol()` (page 814)

```python
>>> sol = [Eq(f, s) for f, s in zip(funcs, sol_vector)]
>>> checkodesol(eqs, sol) (True, [0, 0])
```

We can also use the `doit` method to evaluate the solutions passed by the function.

```python
>>> sol_vector_evaluated = linodesolve(A, x, b=b, type="type2", doit=True)
```

Now, we will look at a system of ODEs which is non-constant.

```python
>>> eqs = [Eq(f(x).diff(x), f(x) + x*g(x)), Eq(g(x).diff(x), -x*f(x) + g(x))]
```

The system defined above is already in the desired form, so we do not have to convert it.

```python
>>> (A1, A0), b = linear_ode_to_matrix(eqs, funcs, x, 1)
>>> A = A0
```

A user can also pass the commutative antiderivative required for type3 and type4 system of ODEs. Passing an incorrect one will lead to incorrect results. If the coefficient matrix is not commutative with its antiderivative, then `sympy.solvers.ode.systems.linodesolve_type()` (page 857) raises a `NotImplementedError`. If it does have a commutative antiderivative, then the function just returns the information about the system.

```python
>>> system_info = linodesolve_type(A, x, b=b)
```

Now, we can pass the antiderivative as an argument to get the solution. If the system information is not passed, then the solver will compute the required arguments internally.

```python
>>> sol_vector = linodesolve(A, x, b=b)
```

Once again, we can verify the solution obtained.

```python
>>> sol = [Eq(f, s) for f, s in zip(funcs, sol_vector)]
>>> checkodesol(eqs, sol) (True, [0, 0])
```

where \( C_1 \) and \( C_2 \) are arbitrary constants.

```python
sympy.solvers.ode.ode._nonlinear_2eq_order1_type2(x, y, t, eq)
```
Equations:

\[
\begin{align*}
x' &= e^{\lambda x} F(x, y) \\
y' &= g(y) F(x, y)
\end{align*}
\]

Solution:

\[
x = \varphi(y), \int \frac{1}{g(y) F(\varphi(y), y)} \, dy = t + C_2
\]

where

if \( \lambda \neq 0 \)

\[
\varphi = -\frac{1}{\lambda} \log(C_1 - \lambda \int \frac{1}{g(y)} \, dy)
\]

if \( \lambda = 0 \)

\[
\varphi = C_1 + \int \frac{1}{g(y)} \, dy
\]

where \( C_1 \) and \( C_2 \) are arbitrary constants.
SymPy Documentation, Release 1.12.1

sympy.solvers.ode.ode._nonlinear_2eq_order1_type3(x, y, t, eq)

Autonomous system of general form

\[ x' = F(x, y) \]
\[ y' = G(x, y) \]

Assuming \( y = y(x, C_1) \) where \( C_1 \) is an arbitrary constant is the general solution of the first-order equation

\[ F(x, y)y_x' = G(x, y) \]

Then the general solution of the original system of equations has the form

\[ \int \frac{1}{F(x, y(x, C_1))} \, dx = t + C_1 \]

sympy.solvers.ode.ode._nonlinear_2eq_order1_type4(x, y, t, eq)

Equation:

\[ x' = f_1(x)g_1(y)\phi(x, y, t) \]
\[ y' = f_2(x)g_2(y)\phi(x, y, t) \]

First integral:

\[ \int \frac{f_2(x)}{f_1(x)} \, dx - \int \frac{g_1(y)}{g_2(y)} \, dy = C \]

where \( C \) is an arbitrary constant.

On solving the first integral for \( x \) (resp., \( y \)) and on substituting the resulting expression into either equation of the original solution, one arrives at a first-order equation for determining \( y \) (resp., \( x \)).

sympy.solvers.ode.ode._nonlinear_2eq_order1_type5(func, t, eq)

Clairaut system of ODEs

\[ x = tx' + F(x', y') \]
\[ y = ty' + G(x', y') \]

The following are solutions of the system

\( (i) \) straight lines:

\[ x = C_1 t + F(C_1, C_2), \quad y = C_2 t + G(C_1, C_2) \]

where \( C_1 \) and \( C_2 \) are arbitrary constants;

\( (ii) \) envelopes of the above lines;

\( (iii) \) continuously differentiable lines made up from segments of the lines \( (i) \) and \( (ii) \).
sympy.solvers.ode.ode._nonlinear_3eq_order1_type1(x, y, z, t, eq)

Equations:
\[ ax' = (b - c)yz, \quad by' = (c - a)zx, \quad cz' = (a - b)xy \]

First Integrals:
\[ ax^2 + by^2 + cz^2 = C_1 \]
\[ a^2x^2 + b^2y^2 + c^2z^2 = C_2 \]

where \( C_1 \) and \( C_2 \) are arbitrary constants. On solving the integrals for \( y \) and \( z \) and on substituting the resulting expressions into the first equation of the system, we arrives at a separable first-order equation on \( x \). Similarly doing that for other two equations, we will arrive at first order equation on \( y \) and \( z \) too.

References

sympy.solvers.ode.ode._nonlinear_3eq_order1_type2(x, y, z, t, eq)

Equations:
\[ ax' = (b - c)yzf(x, y, z, t), \quad by' = (c - a)zx f(x, y, z, t), \quad cz' = (a - b)xy f(x, y, z, t) \]

First Integrals:
\[ ax^2 + by^2 + cz^2 = C_1 \]
\[ a^2x^2 + b^2y^2 + c^2z^2 = C_2 \]

where \( C_1 \) and \( C_2 \) are arbitrary constants. On solving the integrals for \( y \) and \( z \) and on substituting the resulting expressions into the first equation of the system, we arrives at a first-order differential equations on \( x \). Similarly doing that for other two equations we will arrive at first order equation on \( y \) and \( z \).

References

sympy.solvers.ode.ode._nonlinear_3eq_order1_type3(x, y, z, t, eq)

Equations:
\[ x' = cF_2 - bF_3, \quad y' = aF_3 - cF_1, \quad z' = bF_1 - aF_2 \]

where \( F_n = F_n(x, y, z, t) \).

1. First Integral:
\[ ax + by + cz = C_1, \]

where \( C \) is an arbitrary constant.

2. If we assume function \( F_n \) to be independent of \( t \), i.e., \( F_n = F_n(x, y, z) \) Then, on eliminating \( t \) and \( z \) from the first two equations of the system, one arrives at the first-order equation

\[
\frac{dy}{dx} = \frac{aF_3(x, y, z) - cF_1(x, y, z)}{cF_2(x, y, z) - bF_3(x, y, z)}
\]

where \( z = \frac{1}{c}(C_1 - ax - by) \)

**References**

sympy.solvers.ode.ode._nonlinear_3eq_order1_type4(x, y, z, t, eq)

Equations:

\[
x' = czF_2 - byF_3, \quad y' = axF_3 - czF_1, \quad z' = byF_1 - axF_2
\]

where \( F_n = F_n(x, y, z, t) \)

1. First integral:

\[ ax^2 + by^2 + cz^2 = C_1 \]

where \( C \) is an arbitrary constant.

2. Assuming the function \( F_n \) is independent of \( t \): \( F_n = F_n(x, y, z) \). Then on eliminating \( t \) and \( z \) from the first two equations of the system, one arrives at a first-order equation.

\[
\frac{dy}{dx} = \frac{aF_3(x, y, z) - cF_1(x, y, z)}{cF_2(x, y, z) - bF_3(x, y, z)}
\]

where \( z = \pm \sqrt{\frac{1}{c}(C_1 - ax^2 - by^2)} \)

**References**

sympy.solvers.ode.ode._nonlinear_3eq_order1_type5(x, y, z, t, eq)

\[
x' = x(cF_2 - bF_3), \quad y' = y(aF_3 - cF_1), \quad z' = z(bF_1 - aF_2)
\]

where \( F_n = F_n(x, y, z, t) \) and are arbitary functions.

First Integral:

\[ |x|^a |y|^b |z|^c = C_1 \]

where \( C \) is an arbitrary constant. If the function \( F_n \) is independent of \( t \), then, by eliminating \( t \) and \( z \) from the first two equations of the system, one arrives at a first-order equation.
Information on the ode module

This module contains \texttt{dsolve()} (page 807) and different helper functions that it uses.

\texttt{dsolve()} (page 807) solves ordinary differential equations. See the docstring on the various functions for their uses. Note that partial differential equations support is in \texttt{pde.py}. Note that hint functions have docstrings describing their various methods, but they are intended for internal use. Use \texttt{dsolve(ode, func, hint=hint)} to solve an ODE using a specific hint. See also the docstring on \texttt{dsolve()} (page 807).

Functions in this module

These are the user functions in this module:

- \texttt{dsolve()} (page 807) - Solves ODEs.
- \texttt{classify_ode()} (page 812) - Classifies ODEs into possible hints for \texttt{dsolve()} (page 807).
- \texttt{checkodesol()} (page 814) - Checks if an equation is the solution to an ODE.
- \texttt{homogeneous_order()} (page 815) - Returns the homogeneous order of an expression.
- \texttt{infinitesimals()} (page 816) - Returns the infinitesimals of the Lie group of point transformations of an ODE, such that it is invariant.
- \texttt{checkinfsol()} (page 817) - Checks if the given infinitesimals are the actual infinitesimals of a first order ODE.

These are the non-solver helper functions that are for internal use. The user should use the various options to \texttt{dsolve()} (page 807) to obtain the functionality provided by these functions:

- \texttt{odesimp()} (page 819) - Does all forms of ODE simplification.
- \texttt{ode_sol_simplicity()} (page 821) - A key function for comparing solutions by simplicity.
- \texttt{constantsimp()} (page 817) - Simplifies arbitrary constants.
- \texttt{constant_renumber()} (page 820) - Renumber arbitrary constants.
- \texttt{_handle_Integral()} (page 872) - Evaluate unevaluated Integrals.

See also the docstrings of these functions.

Currently implemented solver methods

The following methods are implemented for solving ordinary differential equations. See the docstrings of the various hint functions for more information on each (run \texttt{help(ode)}):

- 1st order separable differential equations.
- 1st order differential equations whose coefficients or $dx$ and $dy$ are functions homogeneous of the same order.
- 1st order exact differential equations.
- 1st order linear differential equations.
- 1st order Bernoulli differential equations.
- Power series solutions for first order differential equations.
- 2nd order Liouville differential equations.
- Power series solutions for second order differential equations at ordinary and regular singular points.
- $n$th order differential equation that can be solved with algebraic rearrangement and integration.
- $n$th order linear homogeneous differential equation with constant coefficients.
- $n$th order linear inhomogeneous differential equation with constant coefficients using the method of undetermined coefficients.
- $n$th order linear inhomogeneous differential equation with constant coefficients using the method of variation of parameters.

**Philosophy behind this module**

This module is designed to make it easy to add new ODE solving methods without having to mess with the solving code for other methods. The idea is that there is a `classify_ode()` function, which takes in an ODE and tells you what hints, if any, will solve the ODE. It does this without attempting to solve the ODE, so it is fast. Each solving method is a hint, and it has its own function, named `ode_<hint>`. That function takes in the ODE and any match expression gathered by `classify_ode()` (page 812) and returns a solved result. If this result has any integrals in it, the hint function will return an unevaluated `Integral` class. `dsolve()` (page 807), which is the user wrapper function around all of this, will then call `odesimp()` (page 819) on the result, which, among other things, will attempt to solve the equation for the dependent variable (the function we are solving for), simplify the arbitrary constants in the expression, and evaluate any integrals, if the hint allows it.

**How to add new solution methods**

If you have an ODE that you want `dsolve()` (page 807) to be able to solve, try to avoid adding special case code here. Instead, try finding a general method that will solve your ODE, as well as others. This way, the `ode` (page 807) module will become more robust, and unhindered by special case hacks. WolphramAlpha and Maple’s DTools[odeadvisor] function are two resources you can use to classify a specific ODE. It is also better for a method to work with an $n$th order ODE instead of only with specific orders, if possible.

To add a new method, there are a few things that you need to do. First, you need a hint name for your method. Try to name your hint so that it is unambiguous with all other methods, including ones that may not be implemented yet. If your method uses integrals, also include a hint_Integral hint. If there is more than one way to solve ODEs with your method, include a hint for each one, as well as a <hint>_best hint. Your ode_<hint>_best() function should choose the best using min with `ode_sol_simplicity` as the key argument. See `HomogeneousCoeffBest` (page 823), for example. The function that uses your method will be called `ode_<hint>()`, so the hint must only use characters that are allowed in a Python function name (alphanumeric characters and the underscore ‘_’ character). Include a function for every hint, except for _Integral hints (`dsolve()` (page 807) takes care of those automatically). Hint names should be all lowercase, unless a word is commonly capitalized (such as Integral or Bernoulli). If you have a hint that you do not want to run with all_Integral that does not have an _Integral counterpart (such as a best hint that would defeat the purpose of all_Integral), you will need to remove it manually in the `dsolve()` (page 807) code. See also the `classify_ode()` (page 812) docstring for guidelines on writing a hint name.
Determine *in general* how the solutions returned by your method compare with other methods that can potentially solve the same ODEs. Then, put your hints in the `allhints` (page 818) tuple in the order that they should be called. The ordering of this tuple determines which hints are default. Note that exceptions are ok, because it is easy for the user to choose individual hints with `dsolve()` (page 807). In general, `_Integral` variants should go at the end of the list, and `_best` variants should go before the various hints they apply to. For example, the `undetermined_coefficients` hint comes before the `variation_of_parameters` hint because, even though variation of parameters is more general than undetermined coefficients, undetermined coefficients generally returns cleaner results for the ODEs that it can solve than variation of parameters does, and it does not require integration, so it is much faster.

Next, you need to have a match expression or a function that matches the type of the ODE, which you should put in `classify_ode()` (page 812) (if the match function is more than just a few lines. It should match the ODE without solving for it as much as possible, so that `classify_ode()` (page 812) remains fast and is not hindered by bugs in solving code. Be sure to consider corner cases. For example, if your solution method involves dividing by something, make sure you exclude the case where that division will be 0.

In most cases, the matching of the ODE will also give you the various parts that you need to solve it. You should put that in a dictionary (`.match()` will do this for you), and add that as matching_hints[‘hint’] = matchdict in the relevant part of `classify_ode()` (page 812). `classify_ode()` (page 812) will then send this to `dsolve()` (page 807), which will send it to your function as the match argument. Your function should be named `ode_<hint>(eq, func, order, match)` If you need to send more information, put it in the `match` dictionary. For example, if you had to substitute in a dummy variable in `classify_ode()` (page 812) to match the ODE, you will need to pass it to your function using the `match` dict to access it. You can access the independent variable using `func.args[0]`, and the dependent variable (the function you are trying to solve for) as `func`. If, while trying to solve the ODE, you find that you cannot, raise `NotImplementedError`. `dsolve()` (page 807) will catch this error with the all meta-hint, rather than causing the whole routine to fail.

Add a docstring to your function that describes the method employed. Like with anything else in SymPy, you will need to add a doctest to the docstring, in addition to real tests in `test_ode.py`. Try to maintain consistency with the other hint functions’ docstrings. Add your method to the list at the top of this docstring. Also, add your method to `ode.rst` in the `docs/src` directory, so that the Sphinx docs will pull its docstring into the main SymPy documentation. Be sure to make the Sphinx documentation by running `make html` from within the `doc` directory to verify that the docstring formats correctly.

If your solution method involves integrating, use `Integral` (page 660) instead of `integrate()` (page 1016). This allows the user to bypass hard/slow integration by using the `_Integral` variant of your hint. In most cases, calling `sympy.core.basic.Basic.doit()` (page 983) will integrate your solution. If this is not the case, you will need to write special code in `_handle_Integral()` (page 872). Arbitrary constants should be symbols named `C1`, `C2`, and so on. All solution methods should return an equality instance. If you need an arbitrary number of arbitrary constants, you can use `constants = numbered_symbols(prefix='C', cls=Symbol, start=1)`. If it is possible to solve for the dependent function in a general way, do so. Otherwise, do as best as you can, but do not call solve in your `ode_<hint>()` function. `odesimp()` (page 819) will attempt to solve the solution for you, so you do not need to do that. Lastly, if your ODE has a common simplification that can be applied to your solutions, you can add a special case in `odesimp()` (page 819) for it. For example, solutions returned from the `1st_homogeneous_coeff` hints often have many `log` (page 470) terms, so `odesimp()` (page 819) calls `logcombine()` (page 726) on them (it also helps to write the arbitrary constant as `log(C1)` instead of `C1` in this case). Also consider common ways that you can rearrange your solution to have `constantsimp()` (page 817) take better advantage of it. It is better to
put simplification in `odesimp()` (page 819) than in your method, because it can then be turned off with the `simplify` flag in `dsolve()` (page 807). If you have any extraneous simplification in your function, be sure to only run it using if `match.get('simplify', True)`; especially if it can be slow or if it can reduce the domain of the solution.

Finally, as with every contribution to SymPy, your method will need to be tested. Add a test for each method in `test_ode.py`. Follow the conventions there, i.e., test the solver using `dsolve(eq, f(x), hint=your_hint)`, and also test the solution using `checkodesol()` (page 814) (you can put these in a separate tests and skip/XFAIL if it runs too slow/does not work). Be sure to call your hint specifically in `dsolve()` (page 807), that way the test will not be broken simply by the introduction of another matching hint. If your method works for higher order (>1) ODEs, you will need to run `sol = constant_renumber(sol, 'C', 1, order)` for each solution, where `order` is the order of the ODE. This is because `constant_renumber` renumbers the arbitrary constants by printing order, which is platform dependent. Try to test every corner case of your solver, including a range of orders if it is a `n`th order solver, but if your solver is slow, such as if it involves hard integration, try to keep the test run time down.

Feel free to refactor existing hints to avoid duplicating code or creating inconsistencies. If you can show that your method exactly duplicates an existing method, including in the simplicity and speed of obtaining the solutions, then you can remove the old, less general method. The existing code is tested extensively in `test_ode.py`, so if anything is broken, one of those tests will surely fail.

These functions are not intended for end-user use.

```
sympy.solvers.ode.ode._handle_Integral(expr, func, hint)
```

Converts a solution with Integrals in it into an actual solution.

For most hints, this simply runs `expr.doit()`.

### PDE

#### User Functions

These are functions that are imported into the global namespace with `from sympy import *`. They are intended for user use.

```
sympy.solvers.pde.pde_separate(eq, fun, sep, strategy='mul')
```

Separate variables in partial differential equation either by additive or multiplicative separation approach. It tries to rewrite an equation so that one of the specified variables occurs on a different side of the equation than the others.

**Parameters**

- `eq` - Partial differential equation
- `fun` - Original function F(x, y, z)
- `sep` - List of separated functions [X(x), u(y, z)]
- `strategy` - Separation strategy. You can choose between additive separation (`'add'`) and multiplicative separation (`'mul'`) which is default.
Examples

```python
>>> from sympy import E, Eq, Function, pde_separate, Derivative as D
>>> from sympy.abc import x, t
>>> u, X, T = map(Function, 'uXT')

>>> eq = Eq(D(u(x, t), x), E**(u(x, t))*D(u(x, t), t))
>>> pde_separate(eq, u(x, t), [X(x), T(t)], strategy='add')
[exp(-X(x))*Derivative(X(x), x), exp(T(t))*Derivative(T(t), t)]

>>> eq = Eq(D(u(x, t), x, 2), D(u(x, t), t, 2))
>>> pde_separate(eq, u(x, t), [X(x), T(t)], strategy='mul')
[Derivative(X(x), (x, 2))/X(x), Derivative(T(t), (t, 2))/T(t)]
```

See also:
pde_separate_add (page 873), pde_separate_mul (page 873)

sympy.solvers.pde.pde_separate_add(eq, fun, sep)
Helper function for searching additive separable solutions.
Consider an equation of two independent variables \(x, y\) and a dependent variable \(w\), we look for the product of two functions depending on different arguments:

\[ w(x, y, z) = X(x) + y(y, z) \]

Examples

```python
>>> from sympy import E, Eq, Function, pde_separate_add, Derivative as D
>>> from sympy.abc import x, t
>>> u, X, T = map(Function, 'uXT')

>>> eq = Eq(D(u(x, t), x), E**(u(x, t))*D(u(x, t), t))
>>> pde_separate_add(eq, u(x, t), [X(x), T(t)])
[exp(-X(x))*Derivative(X(x), x), exp(T(t))*Derivative(T(t), t)]
```

sympy.solvers.pde.pde_separate_mul(eq, fun, sep)
Helper function for searching multiplicative separable solutions.
Consider an equation of two independent variables \(x, y\) and a dependent variable \(w\), we look for the product of two functions depending on different arguments:

\[ w(x, y, z) = X(x) * u(y, z) \]
Examples

```python
>>> from sympy import Function, Eq, pde_separate_mul, Derivative as D
>>> from sympy.abc import x, y
>>> u, X, Y = map(Function, 'uXY')
>>> eq = Eq(D(u(x, y), x, 2), D(u(x, y), y, 2))
>>> pde_separate_mul(eq, u(x, y), [X(x), Y(y)])
[Derivative(X(x), (x, 2))/X(x), Derivative(Y(y), (y, 2))/Y(y)]
```

`sympy.solvers.pde.pdsolve(eq, func=None, hint='default', dict=False, solvefun=None, **kwargs)`

Solves any (supported) kind of partial differential equation.

**Usage**

pdsolve(eq, f(x,y), hint) -> Solve partial differential equation eq for function f(x,y), using method hint.

**Details**

- **eq can be any supported partial differential equation (see**
  - the pde docstring for supported methods). This can either be an Equality, or an expression, which is assumed to be equal to 0.

- **f(x,y) is a function of two variables whose derivatives in that**
  - variable make up the partial differential equation. In many cases it is not necessary to provide this; it will be autodetected (and an error raised if it could not be detected).

- **hint is the solving method that you want pdsolve to use. Use**
  - classify_pde(eq, f(x,y)) to get all of the possible hints for a PDE. The default hint, ‘default’, will use whatever hint is returned first by classify_pde(). See Hints below for more options that you can use for hint.

- **solvefun is the convention used for arbitrary functions returned**
  - by the PDE solver. If not set by the user, it is set by default to be F.

**Hints**

Aside from the various solving methods, there are also some meta-hints that you can pass to pdsolve():

- **“default”:**
  - This uses whatever hint is returned first by classify_pde(). This is the default argument to pdsolve().

- **“all”:**
  - To make pdsolve apply all relevant classification hints, use pdsolve(PDE, func, hint=“all”). This will return a dictionary of hint:solution terms. If a hint causes pdsolve to raise the NotImplementedError, value of that hint’s key will be the exception object raised. The dictionary will also include some special keys:
    - order: The order of the PDE. See also ode_order() in deutils.py
    - default: The solution that would be returned by default. This is the one produced by the hint that appears first in the tuple returned by classify_pde().
“all_Integral”: This is the same as “all”, except if a hint also has a corresponding “Integral” hint, it only returns the “Integral” hint. This is useful if “all” causes pdsolve() to hang because of a difficult or impossible integral. This meta-hint will also be much faster than “all”, because integrate() is an expensive routine.

See also the classify_pde() docstring for more info on hints, and the pde docstring for a list of all supported hints.

Tips

• You can declare the derivative of an unknown function this way:

```python
>>> from sympy import Function, Derivative
>>> from sympy.abc import x, y  # x and y are the independent variables
>>> f = Function('f')(x, y)  # f is a function of x and y
>>> # fx will be the partial derivative of f with respect to x
>>> fx = Derivative(f, x)
>>> # fy will be the partial derivative of f with respect to y
>>> fy = Derivative(f, y)
```

• See test_pde.py for many tests, which serves also as a set of examples for how to use pdsolve().

• pdsolve always returns an Equality class (except for the case when the hint is “all” or “all_Integral”). Note that it is not possible to get an explicit solution for f(x, y) as in the case of ODE’s

• Do help(pde.pde_hintname) to get help more information on a specific hint

Examples

```python
>>> from sympy.solvers.pde import pdsolve
>>> from sympy import Function, Eq
>>> from sympy.abc import x, y
>>> f = Function('f')
>>> u = f(x, y)
>>> ux = u.diff(x)
>>> uy = u.diff(y)
>>> eq = Eq(1 + (2*(ux/u)) + (3*(uy/u)), 0)
>>> pdsolve(eq)
Eq(f(x, y), F(3*x - 2*y)*exp(-2*x/13 - 3*y/13))
```

sympy.solvers.pde.classify_pde(eq, func=None, dict=False, *args, **kwargs)

Returns a tuple of possible pdsolve() classifications for a PDE.

The tuple is ordered so that first item is the classification that pdsolve() uses to solve the PDE by default. In general, classifications near the beginning of the list will produce better solutions faster than those near the end, though there are always exceptions. To make pdsolve use a different classification, use pdsolve(PDE, func, hint=<classification>). See also the pdsolve() docstring for different meta-hints you can use.
If `dict` is true, `classify_pde()` will return a dictionary of hint:match expression terms. This is intended for internal use by `pdsolve()`. Note that because dictionaries are ordered arbitrarily, this will most likely not be in the same order as the tuple.

You can get help on different hints by doing `help(pde.pde_hintname)`, where `hintname` is the name of the hint without “Integral”.

See `sympy.pde.allhints` or the `sympy.pde` docstring for a list of all supported hints that can be returned from `classify_pde`.

**Examples**

```python
from sympy import classify_pde
from sympy import Function, Eq, x, y
f = Function('f')
u = f(x, y)
ux = u.diff(x)
uy = u.diff(y)
eq = Eq(1 + (2*(ux/u)) + (3*(uy/u)), 0)
classify_pde(eq)
('1st_linear_constant_coeff_homogeneous',)
```

`sympy.solvers.pde.checkpdesol(pde, sol, func=None, solve_for_func=True)`
Checks if the given solution satisfies the partial differential equation.

`pde` is the partial differential equation which can be given in the form of an equation or an expression. `sol` is the solution for which the `pde` is to be checked. This can also be given in an equation or an expression form. If the function is not provided, the helper function `_preprocess` from deutils is used to identify the function.

If a sequence of solutions is passed, the same sort of container will be used to return the result for each solution.

The following methods are currently being implemented to check if the solution satisfies the PDE:

1. Directly substitute the solution in the PDE and check. If the solution has not been solved for f, then it will solve for f provided `solve_for_func` has not been set to False.

If the solution satisfies the PDE, then a tuple (True, 0) is returned. Otherwise a tuple (False, expr) where expr is the value obtained after substituting the solution in the PDE. However if a known solution returns False, it may be due to the inability of `doit()` to simplify it to zero.

**Examples**

```python
from sympy import Function, symbols
from sympy import checkpdesol, pdsolve
x, y = symbols('x y')
f = Function('f')
eq = 2*f(x,y) + 3*f(x,y).diff(x) + 4*f(x,y).diff(y)
sol = pdsolve(eq)
assert checkpdesol(eq, sol)[0]
```
>>> eq = x*f(x,y) + f(x,y).diff(x)
>>> checkpdesol(eq, sol)
(False, (x*F(4*x - 3*y) - 6*F(4*x - 3*y)/25 + 4*Subs(Derivative(F(_xi_1), _xi_1), _xi_1, 4*x - 3*y))*exp(-6*x/25 - 8*y/25))

Hint Methods

These functions are meant for internal use. However they contain useful information on the various solving methods.

`sympy.solvers.pde.pde_1st_linear_constant_coeff_homogeneous(eq, func, order, match, solvefun)`

Solves a first order linear homogeneous partial differential equation with constant coefficients.

The general form of this partial differential equation is

\[ a \frac{\partial f(x, y)}{\partial x} + b \frac{\partial f(x, y)}{\partial y} + cf(x, y) = 0 \]

where \(a\), \(b\) and \(c\) are constants.

The general solution is of the form:

\[ f(x, y) = F(-ay + bx)e^{\frac{-c(ay+bx)}{a^2+b^2}} \]

and can be found in SymPy with `pdsolve`:

```python
>>> from sympy.solvers import pdsolve
>>> from sympy.abc import x, y, a, b, c
>>> f = Function('f')
>>> u = f(x,y)
>>> ux = u.diff(x)
>>> uy = u.diff(y)
>>> genform = a*ux + b*uy + c*u
>>> pprint(genform)
\[\frac{\partial f(x, y)}{\partial x} + \frac{\partial f(x, y)}{\partial y} + cf(x, y)\]

>>> pprint(pdsolve(genform))
\[-c(ay+bx)\]
\[\frac{-c(a^2+b^2)}{a^2+b^2}\]

f(x, y) = F(-ay + bx)*e^{-\frac{c(a^2+b^2)}{a^2+b^2}}
```
Examples

```python
>>> from sympy import pdsolve
>>> from sympy import Function, pprint
>>> from sympy.abc import x, y

>>> f = Function('f')
>>> pdsolve(f(x,y) + f(x,y).diff(x) + f(x,y).diff(y))
Eq(f(x, y), F(x - y)*exp(-x/2 - y/2))
>>> pprint(pdsolve(f(x,y) + f(x,y).diff(x) + f(x,y).diff(y)))
\[ f(x, y) = F(x - y)\cdot e^{-\frac{x}{2} - \frac{y}{2}} \]
```

References

sympy.solvers.pde.pde_1st_linear_constant_coeff(eq, func, order, match, solvefun)
Solves a first order linear partial differential equation with constant coefficients.

The general form of this partial differential equation is

\[
a \frac{\partial f(x, y)}{\partial x} + b \frac{\partial f(x, y)}{\partial y} + cf(x, y) = G(x, y)
\]

where \(a, b\) and \(c\) are constants and \(G(x, y)\) can be an arbitrary function in \(x\) and \(y\).

The general solution of the PDE is:

\[
f(x, y) = \left[ F(\eta) + \frac{1}{a^2 + b^2} \int \frac{a\xi + b\eta}{a^2 + b^2} - \frac{a\eta + b\xi}{a^2 + b^2} e^{-\frac{c\xi}{a^2 + b^2}} d\xi \right] e^{-\frac{c\eta}{a^2 + b^2}}.
\]

where \(F(\eta)\) is an arbitrary single-valued function. The solution can be found in SymPy with pdsolve:

```python
>>> from sympy.solvers import pdsolve
>>> from sympy.abc import x, y, a, b, c

>>> f = Function('f')
>>> G = Function('G')
>>> u = f(x,y)
>>> ux = u.diff(x)
>>> uy = u.diff(y)

>>> genform = a*ux + b*uy + c*u - G(x,y)
>>> pprint(genform)
\[ \frac{\partial f(x, y)}{\partial x} + \frac{\partial f(x, y)}{\partial y} + cf(x, y) - G(x, y) \]

```
(continued from previous page)

\[ f(x, y) = \frac{F(\eta) + \frac{G}{2^2}}{\alpha + \beta} \]

\[
\begin{align*}
\frac{d}{d\xi} & \left( \frac{-c\xi}{\alpha + \beta} \right)
= \frac{1}{\alpha \beta} \left( \frac{2^2}{\alpha + \beta} \right) \eta - a \xi + b \eta
\end{align*}
\]

5.8. Topics
Examples

```python
>>> from sympy.solvers.pde import pdsolve
>>> from sympy import Function, pprint, exp
>>> from sympy.abc import x,y
>>> f = Function('f')
>>> eq = -2*f(x,y).diff(x) + 4*f(x,y).diff(y) + 5*f(x,y) - exp(x + 3*y)
>>> pdsolve(eq)
Eq(f(x, y), (F(4*x + 2*y)*exp(x/2) + exp(x + 4*y)/15)*exp(-y))
```

References

`sistema.solvers.pde.pde_1st_linear_variable_coeff(eq, func, order, match, solvefun)
Solves a first order linear partial differential equation with variable coefficients. The
general form of this partial differential equation is

\[
a(x, y) \frac{\partial f(x, y)}{\partial x} + b(x, y) \frac{\partial f(x, y)}{\partial y} + c(x, y) f(x, y) = G(x, y)
\]

where \(a(x, y), b(x, y), c(x, y)\) and \(G(x, y)\) are arbitrary functions in \(x\) and \(y\). This PDE is
converted into an ODE by making the following transformation:

1. \(\xi\) as \(x\)
2. \(\eta\) as the constant in the solution to the differential equation \(\frac{du}{d\xi} = -\frac{1}{a}\)

Making the previous substitutions reduces it to the linear ODE

\[
a(\xi, \eta) \frac{du}{d\xi} + c(\xi, \eta)u - G(\xi, \eta) = 0
\]

which can be solved using dsolve.

```python
>>> from sympy.abc import x, y
>>> from sympy import Function, pprint
>>> a, b, c, G, f= [Function(i) for i in ['a', 'b', 'c', 'G', 'f']]
>>> u = f(x,y)
>>> ux = u.diff(x)
>>> uy = u.diff(y)
>>> genform = a(x, y)*u + b(x, y)*ux + c(x, y)*uy - G(x,y)
>>> pprint(genform)
-G(x, y) + a(x, y)*f(x, y) + b(x, y)*-(f(x, y)) + c(x, y)*-(f(x, y))
```

Chapter 5. API Reference
Examples

```python
>>> from sympy.solvers.pde import pdsolve
>>> from sympy import Function, pprint
>>> from sympy.abc import x,y
>>> f = Function('f')
>>> eq = x*(u.diff(x)) - y*(u.diff(y)) + y**2*u - y**2
>>> pdsolve(eq)
Eq(f(x, y), F(x*y)*exp(y**2/2) + 1)
```

References

Information on the pde module

This module contains pdsolve() and different helper functions that it uses. It is heavily inspired by the ode module and hence the basic infrastructure remains the same.

Functions in this module

These are the user functions in this module:

- **pdsolve()** - Solves PDE’s
- **classify_pde()** - Classifies PDEs into possible hints for dsolve().
- **pde_separate()** - Separate variables in partial differential equation either by additive or multiplicative separation approach.

These are the helper functions in this module:

- **pde_separate_add()** - Helper function for searching additive separable solutions.
- **pde_separate_mul()** - Helper function for searching multiplicative separable solutions.

Currently implemented solver methods

The following methods are implemented for solving partial differential equations. See the docstrings of the various pde_hint() functions for more information on each (run help(pde)):

- 1st order linear homogeneous partial differential equations with constant coefficients.
- 1st order linear general partial differential equations with constant coefficients.
- 1st order linear partial differential equations with variable coefficients.
Solvers

The solvers module in SymPy implements methods for solving equations.

Note: For a beginner-friendly guide focused on solving common types of equations, refer to Solve Equations (page 131).

Note: solve() (page 882) is an older more mature general function for solving many types of equations. solve() (page 882) has many options and uses different methods internally to determine what type of equations you pass it, so if you know what type of equation you are dealing with you may want to use the newer solveset() (page 905) which solves univariate equations, linsolve() (page 919) which solves system of linear equations, and nonlinsolve() (page 921) which solves systems of non-linear equations.

Algebraic equations

Use solve() (page 882) to solve algebraic equations. We suppose all equations are equaled to 0, so solving x**2 == 1 translates into the following code:

```python
>>> from sympy.solvers import solve
>>> from sympy import Symbol
>>> x = Symbol('x')
>>> solve(x**2 - 1, x)
[-1, 1]
```

The first argument for solve() (page 882) is an equation (equaled to zero) and the second argument is the symbol that we want to solve the equation for.

sympy.solvers.solvers.solve(f, *symbols, **flags)

Algebraically solves equations and systems of equations.

Parameters
f:
- a single Expr or Poly that must be zero
- an Equality
- a Relational expression
- a Boolean
- iterable of one or more of the above

symbols : (object(s) to solve for) specified as
- none given (other non-numeric objects will be used)
- single symbol
- denested list of symbols (e.g., solve(f, x, y))
- ordered iterable of symbols (e.g., solve(f, [x, y]))

flags :
dict=True (default is False)
   Return list (perhaps empty) of solution mappings.

set=True (default is False)
   Return list of symbols and set of tuple(s) of solution(s).

exclude=[] (default)
   Do not try to solve for any of the free symbols in exclude; if expres-
sions are given, the free symbols in them will be extracted automatic-
ically.

check=True (default)
   If False, do not do any testing of solutions. This can be useful if you
   want to include solutions that make any denominator zero.

numerical=True (default)
   Do a fast numerical check if f has only one symbol.

minimal=True (default is False)
   A very fast, minimal testing.

warn=True (default is False)
   Show a warning if checksol() could not conclude.

simplify=True (default)
   Simplify all but polynomials of order 3 or greater before returning
   them and (if check is not False) use the general simplify function
   on the solutions and the expression obtained when they are substi-
tuted into the function which should be zero.

force=True (default is False)
   Make positive all symbols without assumptions regarding sign.

rational=True (default)
   Recast Floats as Rational; if this option is not used, the system con-
taining Floats may fail to solve because of issues with polys. If ra-
tional=None, Floats will be recast as rationals but the answer will
   be recast as Floats. If the flag is False then nothing will be done to
   the Floats.

manual=True (default is False)
   Do not use the polys/matrix method to solve a system of equations,
   solve them one at a time as you might “manually.”

implicit=True (default is False)
   Allows solve to return a solution for a pattern in terms of other
   functions that contain that pattern; this is only needed if the pattern
   is inside of some invertible function like cos, exp, ect.

particular=True (default is False)
   Instructs solve to try to find a particular solution to a linear system
   with as many zeros as possible; this is very expensive.

quick=True (default is False; particular must be True)
   Selects a fast heuristic to find a solution with many zeros whereas
   a value of False uses the very slow method guaranteed to find the
   largest number of zeros possible.

cubics=True (default)
   Return explicit solutions when cubic expressions are encountered.
   When False, quartics and quintics are disabled, too.
quartics=True (default)
Return explicit solutions when quartic expressions are encountered. When False, quintics are disabled, too.

quintics=True (default)
Return explicit solutions (if possible) when quintic expressions are encountered.

Explanation

Currently supported:
• polynomial
• transcendental
• piecewise combinations of the above
• systems of linear and polynomial equations
• systems containing relational expressions
• systems implied by undetermined coefficients

Examples

The default output varies according to the input and might be a list (possibly empty), a dictionary, a list of dictionaries or tuples, or an expression involving relationals. For specifics regarding different forms of output that may appear, see Solve Output by Type (page 204). Let it suffice here to say that to obtain a uniform output from solve use dict=True or set=True (see below).

```python
>>> from sympy import solve, Poly, Eq, Matrix, Symbol
>>> from sympy.abc import x, y, z, a, b
```

The expressions that are passed can be Expr, Equality, or Poly classes (or lists of the same); a Matrix is considered to be a list of all the elements of the matrix:

```python
>>> solve(x - 3, x)
[3]
>>> solve(Eq(x, 3), x)
[3]
>>> solve(Poly(x - 3), x)
[3]
>>> solve(Matrix([[x, x + y]]), x, y) == solve([x, x + y], x, y)
True
```

If no symbols are indicated to be of interest and the equation is univariate, a list of values is returned; otherwise, the keys in a dictionary will indicate which (of all the variables used in the expression(s)) variables and solutions were found:

```python
>>> solve(x**2 - 4)
[-2, 2]
>>> solve((x - a)*(y - b))
[{a: x}, {b: y}]
```

(continues on next page)
If you pass symbols for which solutions are sought, the output will vary depending on the number of symbols you passed, whether you are passing a list of expressions or not, and whether a linear system was solved. Uniform output is attained by using dict=True or set=True.

```python
>>> solve([x - 3, y - 1])
{x: 3, y: 1}
>>> solve([x - 3, y**2 - 1])
[{x: 3, y: -1}, {x: 3, y: 1}]
```

If any equation does not depend on the symbol(s) given, it will be eliminated from the equation set and an answer may be given implicitly in terms of variables that were not of interest:

```python
>>> solve([x - y, y - 3], x)
{x: y}
```

When you pass all but one of the free symbols, an attempt is made to find a single solution based on the method of undetermined coefficients. If it succeeds, a dictionary of values is returned. If you want an algebraic solutions for one or more of the symbols, pass the

```python
>>> solve([x - y, y - 3], x)
{x: y}
```
expression to be solved in a list:

```python
>>> e = a*x + b - 2*x - 3
>>> solve(e, [a, b])
{a: 2, b: 3}
>>> solve([e], [a, b])
{a: -b/x + (2*x + 3)/x}
```

When there is no solution for any given symbol which will make all expressions zero, the empty list is returned (or an empty set in the tuple when set=True):

```python
>>> from sympy import sqrt
>>> solve(3, x)
[]
>>> solve(x - 3, y)
[]
>>> solve(sqrt(x) + 1, x, set=True)
([x], set())
```

When an object other than a Symbol is given as a symbol, it is isolated algebraically and an implicit solution may be obtained. This is mostly provided as a convenience to save you from replacing the object with a Symbol and solving for that Symbol. It will only work if the specified object can be replaced with a Symbol using the `subs` method:

```python
>>> from sympy import exp, Function
>>> f = Function('f')
>>> solve(f(x) - x, f(x))
[x]
>>> solve(f(x).diff(x) - f(x) - x, f(x).diff(x))
[x + f(x)]
>>> solve(f(x).diff(x) - f(x) - x, f(x))
[-x + Derivative(f(x), x)]
>>> solve(x + exp(x)**2, exp(x), set=True)
[(-exp(x),), (sqrt(-x),), (-sqrt(-x),)]
```

```python
>>> from sympy import Indexed, IndexedBase, Tuple
>>> A = IndexedBase('A')
>>> solve(eqs, eqs.atoms(Indexed))
{A[1]: 1, A[2]: 2}
```

- To solve for a function within a derivative, use `dsolve()` (page 807).

To solve for a symbol implicitly, use `implicit=True`:

```python
>>> solve(x + exp(x), x)
[-LambertW(1)]
>>> solve(x + exp(x), x, implicit=True)
[-exp(x)]
```

It is possible to solve for anything in an expression that can be replaced with a symbol using `subs` (page 993):
```
>>> solve(x + 2 + sqrt(3), x + 2)
[-sqrt(3)]
>>> solve((x + 2 + sqrt(3), x + 4 + y), y, x + 2)
{y: -2 + sqrt(3), x + 2: -sqrt(3)}
• Nothing heroic is done in this implicit solving so you may end up with a
  symbol still in the solution:
  >>> eqs = (x*y + 3*y + sqrt(3), x + 4 + y)
  >>> solve(eqs, y, x + 2)
  {y: -sqrt(3)/(x + 3), x + 2: -2*x/(x + 3) - 6/(x + 3) + \n  sqrt(3)/(x + 3)}
  >>> solve(eqs, y*x, x)
  {x: -y - 4, x*y: -3*y - sqrt(3)}
• If you attempt to solve for a number, remember that the number you have
  obtained does not necessarily mean that the value is equivalent to the ex-
  pression obtained:
  >>> solve(sqrt(2) - 1, 1)
  [sqrt(2)]
  >>> solve(x - y + 1, 1)  # !/\ -1 is targeted, too
  [x/(y - 1)]
  >>> [_.subs(z, -1) for _ in solve((x - y + 1).subs(-1, z), 1)]
  [-x + y]
```

**Additional Examples**

`solve()` with `check=True` (default) will run through the symbol tags to eliminate un-
wanted solutions. If no assumptions are included, all possible solutions will be returned:

```
>>> x = Symbol("x")
>>> solve(x**2 - 1)
[-1, 1]
```

By setting the `positive` flag, only one solution will be returned:

```
>>> pos = Symbol("pos", positive=True)
>>> solve(pos**2 - 1)
[1]
```

When the solutions are checked, those that make any denominator zero are automatically
excluded. If you do not want to exclude such solutions, then use the `check=False` option:

```
>>> from sympy import sin, limit
>>> solve(sin(x)/x)  # 0 is excluded
[pi]
```

If `check=False`, then a solution to the numerator being zero is found but the value of
\( x = 0 \) is a spurious solution since \( \sin(x)/x \) has the well known limit (without discontinuity)
of \( 1 \) at \( x = 0 \):

```
>>> solve(sin(x)/x, check=False)
[0, pi]
```
In the following case, however, the limit exists and is equal to the value of $x = 0$ that is excluded when `check=True`:

```python
>>> eq = x**2*(1/x - z**2/x)
>>> solve(eq, x)
[]
>>> solve(eq, x, check=False)
[0]
>>> limit(eq, x, 0, '-')
0
>>> limit(eq, x, 0, '+')
0
```

**Solving Relationships**

When one or more expressions passed to `solve` is a relational, a relational result is returned (and the `dict` and `set` flags are ignored):

```python
>>> solve(x < 3)
(-oo < x) & (x < 3)
>>> solve([x < 3, x**2 > 4], x)
((-oo < x) & (x < -2)) | ((2 < x) & (x < 3))
>>> solve([x + y - 3, x > 3], x)
(3 < x) & (x < oo) & Eq(x, 3 - y)
```

Although checking of assumptions on symbols in relationals is not done, setting assumptions will affect how certain relationals might automatically simplify:

```python
>>> solve(x**2 > 4)
((-oo < x) & (x < -2)) | ((2 < x) & (x < oo))
```

```python
>>> r = Symbol('r', real=True)
>>> solve(r**2 > 4)  # (2 < r) | (r < -2)
```

There is currently no algorithm in SymPy that allows you to use relationships to resolve more than one variable. So the following does not determine that $q < 0$ (and trying to solve for $r$ and $q$ will raise an error):

```python
>>> from sympy import symbols
>>> r, q = symbols('r, q', real=True)
>>> solve([r + q - 3, r > 3], r)  # (3 < r) & Eq(r, 3 - q)
```

You can directly call the routine that `solve` calls when it encounters a relational: `reduce_inequalities()` (page 805). It treats `Expr` like `Equality`.

```python
>>> from sympy import reduce_inequalities
>>> reduce_inequalities([x**2 - 4])  # Eq(x, -2) | Eq(x, 2)
```

If each relationship contains only one symbol of interest, the expressions can be processed for multiple symbols:
But an error is raised if any relationship has more than one symbol of interest:

```python
>>> reduce_inequalities([0 <= x*y - 1, y < 3], [x, y])
Traceback (most recent call last):
  ... errors.NotImplementedError;
  inequality has more than one symbol of interest.
```

### Disabling High-Order Explicit Solutions

When solving polynomial expressions, you might not want explicit solutions (which can be quite long). If the expression is univariate, `CRootOf` instances will be returned instead:

```python
>>> solve(x**3 - x + 1)
[-1/((-1/2 - sqrt(3)*I/2)*(3*sqrt(69)/2 + 27/2)**(1/3)) -
(-1/2 - sqrt(3)*I/2)*(3*sqrt(69)/2 + 27/2)**(1/3)/3,
(-1/2 + sqrt(3)*I/2)*(3*sqrt(69)/2 + 27/2)**(1/3)/3 -
1/((-1/2 + sqrt(3)*I/2)*(3*sqrt(69)/2 + 27/2)**(1/3)),
-(3*sqrt(69)/2 + 27/2)**(1/3)/3 -
1/(3*sqrt(69)/2 + 27/2)**(1/3)]
```

If the expression is multivariate, no solution might be returned:

```python
>>> solve(x**3 - x + a, x, cubics=False)
[]
```

Sometimes solutions will be obtained even when a flag is False because the expression could be factored. In the following example, the equation can be factored as the product of a linear and a quadratic factor so explicit solutions (which did not require solving a cubic expression) are obtained:

```python
>>> eq = x**3 + 3*x**2 + x - 1
>>> solve(eq, cubics=False)
[-1, -1 + sqrt(2), -sqrt(2) - 1]
```

### Solving Equations Involving Radicals

Because of SymPy’s use of the principle root, some solutions to radical equations will be missed unless check=False:

```python
>>> from sympy import root
>>> eq = root(x**3 - 3*x**2, 3) + 1 - x
>>> solve(eq)
[]
>>> solve(eq, check=False)
[1/3]
```

In the above example, there is only a single solution to the equation. Other expressions
will yield spurious roots which must be checked manually; roots which give a negative argument to odd-powered radicals will also need special checking:

```python
>>> from sympy import real_root, S
>>> eq = real_root(x, 3) - real_root(x, 5) + S(1)/7
>>> solve(eq)  # this gives 2 solutions but misses a 3rd
[CRootOf(7*x**5 - 7*x**3 + 1, 1)**15,
 CRootOf(7*x**5 - 7*x**3 + 1, 2)**15]
>>> sol = solve(eq, check=False)
>>> [abs(eq.subs(x,i).n(2)) for i in sol]
[0.48, 0.e-110, 0.e-110, 0.052, 0.052]
```

The first solution is negative so `real_root` must be used to see that it satisfies the expression:

```python
>>> abs(real_root(eq.subs(x, sol[0])).n(2))
0.e-110
```

If the roots of the equation are not real then more care will be necessary to find the roots, especially for higher order equations. Consider the following expression:

```python
>>> expr = real_root(x, 3) - real_root(x, 5)
```

We will construct a known value for this expression at $x = 3$ by selecting the 1-th root for each radical:

```python
>>> expr1 = real_root(x, 3, 1) - real_root(x, 5, 1)
>>> v = expr1.subs(x, -3)
```

The `solve` function is unable to find any exact roots to this equation:

```python
>>> eq = Eq(expr, v); eq1 = Eq(expr1, v)
>>> solve(eq, check=False), solve(eq1, check=False)
([], [])
```

The function `unrad`, however, can be used to get a form of the equation for which numerical roots can be found:

```python
>>> from sympy.solvers import unrad
>>> from sympy import nroots

>>> e, (p, cov) = unrad(eq)
>>> pvals = nroots(e)
>>> inversion = solve(cov, x)[0]
>>> xvals = [inversion.subs(p, i) for i in pvals]
```

Although `eq` or `eq1` could have been used to find `xvals`, the solution can only be verified with `expr1`:

```python
>>> z = expr - v
>>> [xi.n(chop=1e-9) for xi in xvals if abs(z.subs(x, xi).n()) < 1e-9]
[]
>>> z1 = expr1 - v
>>> [xi.n(chop=1e-9) for xi in xvals if abs(z1.subs(x, xi).n()) < 1e-9]
[-3.0]
```

See also:
**rsolve (page 900)**
For solving recurrence relationships

**dsolve (page 807)**
For solving differential equations

```python
sympy.solvers.solvers.solve_linear(lhs, rhs=0, symbols=[], exclude=[])```

Return a tuple derived from \( f = \text{lhs} - \text{rhs} \) that is one of the following: \((0, 1), (0, 0), (\text{symbol}, \text{solution}), (n, d)\).

**Explanation**

\((0, 1)\) meaning that \( f \) is independent of the symbols in \( \text{symbols} \) that are not in \( \text{exclude} \).

\((0, 0)\) meaning that there is no solution to the equation amongst the symbols given. If the first element of the tuple is not zero, then the function is guaranteed to be dependent on a symbol in \( \text{symbols} \).

\((\text{symbol}, \text{solution})\) where symbol appears linearly in the numerator of \( f \), is in \( \text{symbols} \) (if given), and is not in \( \text{exclude} \) (if given). No simplification is done to \( f \) other than a \text{mul=True} expansion, so the solution will correspond strictly to a unique solution.

\((n, d)\) where \( n \) and \( d \) are the numerator and denominator of \( f \) when the numerator was not linear in any symbol of interest; \( n \) will never be a symbol unless a solution for that symbol was found (in which case the second element is the solution, not the denominator).

**Examples**

```python
>>> from sympy import cancel, Pow

f is independent of the symbols in \( \text{symbols} \) that are not in \( \text{exclude} \):

```
If the numerator of the expression is a symbol, then \((0, 0)\) is returned if the solution for that symbol would have set any denominator to 0:

```python
>>> eq = 1/(1/x - 2)
>>> eq.as_numer_denom()
(x, 1 - 2*x)
>>> solve_linear(eq)
(0, 0)
```

But automatic rewriting may cause a symbol in the denominator to appear in the numerator so a solution will be returned:

```python
>>> (1/x)**-1
x
>>> solve_linear((1/x)**-1)
(x, 0)
```

Use an unevaluated expression to avoid this:

```python
>>> solve_linear(Pow(1/x, -1, evaluate=False))
(0, 0)
```

If \(x\) is allowed to cancel in the following expression, then it appears to be linear in \(x\), but this sort of cancellation is not done by `solve_linear` so the solution will always satisfy the original expression without causing a division by zero error.

```python
>>> eq = x**2*(1/x - z**2/x)
>>> solve_linear(cancel(eq))
(x, 0)
>>> solve_linear(eq)
(x**2*(1 - z**2), x)
```

A list of symbols for which a solution is desired may be given:

```python
>>> solve_linear(x + y + z, symbols=[y])
(y, -x - z)
```

A list of symbols to ignore may also be given:

```python
>>> solve_linear(x + y + z, exclude=[x])
(y, -x - z)
```

(A solution for \(y\) is obtained because it is the first variable from the canonically sorted list of symbols that had a linear solution.)

```python
sympy.solvers.solvers.solve_linear_system(system, *symbols, **flags)
```

Solve system of \(N\) linear equations with \(M\) variables, which means both under- and overdetermined systems are supported.
Explanation

The possible number of solutions is zero, one, or infinite. Respectively, this procedure will return None or a dictionary with solutions. In the case of underdetermined systems, all arbitrary parameters are skipped. This may cause a situation in which an empty dictionary is returned. In that case, all symbols can be assigned arbitrary values.

Input to this function is a $N \times M + 1$ matrix, which means it has to be in augmented form. If you prefer to enter $N$ equations and $M$ unknowns then use solve(Neqs, *Msymbols) instead. Note: a local copy of the matrix is made by this routine so the matrix that is passed will not be modified.

The algorithm used here is fraction-free Gaussian elimination, which results, after elimination, in an upper-triangular matrix. Then solutions are found using back-substitution. This approach is more efficient and compact than the Gauss-Jordan method.

Examples

```python
>>> from sympy import Matrix, solve_linear_system
>>> from sympy.abc import x, y

Solve the following system:

\[
\begin{align*}
x + 4y &= 2 \\
-2x + y &= 14
\end{align*}
\]

```python
>>> system = Matrix((
    (1, 4, 2),
    (-2, 1, 14)
))
>>> solve_linear_system(system, x, y)
{x: -6, y: 2}
```

A degenerate system returns an empty dictionary:

```python
>>> system = Matrix((
    (0, 0, 0),
    (0, 0, 0)
))
>>> solve_linear_system(system, x, y)
{}
```

```python
sympy.solvers.solvers.solve_linear_system_LU(matrix, syms)
```

Solves the augmented matrix system using LUsolve and returns a dictionary in which solutions are keyed to the symbols of `syms` as ordered.

Explanation

The matrix must be invertible.
Examples

```python
>>> from sympy import Matrix, solve_linear_system_LU
>>> from sympy.abc import x, y, z

>>> solve_linear_system_LU(Matrix([[1, 2, 0, 1],
... [3, 2, 2, 1],
... [2, 0, 0, 1]]), [x, y, z])
{x: 1/2, y: 1/4, z: -1/2}
```

See also:

* `LUsolve` (page 1328)

`sympy.solvers.solvers.solve_undetermined_coeffs(equ, coeffs, *syms, **flags)`

Solve a system of equations in $k$ parameters that is formed by matching coefficients in variables `coeffs` that are on factors dependent on the remaining variables (or those given explicitly by `syms`).

**Explanation**

The result of this function is a dictionary with symbolic values of those parameters with respect to coefficients in $q$ - empty if there is no solution or coefficients do not appear in the equation - else None (if the system was not recognized). If there is more than one solution, the solutions are passed as a list. The output can be modified using the same semantics as for `solve` since the flags that are passed are sent directly to `solve` so, for example the flag `dict=True` will always return a list of solutions as dictionaries.

This function accepts both Equality and Expr class instances. The solving process is most efficient when symbols are specified in addition to parameters to be determined, but an attempt to determine them (if absent) will be made. If an expected solution is not obtained (and symbols were not specified) try specifying them.

**Examples**

```python
>>> from sympy import Eq, solve_undetermined_coeffs
>>> from sympy.abc import a, b, c, h, p, k, x, y

>>> solve_undetermined_coeffs(Eq(a*x + a + b, x/2), [a, b], x)
{a: 1/2, b: -1/2}
>>> solve_undetermined_coeffs(a - 2, [a])
{a: 2}
```

The equation can be nonlinear in the symbols:

```python
>>> X, Y, Z = y, x**y, y*x**y
>>> eq = a*X + b*Y + c*Z - X - 2*Y - 3*Z
>>> coeffs = a, b, c
>>> syms = x, y
>>> solve_undetermined_coeffs(eq, coeffs, syms)
{a: 1, b: 2, c: 3}
```
And the system can be nonlinear in coefficients, too, but if there is only a single solution, it will be returned as a dictionary:

```python
>>> eq = a*x**2 + b*x + c - ((x - h)**2 + 4*p*k)/4/p
>>> solve_undetermined_coeffs(eq, (h, p, k), x)
{h: -b/(2*a), k: (4*a*c - b**2)/(4*a), p: 1/(4*a)}
```

Multiple solutions are always returned in a list:

```python
>>> solve_undetermined_coeffs(a**2*x + b - x, [a, b], x)
\[\{a: -1, b: 0\}, \{a: 1, b: 0\}\]
```

Using flag `dict=True` (in keeping with semantics in `solve()` (page 882)) will force the result to always be a list with any solutions as elements in that list.

```python
>>> solve_undetermined_coeffs(a*x - 2*x, [a], dict=True)
\[\{a: 2\}\]
```

**sympy.solvers.solvers.nsolve(**`*args, dict=False, **kwargs`**)

Solve a nonlinear equation system numerically: `nsolve(f, [args], x0, modules=['mpmath'], **kwargs)`.

**Explanation**

`f` is a vector function of symbolic expressions representing the system. `args` are the variables. If there is only one variable, this argument can be omitted. `x0` is a starting vector close to a solution.

Use the modules keyword to specify which modules should be used to evaluate the function and the Jacobian matrix. Make sure to use a module that supports matrices. For more information on the syntax, please see the docstring of lambdify.

If the keyword arguments contain `dict=True` (default is False) `nsolve` will return a list (perhaps empty) of solution mappings. This might be especially useful if you want to use `nsolve` as a fallback to solve since using the dict argument for both methods produces return values of consistent type structure. Please note: to keep this consistent with `solve`, the solution will be returned in a list even though `nsolve` (currently at least) only finds one solution at a time.

Overdetermined systems are supported.

**Examples**

```python
>>> from sympy import Symbol, nsolve
>>> import mpmath
>>> mpmath.mp.dps = 15
>>> x1 = Symbol('x1')
>>> x2 = Symbol('x2')
>>> f1 = 3 * x1**2 - 2 * x2**2 - 1
>>> f2 = x1**2 - 2 * x1 + x2**2 + 2 * x2 - 8
>>> print(nsolve((f1, f2), (x1, x2), (-1, 1)))
Matrix([[\[-1.19287309935246\], \[1.27844411169911\]]])
```
For one-dimensional functions the syntax is simplified:

```python
>>> from sympy import sin, nsolve
>>> from sympy.abc import x

>>> nsolve(sin(x), x, 2)
3.14159265358979
>>> nsolve(sin(x), 2)
3.14159265358979
```

To solve with higher precision than the default, use the prec argument:

```python
>>> from sympy import cos

>>> nsolve(cos(x) - x, 1)
0.739085133215161
>>> nsolve(cos(x) - x, 1, prec=50)
0.73908513321516064165531208767387340401341175890076

>>> cos(_)
0.73908513321516064165531208767387340401341175890076
```

To solve for complex roots of real functions, a nonreal initial point must be specified:

```python
>>> from sympy import I

>>> nsolve(x**2 + 2, I)
1.4142135623731*I
```

`mpmath.findroot` is used and you can find their more extensive documentation, especially concerning keyword parameters and available solvers. Note, however, that functions which are very steep near the root, the verification of the solution may fail. In this case you should use the flag verify=False and independently verify the solution.

```python
>>> from sympy import cos, cosh

>>> f = cos(x)*cosh(x) - 1
>>> nsolve(f, 3.14*100)
Traceback (most recent call last):
...
ValueError: Could not find root within given tolerance. (1.39267e+230 > 2.1684e-19)
>>> ans = nsolve(f, 3.14*100, verify=False); ans
312.588469032184
>>> f.subs(x, ans).n(2)
2.1e+121
>>> (f/f.diff(x)).subs(x, ans).n(2)
7.4e-15
```

One might safely skip the verification if bounds of the root are known and a bisection method is used:

```python
>>> bounds = lambda i: (3.14*i, 3.14*(i + 1))
>>> nsolve(f, bounds(100), solver='bisect', verify=False)
315.730061685774
```

Alternatively, a function may be better behaved when the denominator is ignored. Since this is not always the case, however, the decision of what function to use is left to the discretion of the user.
sympy.solvers.solvers.checksol(f, symbol, sol=None, **flags)

Checks whether sol is a solution of equation \( f = 0 \).

**Explanation**

Input can be either a single symbol and corresponding value or a dictionary of symbols and values. When given as a dictionary and flag simplify=True, the values in the dictionary will be simplified. \( f \) can be a single equation or an iterable of equations. A solution must satisfy all equations in \( f \) to be considered valid; if a solution does not satisfy any equation, False is returned; if one or more checks are inconclusive (and none are False) then None is returned.

**Examples**

```python
>>> from sympy import checksol, symbols
>>> x, y = symbols('x,y')
>>> checksol(x**4 - 1, x, 1)
True
>>> checksol(x**4 - 1, x, 0)
False
>>> checksol(x**2 + y**2 - 5**2, {x: 3, y: 4})
True
```

To check if an expression is zero using checksol(), pass it as \( f \) and send an empty dictionary for symbol:

```python
>>> checksol(x**2 + x - x*(x + 1), {})
True
```

None is returned if checksol() could not conclude.

**flags:**

- **numerical=True (default)**
  - do a fast numerical check if \( f \) has only one symbol.

- **minimal=True (default is False)**
  - a very fast, minimal testing.

- **warn=True (default is False)**
  - show a warning if checksol() could not conclude.
‘simplify=True (default)’
simplify solution before substituting into function and simplify the function before trying specific simplifications

‘force=True (default is False)’
make positive all symbols without assumptions regarding sign.

```python
sympy.solvers.solvers.unrad(eq, *syms, **flags)
```
Remove radicals with symbolic arguments and return (eq, cov), None, or raise an error.

**Explanation**

None is returned if there are no radicals to remove.

NotImplementedError is raised if there are radicals and they cannot be removed or if the relationship between the original symbols and the change of variable needed to rewrite the system as a polynomial cannot be solved.

Otherwise the tuple, (eq, cov), is returned where:

**eq, cov**
- eq is an equation without radicals (in the symbol(s) of interest) whose solutions are a superset of the solutions to the original equation. eq might be rewritten in terms of a new variable; the relationship to the original variables is given by cov which is a list containing v and v**p - b where p is the power needed to clear the radical and b is the radical now expressed as a polynomial in the symbols of interest. For example, for sqrt(2 - x) the tuple would be (c, c**2 - 2 + x). The solutions of eq will contain solutions to the original equation (if there are any).

**syms**
- An iterable of symbols which, if provided, will limit the focus of radical removal: only radicals with one or more of the symbols of interest will be cleared. All free symbols are used if syms is not set.

**flags** are used internally for communication during recursive calls. Two options are also recognized:
- take, when defined, is interpreted as a single-argument function that returns True if a given Pow should be handled.

Radicals can be removed from an expression if:

- All bases of the radicals are the same; a change of variables is done in this case.
- If all radicals appear in one term of the expression.
- There are only four terms with sqrt() factors or there are less than four terms having sqrt() factors.
- There are only two terms with radicals.
Examples

```python
>>> from sympy.solvers.solvers import unrad
>>> from sympy import x
>>> from sympy import sqrt, Rational, root

>>> unrad(sqrt(x)*x**Rational(1, 3) + 2)
(x**5 - 64, [])
>>> unrad(sqrt(x) + root(x + 1, 3))
(-x**3 + x**2 + 2*x + 1, [])
>>> eq = sqrt(x) + root(x, 3) - 2
>>> unrad(eq)
(_p**3 + _p**2 - 2, [_p, _p**6 - x])
```

Ordinary Differential equations (ODEs)

See *ODE* (page 807).

Partial Differential Equations (PDEs)

See *PDE* (page 872).

Deutils (Utilities for solving ODE's and PDE's)

`sympy.solvers.deutils.ode_order(expr, func)`

Returns the order of a given differential equation with respect to func.

This function is implemented recursively.

Examples

```python
>>> from sympy import Function
>>> from sympy.solvers.deutils import ode_order
>>> from sympy import x
>>> f, g = map(Function, ['f', 'g'])
>>> ode_order(f(x).diff(x, 2) + f(x).diff()**2 +
... f(x).diff(), f(x))
2
>>> ode_order(f(x).diff(x, 2) + g(x).diff(x, 3), f(x))
2
>>> ode_order(f(x).diff(x, 2) + g(x).diff(x, 3), g(x))
3
```
SymPy Documentation, Release 1.12.1

Recurrence Equations

**sympy.solvers.recurr.rsolve**(*f, y, init=None*)

Solve univariate recurrence with rational coefficients.

Given k-th order linear recurrence \( L_y = f \), or equivalently:

\[
a_k(n)y(n + k) + a_{k-1}(n)y(n + k - 1) + \cdots + a_0(n)y(n) = f(n)
\]

where \( a_i(n) \), for \( i = 0, \ldots, k \), are polynomials or rational functions in \( n \), and \( f \) is a hypergeometric function or a sum of a fixed number of pairwise dissimilar hypergeometric terms in \( n \), finds all solutions or returns \( \text{None} \), if none were found.

Initial conditions can be given as a dictionary in two forms:

1. \( \{ n_0 : v_0, n_1 : v_1, \ldots, n_m : v_m \} \)
2. \( \{ y(n_0) : v_0, y(n_1) : v_1, \ldots, y(n_m) : v_m \} \)

or as a list \( L \) of values:

\[
L = [v_0, v_1, \ldots, v_m]
\]

where \( L[i] = v_i \), for \( i = 0, \ldots, m \), maps to \( y(n_i) \).

**Examples**

Lets consider the following recurrence:

\[
(n-1)y(n+2) - (n^2 + 3n - 2)y(n+1) + 2n(n+1)y(n) = 0
\]

```python
>>> from sympy import Function, rsolve
>>> from sympy.abc import n
>>> y = Function('y')

>>> f = (n - 1)*y(n + 2) - (n**2 + 3*n - 2)*y(n + 1) + 2*n*(n + 1)*y(n)

>>> rsolve(f, y(n))
2**n*C0 + C1*factorial(n)

>>> rsolve(f, y(n), {y(0):0, y(1):3})
3*2**n - 3*factorial(n)
```

See also:

- **rsolve_poly** (page 900), **rsolve_ratio** (page 901), **rsolve_hyper** (page 902)

**sympy.solvers.recurr.rsolve_poly**(*coeffs, f, n, shift=0, **hints*)

Given linear recurrence operator \( L \) of order \( k \) with polynomial coefficients and inhomogeneous equation \( L_y = f \), where \( f \) is a polynomial, we seek for all polynomial solutions over field \( K \) of characteristic zero.

The algorithm performs two basic steps:

1. Compute degree \( N \) of the general polynomial solution.
2. Find all polynomials of degree \( N \) or less of \( L_y = f \).
There are two methods for computing the polynomial solutions. If the degree bound is relatively small, i.e. it’s smaller than or equal to the order of the recurrence, then naive method of undetermined coefficients is being used. This gives a system of algebraic equations with $N + 1$ unknowns.

In the other case, the algorithm performs transformation of the initial equation to an equivalent one for which the system of algebraic equations has only $r$ indeterminates. This method is quite sophisticated (in comparison with the naive one) and was invented together by Abramov, Bronstein and Petkovsek.

It is possible to generalize the algorithm implemented here to the case of linear q-difference and differential equations.

Let’s say that we would like to compute $m$-th Bernoulli polynomial up to a constant. For this we can use $b(n+1) - b(n) = mn^{m-1}$ recurrence, which has solution $b(n) = B_m + C$. For example:

```python
>>> from sympy import Symbol, rsolve_poly
>>> n = Symbol('n', integer=True)

>>> rsolve_poly([-1, 1], 4*n**3, n)
C0 + n**4 - 2*n**3 + n**2
```

References

[R822], [R823], [R824]

`sympy.solvers.recurr.rsolve_ratio(coeffs, f, n, **hints)`

Given linear recurrence operator $L$ of order $k$ with polynomial coefficients and inhomogeneous equation $L\ y = f$, where $f$ is a polynomial, we seek for all rational solutions over field $K$ of characteristic zero.

This procedure accepts only polynomials, however if you are interested in solving recurrence with rational coefficients then use `rsolve` which will pre-process the given equation and run this procedure with polynomial arguments.

The algorithm performs two basic steps:

1. Compute polynomial $v(n)$ which can be used as universal denominator of any rational solution of equation $L\ y = f$.

2. Construct new linear difference equation by substitution $y(n) = u(n)/v(n)$ and solve it for $u(n)$ finding all its polynomial solutions. Return None if none were found.

The algorithm implemented here is a revised version of the original Abramov’s algorithm, developed in 1989. The new approach is much simpler to implement and has better overall efficiency. This method can be easily adapted to the q-difference equations case.

Besides finding rational solutions alone, this function is an important part of Hyper algorithm where it is used to find a particular solution for the inhomogeneous part of a recurrence.
Examples

```python
>>> from sympy import import x
>>> from sympy import import rsolve_ratio
>>> rsolve_ratio([-2*x**3 + x**2 + 2*x - 1, 2*x**3 + x**2 - 6*x,
... - 2*x**3 - 11*x**2 - 18*x - 9, 2*x**3 + 13*x**2 + 22*x + 8], 0, x)
C0*(2*x - 3)/(2*(x**2 - 1))
```

See also:
rsolve_hyper (page 902)

References

[R825]
sympy.solvers.recurr.rsolve_hyper(coefficients, f, n, **hints)

Given linear recurrence operator $L$ of order $k$ with polynomial coefficients and inhomogeneous equation $L_y = f$ we seek for all hypergeometric solutions over field $K$ of characteristic zero.

The inhomogeneous part can be either hypergeometric or a sum of a fixed number of pairwise dissimilar hypergeometric terms.

The algorithm performs three basic steps:

1. Group together similar hypergeometric terms in the inhomogeneous part of $L_y = f$, and find particular solution using Abramov’s algorithm.
2. Compute generating set of $L$ and find basis in it, so that all solutions are linearly independent.
3. Form final solution with the number of arbitrary constants equal to dimension of basis of $L$.

Term $a(n)$ is hypergeometric if it is annihilated by first order linear difference equations with polynomial coefficients or, in simpler words, if consecutive term ratio is a rational function.

The output this procedure is a linear combination of fixed number of hypergeometric terms. However the underlying method can generate larger class of solutions - D’Alembertian terms.

Note also that this method not only computes the kernel of the inhomogeneous equation, but also reduces in to a basis so that solutions generated by this procedure are linearly independent.
Examples

```python
>>> from sympy.solvers import rsolve_hyper
>>> from sympy.abc import x

>>> rsolve_hyper([-1, -1, 1], 0, x)
C0*(1/2 - sqrt(5)/2)**x + C1*(1/2 + sqrt(5)/2)**x

>>> rsolve_hyper([-1, 1], 1 + x, x)
C0 + x*(x + 1)/2
```

Systems of Polynomial Equations

`sympy.solvers.polysys.solve_poly_system(seq, *gens, strict=False, **args)`

Return a list of solutions for the system of polynomial equations or else None.

Parameters

- `seq`: a list/tuple/set
  - Listing all the equations that are needed to be solved
- `gens`: generators
  - generators of the equations in seq for which we want the solutions
- `strict`: a boolean (default is False)
  - if strict is True, NotImplementedError will be raised if the solution is known to be incomplete (which can occur if not all solutions are expressible in radicals)
- `args`: Keyword arguments
  - Special options for solving the equations.

Returns

- List[Tuple]
  - a list of tuples with elements being solutions for the symbols in the order they were passed as gens
- None
  - None is returned when the computed basis contains only the ground.
Examples

```python
>>> from sympy import solve_poly_system
>>> from sympy.abc import x, y

>>> solve_poly_system([x*y - 2*y, 2*y**2 - x**2], x, y)
[(0, 0), (2, -sqrt(2)), (2, sqrt(2))]

>>> solve_poly_system([x**5 - x + y**3, y**2 - 1], x, y, strict=True)
Traceback (most recent call last):
  ... UnsolvableFactorError
```

`sympy.solvers.polysys.solve_triangulated(polys, *gens, **args)`
Solve a polynomial system using Gianni-Kalkbrenner algorithm.

The algorithm proceeds by computing one Groebner basis in the ground domain and then by iteratively computing polynomial factorizations in appropriately constructed algebraic extensions of the ground domain.

**Parameters**
- **polys**: a list/tuple/set
  - Listing all the equations that are needed to be solved
- **gens**: generators
  - generators of the equations in polys for which we want the solutions
- **args**: Keyword arguments
  - Special options for solving the equations

**Returns**
- List[Tuple]
  - A List of tuples. Solutions for symbols that satisfy the equations listed in polys

Examples

```python
>>> from sympy import solve_triangulated
>>> from sympy.abc import x, y, z

>>> F = [x**2 + y + z - 1, x + y**2 + z - 1, x + y + z**2 - 1]

>>> solve_triangulated(F, x, y, z)
[((0, 0, 1), (0, 1, 0), (1, 0, 0))]
```

Inequalities

See Inequality Solvers (page 803)

Solveset

This is the official documentation of the solveset module in solvers. It contains the frequently asked questions about our new module to solve equations.

Note: For a beginner-friendly guide focused on solving common types of equations, refer to Solve Equations (page 131).

What’s wrong with solve():

SymPy already has a pretty powerful solve function. But it has some deficiencies. For example:

1. It doesn’t have a consistent output for various types of solutions It needs to return a lot of types of solutions consistently:
   • Single solution : \( x = 1 \)
   • Multiple solutions: \( x^2 = 1 \)
   • No Solution: \( x^2 + 1 = 0; x \in \mathbb{R} \)
   • Interval of solution: \(|x| = 0\)
   • Infinitely many solutions: \( \sin(x) = 0 \)
   • Multivariate functions with point solutions: \( x^2 + y^2 = 0 \)
   • Multivariate functions with non-point solution: \( x^2 + y^2 = 1 \)
   • System of equations: \( x + y = 1 \) and \( x - y = 0 \)
   • Relational: \( x > 0 \)
   • And the most important case: “We don’t Know”

2. The input API has a lot of parameters and it can be difficult to use.
3. There are cases like finding the maxima and minima of function using critical points where it is important to know if it has returned all the solutions. `solve` does not guarantee this.

**Why `solve set`?**

- `solve set` has an alternative consistent input and output interface: `solve set` returns a set object and a set object takes care of all types of output. For cases where it does not “know” all the solutions a `ConditionSet` with a partial solution is returned. For input it only takes the equation, the variables to solve for and the optional argument `domain` over which the equation is to be solved.
- `solve set` can return infinitely many solutions. For example solving for \( \sin(x) = 0 \) returns \( \{2n\pi | n \in \mathbb{Z}\} \cup \{2n\pi + \pi | n \in \mathbb{Z}\} \), whereas `solve` only returns \( [0, \pi] \).
- There is a clear code level and interface level separation between solvers for equations in the complex domain and the real domain. For example solving \( e^x = 1 \) when \( x \) is to be solved in the complex domain, returns the set of all solutions, that is \( \{2ni\pi | n \in \mathbb{Z}\} \), whereas if \( x \) is to be solved in the real domain then only \( \{0\} \) is returned.

**Why do we use Sets as an output type?**

SymPy has a well developed sets module, which can represent most of the set containers in mathematics such as:

- **FiniteSet** (page 1241)
  
  Represents a finite set of discrete numbers.

- **Interval** (page 1239)
  
  Represents a real interval as a set.

- **ProductSet** (page 1242)
  
  Represents a Cartesian product of sets.

- **ImageSet** (page 1248)
  
  Represents the image of a set under a mathematical function

```python
>>> from sympy import ImageSet, S, Lambda
>>> from sympyabc import x
>>> squares = ImageSet(Lambda(x, x**2), S.Naturals)  # \{x^2 for x in N\}
>>> 4 in squares
True
```

- **ComplexRegion** (page 1251)
  
  Represents the set of all complex numbers in a region in the Argand plane.

- **ConditionSet** (page 1257)
  
  Represents the set of elements, which satisfies a given condition.

Also, the predefined set classes such as:
• **Naturals** (page 1246), \$\mathbb{N}\$
  Represents the natural numbers (or counting numbers), which are all positive integers starting from 1.

• **Naturals0** (page 1247), \$\mathbb{N}_0\$
  Represents the whole numbers, which are all the non-negative integers, inclusive of 0.

• **Integers** (page 1247), \$\mathbb{Z}\$
  Represents all integers: positive, negative and zero.

• **Reals** (page 1248), \$\mathbb{R}\$
  Represents the set of all real numbers.

• **Complexes** (page 1248), \$\mathbb{C}\$
  Represents the set of all complex numbers.

• **EmptySet** (page 1245), \$\emptyset\$
  Represents the empty set.

The above six sets are available as Singletons, like \$\texttt{S.Integers}\$.

It is capable of most of the set operations in mathematics:

• Union
• Intersection
• Complement
• SymmetricDifference

The main reason for using sets as output to solvers is that it can consistently represent many types of solutions. For the single variable case it can represent:

• No solution (by the empty set).
• Finitely many solutions (by \texttt{FiniteSet}).
• Infinitely many solutions, both countably and uncountably infinite solutions (using the \texttt{ImageSet} module).
• Interval
• There can also be bizarre solutions to equations like the set of rational numbers.

No other Python object (list, dictionary, generator, Python sets) provides the flexibility of mathematical sets which our sets module tries to emulate. The second reason to use sets is that they are close to the entities which mathematicians deal with and it makes it easier to reason about them. Set objects conform to Pythonic conventions when possible, i.e., \texttt{x in A} and \texttt{for i in A} both work when they can be computed. Another advantage of using objects closer to mathematical entities is that the user won’t have to “learn” our representation and she can have her expectations transferred from her mathematical experience.

For the multivariate case we represent solutions as a set of points in a \$n\$-dimensional space and a point is represented by a \texttt{FiniteSet} of ordered tuples, which is a point in \$\mathbb{R}^n\$ or \$\mathbb{C}^n\$.

Please note that, the general \texttt{FiniteSet} is unordered, but a \texttt{FiniteSet} with a tuple as its only argument becomes ordered, since a tuple is ordered. So the order in the tuple is mapped to a pre-defined order of variables while returning solutions.
For example:

```python
>>> from sympy import FiniteSet
>>> FiniteSet(1, 2, 3)  # Unordered
{1, 2, 3}
>>> FiniteSet((1, 2, 3))  # Ordered
{(1, 2, 3)}
```

Why not use dicts as output?

Dictionary are easy to deal with programmatically but mathematically they are not very precise and use of them can quickly lead to inconsistency and a lot of confusion. For example:

- There are a lot of cases where we don’t know the complete solution and we may like to output a partial solution, consider the equation $fg = 0$. The solution of this equation is the union of the solution of the following two equations: $f = 0$, $g = 0$. Let’s say that we are able to solve $f = 0$ but solving $g = 0$ isn’t supported yet. In this case we cannot represent partial solution of the given equation $fg = 0$ using dicts. This problem is solved with sets using a `ConditionSet` object:

  \[ sol_f \cup \{x|x \in \mathbb{R} \land g = 0\}, \text{where } sol_f \text{ is the solution of the equation } f = 0. \]

- Using a dict may lead to surprising results like:

  ```python
  - solve(Eq(x**2, 1), x) != solve(Eq(y**2, 1), y)
  ```

  Mathematically, this doesn’t make sense. Using `FiniteSet` here solves the problem.

- It also cannot represent solutions for equations like $|x| < 1$, which is a disk of radius 1 in the Argand Plane. This problem is solved using complex sets implemented as `ComplexRegion`.

**Input API of solveset**

`solveset` has simpler input API, unlike `solve`. It takes a maximum of three arguments:

```python
solveset(equation, variable=None, domain=S.Complexes)
```

**Equation**

The equation to solve.

**Variable**

The variable for which the equation is to be solved.

**Domain**

The domain in which the equation is to be solved.

`solveset` removes the `flags` argument of `solve`, which had made the input API more complicated and output API inconsistent.
What is this domain argument about?

Solveset is designed to be independent of the assumptions on the variable being solved for and instead, uses the domain argument to decide the solver to dispatch the equation to, namely solveset_real or solveset_complex. It's unlike the old solve which considers the assumption on the variable.

```python
>>> from sympy import solveset, S
>>> from sympy.abc import x
>>> solveset(x**2 + 1, x) # domain=S.Complexes is default
{-I, I}
>>> solveset(x**2 + 1, x, domain=S.Reals)
EmptySet
```

What are the general methods employed by solveset to solve an equation?

Solveset uses various methods to solve an equation, here is a brief overview of the methodology:

- The domain argument is first considered to know the domain in which the user is interested to get the solution.

- If the given function is a relational (>=, <=, >, <), and the domain is real, then solve_univariate_inequality and solutions are returned. Solving for complex solutions of inequalities, like \( x^2 < 0 \) is not yet supported.

- Based on the domain, the equation is dispatched to one of the two functions solveset_real or solveset_complex, which solves the given equation in the complex or real domain, respectively.

- If the given expression is a product of two or more functions, like say \( gh = 0 \), then the solution to the given equation is the Union of the solution of the equations \( g = 0 \) and \( h = 0 \), if and only if both \( g \) and \( h \) are finite for a finite input. So, the solution is built up recursively.

- If the function is trigonometric or hyperbolic, the function _solve_real_trig is called, which solves it by converting it to complex exponential form.

- The function is now checked if there is any instance of a Piecewise expression, if it is, then it’s converted to explicit expression and set pairs and then solved recursively.

- The respective solver now tries to invert the equation using the routines invert_real and invert_complex. These routines are based on the concept of mathematical inverse (though not exactly). It reduces the real/complex valued equation \( f(x) = y \) to a set of equations: \( \{g(x) = h_1(y), g(x) = h_2(y), \ldots, g(x) = h_n(y)\} \) where \( g(x) \) is a simpler function than \( f(x) \). There is some work needed to be done in this to find invert of more complex expressions.

- After the invert, the equations are checked for radical or Abs (Modulus), then the method _solve_radical tries to simplify the radical, by removing it using techniques like squaring, cubing etc, and _solve_abs solves nested Modulus by considering the positive and negative variants, iteratively.

- If none of the above method is successful, then methods of polynomial is used as follows:
- The method to solve the rational function, _solve_as_rational, is called. Based on the domain, the respective poly solver _solve_as_poly_real or _solve_as_poly_complex is called to solve f as a polynomial.

- The underlying method _solve_as_poly solves the equation using polynomial techniques if it’s already a polynomial equation or, with a change of variables, can be made so.

- The final solution set returned by solveset is the intersection of the set of solutions found above and the input domain.

How do we manipulate and return an infinite solution?

- In the real domain, we use our ImageSet class in the sets module to return infinite solutions. ImageSet is an image of a set under a mathematical function. For example, to represent the solution of the equation \( \sin(x) = 0 \), we can use the ImageSet as:

```python
>>> from sympy import ImageSet, Lambda, pi, S, Dummy, pprint
>>> n = Dummy('n')
>>> pprint(ImageSet(Lambda(n, 2*pi*n), S.Integers), use_unicode=True)
{2⋅n⋅π │ n ∊ ℤ}
```

Where \( n \) is a dummy variable. It is basically the image of the set of integers under the function \( 2\pi n \).

- In the complex domain, we use complex sets, which are implemented as the ComplexRegion class in the sets module, to represent infinite solution in the Argand plane. For example to represent the solution of the equation \( |z| = 1 \), which is a unit circle, we can use the ComplexRegion as:

```python
>>> from sympy import ComplexRegion, FiniteSet, Interval, pi, pprint
>>> pprint(ComplexRegion(FiniteSet(1)*Interval(0, 2*pi), polar=True), use_unicode=True)
{r⋅(i⋅sin(θ) + cos(θ)) │ r, θ ∊ {1} × [0, 2⋅π)}
```

Where the FiniteSet in the ProductSet is the range of the value of \( r \), which is the radius of the circle and the Interval is the range of \( θ \), the angle from the \( x \) axis representing a unit circle in the Argand plane.

Note: We also have non-polar form notation for representing solution in rectangular form. For example, to represent first two quadrants in the Argand plane, we can write the ComplexRegion as:

```python
>>> from sympy import ComplexRegion, Interval, pi, oo, pprint
>>> pprint(ComplexRegion(Interval(-oo, oo)*Interval(0, oo)), use_unicode=True)
{x + y⋅i │ x, y ∊ (-∞, ∞) × [0, ∞)}
```

where the Intervals are the range of \( x \) and \( y \) for the set of complex numbers \( x + iy \).
How does solveset ensure that it is not returning any wrong solution?

Solvers in a Computer Algebra System are based on heuristic algorithms, so it’s usually very hard to ensure 100% percent correctness, in every possible case. However there are still a lot of cases where we can ensure correctness. Solveset tries to verify correctness wherever it can. For example:

Consider the equation $|x| = n$. A naive method to solve this equation would return \{-n, n\} as its solution, which is not correct since \{-n, n\} can be its solution if and only if n is positive. Solveset returns this information as well to ensure correctness.

```python
>>> from sympy import symbols, S, pprint, solveset
>>> x, n = symbols('x, n')
>>> pprint(solveset(abs(x) - n, x, domain=S.Reals), use_unicode=True)
{x │ x ∈ {-n, n} ∧ (n ∈ [0, ∞))}
```

Though, there still a lot of work needs to be done in this regard.

Search based solver and step-by-step solution

Note: This is under Development.

After the introduction of ConditionSet (page 1257), the solving of equations can be seen as set transformations. Here is an abstract view of the things we can do to solve equations.

- Apply various set transformations on the given set.
- Define a metric of the usability of solutions, or a notion of some solutions being better than others.
- Different transformations would be the nodes of a tree.
- Suitable searching techniques could be applied to get the best solution.

ConditionSet gives us the ability to represent unevaluated equations and inequalities in forms like \{x|f(x) = 0; x ∈ S\} and \{x|f(x) > 0; x ∈ S\} but a more powerful thing about ConditionSet is that it allows us to write the intermediate steps as set to set transformation. Some of the transformations are:

- **Composition:** \{x|f(g(x)) = 0; x ∈ S\} ⇒ \{x|g(x) = y; x ∈ S, y ∈ \{z|f(z) = 0; z ∈ S\}\}
- **Polynomial Solver:** \{x|P(x) = 0; x ∈ S\} ⇒ \{x_1, x_2, ..., x_n\} ∩ S, where $x_i$ are roots of $P(x)$.
- **Invert solver:** \{x|f(x) = 0; x ∈ S\} ⇒ \{g(0)| all g such that f(g(x)) = x\}
- **logcombine:** \{x|\log(f(x)) + \log(g(x)); x ∈ S\} ⇒ \{x|\log(f(x),g(x)); x ∈ S\} if $f(x) > 0$ and $g(x) > 0$ ⇒ \{x|\log(f(x)) + \log(g(x)); x ∈ S\} otherwise
- **product solve:** \{x|f(x)g(x) = 0; x ∈ S\} ⇒ \{x|f(x) = 0; x ∈ S\}U\{x|g(x) = 0; x ∈ S\} given $f(x)$ and $g(x)$ are bounded. ⇒ \{x|f(x)g(x) = 0; x ∈ S\}, otherwise

Since the output type is same as the input type any composition of these transformations is also a valid transformation. And our aim is to find the right sequence of compositions (given the atoms) which transforms the given condition set to a set which is not a condition set i.e., FiniteSet, Interval, Set of Integers and their Union,
Intersection, Complement or ImageSet. We can assign a cost function to each set, such that, the more desirable that form of set is to us, the less the value of the cost function. This way our problem is now reduced to finding the path from the initial ConditionSet to the lowest valued set on a graph where the atomic transformations forms the edges.

**How do we deal with cases where only some of the solutions are known?**

Creating a universal equation solver, which can solve each and every equation we encounter in mathematics is an ideal case for solvers in a Computer Algebra System. When cases which are not solved or can only be solved incompletely, a ConditionSet is used and acts as an unevaluated solveset object.

Note that, mathematically, finding a complete set of solutions for an equation is undecidable. See Richardson’s theorem.

ConditionSet is basically a Set of elements which satisfy a given condition. For example, to represent the solutions of the equation in the real domain:

\[(x^2 - 4)(\sin(x) + x)\]

We can represent it as:

\[\{-2, 2\} \cup \{x \in \mathbb{R} \land x + \sin(x) = 0\}\]

**What is the plan for solve and solveset?**

There are still a few things solveset can’t do, which solve can, such as solving nonlinear multivariate & LambertW type equations. Hence, it’s not yet a perfect replacement for solve. As the algorithms in solveset mature, solveset may be able to be used within solve to replace some of its algorithms.

**How are symbolic parameters handled in solveset?**

Solveset is in its initial phase of development, so the symbolic parameters aren’t handled well for all the cases, but some work has been done in this regard to depict our ideology towards symbolic parameters. As an example, consider the solving of \(|x| = n\) for real \(x\), where \(n\) is a symbolic parameter. Solveset returns the value of \(x\) considering the domain of the symbolic parameter \(n\) as well:

\[([0, \infty) \cap \{n\}) \cup ((-\infty, 0] \cap \{-n\})\]

This simply means \(n\) is the solution only when it belongs to the Interval \([0, \infty)\) and \(-n\) is the solution only when \(-n\) belongs to the Interval \((-\infty, 0]\).

There are other cases to address too, like solving \(2^x + (a - 2)\) for \(x\) where \(a\) is a symbolic parameter. As of now, It returns the solution as an intersection with \(\mathbb{R}\), which is trivial, as it doesn’t reveal the domain of \(a\) in the solution.

Recently, we have also implemented a function to find the domain of the expression in a FiniteSet (Intersection with the interval) in which it is not-empty. It is a useful addition for dealing with symbolic parameters. For example:
SymPy Documentation, Release 1.12.1

>>> from sympy import Symbol, FiniteSet, Interval, not_empty_in, √, oo

>>> from sympy.abc import x

>>> not_empty_in(FiniteSet(x/2).intersect(Interval(0, 1)), x)
Interval(0, 2)

>>> not_empty_in(FiniteSet(x, x**2).intersect(Interval(1, 2)), x)
Union(Interval(1, 2), Interval(-√2, -1))

References

Solveset Module Reference

Use solveset() (page 913) to solve equations or expressions (assumed to be equal to 0) for a single variable. Solving an equation like \( x^2 = 1 \) can be done as follows:

```python
>>> from sympy import solveset

>>> from sympy import Symbol, Eq

>>> x = Symbol('x')

>>> solveset(Eq(x**2, 1), x)
{-1, 1}
```

Or one may manually rewrite the equation as an expression equal to 0:

```python
>>> solveset(x**2 - 1, x)
{-1, 1}
```

The first argument for solveset() (page 913) is an expression (equal to zero) or an equation and the second argument is the symbol that we want to solve the equation for.

sympy.solvers.solveset.solveset(f, symbol=None, domain=Complexes)

Solves a given inequality or equation with set as output

**Parameters**

- **f**: Expr or a relational.
  
  The target equation or inequality

- **symbol**: Symbol
  
  The variable for which the equation is solved

- **domain**: Set
  
  The domain over which the equation is solved

**Returns**

Set

A set of values for symbol for which \( f \) is True or is equal to zero. An EmptySet (page 1245) is returned if \( f \) is False or nonzero. A ConditionSet (page 1257) is returned as unsolved object if algorithms to evaluate complete solution are not yet implemented.

solveset claims to be complete in the solution set that it returns.

5.8. Topics 913
SymPy Documentation, Release 1.12.1

Raises

NotImplementedError
The algorithms to solve inequalities in complex domain are not yet implemented.

ValueError
The input is not valid.

RuntimeError
It is a bug, please report to the github issue tracker.

Notes

Python interprets 0 and 1 as False and True, respectively, but in this function they refer to solutions of an expression. So 0 and 1 return the domain and EmptySet, respectively, while True and False return the opposite (as they are assumed to be solutions of relational expressions).

Examples

```python
>>> from sympy import exp, sin, Symbol, pprint, S, Eq
>>> from sympy.solvers.solveset import solveset, solveset_real

• The default domain is complex. Not specifying a domain will lead to the solving of the equation in the complex domain (and this is not affected by the assumptions on the symbol):

  >>> x = Symbol('x')
  >>> pprint(solveset(exp(x) - 1, x), use_unicode=False)
  {2*n*I*pi | n in Integers}

  >>> x = Symbol('x', real=True)
  >>> pprint(solveset(exp(x) - 1, x), use_unicode=False)
  {2*n*I*pi | n in Integers}

• If you want to use solveset to solve the equation in the real domain, provide a real domain. (Using solveset_real does this automatically.)

  >>> R = S.Reals
  >>> x = Symbol('x')
  >>> solveset(exp(x) - 1, x, R)
  {0}
  >>> solveset_real(exp(x) - 1, x)
  {0}

The solution is unaffected by assumptions on the symbol:
```
When a `ConditionSet` (page 1257) is returned, symbols with assumptions that would alter the set are replaced with more generic symbols:

```python
>>> i = Symbol('i', imaginary=True)
>>> solveset(Eq(i**2 + i*sin(i), 1), i, domain=S.Reals)
ConditionSet(_R, Eq(_R**2 + _R*sin(_R) - 1, 0), Reals)
```

- Inequalities can be solved over the real domain only. Use of a complex domain leads to a `NotImplementedError`.

```python
>>> solveset(exp(x) > 1, x, R)
Interval.open(0, oo)
```

See also:

- `solveset_real` (page 915)
  - solver for real domain
- `solveset_complex` (page 915)
  - solver for complex domain

```python
sympy.solvers.solveset.solveset_real(f, symbol)
sympy.solvers.solveset.solveset_complex(f, symbol)
sympy.solvers.solveset.invert_real(f_x, y, x)
    Inverts a real-valued function. Same as `invert_complex()` (page 915), but sets the domain to `S.Reals` before inverting.
sympy.solvers.solveset.invert_complex(f_x, y, x, domain=Complexes)
    Reduce the complex valued equation \( f(x) = y \) to a set of equations

\[
\{ g(x) = h_1(y), g(x) = h_2(y), \ldots, g(x) = h_n(y) \}
\]

where \( g(x) \) is a simpler function than \( f(x) \). The return value is a tuple \( (g(x), \text{set}_h) \), where \( g(x) \) is a function of \( x \) and \( \text{set}_h \) is the set of function \( \{h_1(y), h_2(y), \ldots, h_n(y)\} \). Here, \( y \) is not necessarily a symbol.

\( \text{set}_h \) contains the functions, along with the information about the domain in which they are valid, through set operations. For instance, if \( y = |x| - n \) is inverted in the real domain, then \( \text{set}_h \) is not simply \( \{-n, n\} \) as the nature of \( n \) is unknown; rather, it is:

\[
\{ \text{left}[0, \text{infty} \text{right}) \cap \text{left}[\text{right} \text{right}) \text{cup} \\
\text{left}[-\text{infty}, 0 \text{right}] \text{cap} \text{left}[0, \text{right} \text{right}) \text{cup} \\
\text{left}[-\text{infty}, -n \text{right}) \text{cup} \text{left}[n, \text{right} \text{right}) \text{cup} \}
\]

By default, the complex domain is used which means that inverting even seemingly simple functions like \( \exp(x) \) will give very different results from those obtained in the real domain. (In the case of \( \exp(x) \), the inversion via \( \log \) is multi-valued in the complex domain, having infinitely many branches.)
If you are working with real values only (or you are not sure which function to use) you should probably set the domain to \texttt{S.Reals} (or use \texttt{invert_real} which does that automatically).

**Examples**

```python
>>> from sympy.solvers.solveset import invert_complex, invert_real
>>> from sympy import exp
```

When does \(\exp(x) = y\)?

```python
>>> invert_complex(exp(x), y, x)
(x, ImageSet(Lambda(_n, I*(2*_n*pi + arg(y)) + log(Abs(y))), Integers))
```

```python
>>> invert_real(exp(x), y, x)
(x, Intersection({log(y)}, Reals))
```

When does \(\exp(x) = 1\)?

```python
>>> invert_complex(exp(x), 1, x)
(x, ImageSet(Lambda(_n, 2*_n*I*pi), Integers))
```

```python
>>> invert_real(exp(x), 1, x)
(x, {0})
```

**See also:**

\texttt{invert_real} (page 915), \texttt{invert_complex} (page 915)

\texttt{sympy.solvers.solveset.domain_check(f, symbol, p)}

Returns False if point \(p\) is infinite or any subexpression of \(f\) is infinite or becomes so after replacing symbol with \(p\). If none of these conditions is met then True will be returned.

**Examples**

```python
>>> from sympy import Mul, oo
>>> from sympy import exp
>>> from sympy.solvers.solveset import domain_check
```

```python
>>> g = 1/(1 + (1/(x + 1))**2)
>>> domain_check(g, x, -1)
False
>>> domain_check(x**2, x, 0)
True
>>> domain_check(1/x, x, oo)
False
```

- The function relies on the assumption that the original form of the equation has not been changed by automatic simplification.

```python
>>> domain_check(x/x, x, 0) # x/x is automatically simplified to 1
True
```
To deal with automatic evaluations use `evaluate=False`:

```python
>>> domain_check(Mul(x, 1/x, evaluate=False), x, 0)
False
```

```python
sympy.solvers.solve\text{set}.\text{solve}\text{fy}(f, \text{symbol}, \text{domain})
```

Solves an equation using `solve\text{set}` and returns the solution in accordance with the `solve` output API.

**Returns**
We classify the output based on the type of solution returned by `solve\text{set}`.

**Raises**

NotImplementedError

A ConditionSet is the input.

**Solution | Output**

| FiniteSet | list |
| ImageSet, | list (if $f$ is periodic) Union |
| Union | list (with FiniteSet) |
| EmptySet | empty list |
| Others | None |

**Examples**

```python
>>> from sympy.solvers.solve\text{set} import solve\text{fy}
>>> from sympy.abc import x
>>> from sympy import S, tan, sin, exp
>>> solve\text{fy}(x**2 - 9, x, S.Reals)
[-3, 3]
>>> solve\text{fy}(\sin(x) - 1, x, S.Reals)
[\pi/2]
>>> solve\text{fy}(\tan(x), x, S.Reals)
[0]
>>> solve\text{fy}(\exp(x) - 1, x, S.Complexes)
```

```python
>>> solve\text{fy}(\exp(x) - 1, x, S.Reals)
[0]
```

```python
sympy.solvers.solve\text{set}.linear_eq\text{to}_\text{matrix}(equations, *symbols)
```

Converts a given System of Equations into Matrix form. Here `equations` must be a linear system of equations in `symbols`. Element $M[i, j]$ corresponds to the coefficient of the $j$th symbol in the $i$th equation.

The Matrix form corresponds to the augmented matrix form. For example:

\[
\begin{align*}
4x + 2y + 3z &= 1 \\
3x + y + z &= -6
\end{align*}
\]
\[2x + 4y + 9z = 2\]

This system will return \(A\) and \(b\) as:

\[$$A = \begin{bmatrix} 4 & 2 & 3 \\ 3 & 1 & 1 \\ 2 & 4 & 9 \end{bmatrix}$$, \(b = \begin{bmatrix} 1 \\ -6 \\ 2 \end{bmatrix}$$\]

The only simplification performed is to convert \(\text{Eq}(a, b) \Rightarrow a - b\).

**Raises**

- **NonlinearError**
  
The equations contain a nonlinear term.

- **ValueError**
  
The symbols are not given or are not unique.

**Examples**

```python
>>> from sympy import linear_eq_to_matrix, symbols

>>> c, x, y, z = symbols('c, x, y, z')

The coefficients (numerical or symbolic) of the symbols will be returned as matrices:

```python
>>> eqns = [c*x + z - 1 - c, y + z, x - y]
>>> A, b = linear_eq_to_matrix(eqns, [x, y, z])

```

This routine does not simplify expressions and will raise an error if nonlinearity is encountered:

```python
>>> eqns = [
    ... (x**2 - 3*x)/(x - 3) - 3,
    ... y**2 - 3*y - y*(y - 4) + x - 4]
>>> linear_eq_to_matrix(eqns, [x, y])
Traceback (most recent call last):
...
NonlinearError:
symbol-dependent term can be ignored using `strict=False`
```

Simplifying these equations will discard the removable singularity in the first and reveal the linear structure of the second:

```python
>>> [e.simplify() for e in eqns]
[x - 3, x + y - 4]
```
Any such simplification needed to eliminate nonlinear terms must be done before calling this routine.

```python
sympy.solvers.solve._set.kinsolve(system, *symbols)
```

Solves system of $N$ linear equations with $M$ variables; both underdetermined and overdetermined systems are supported. The possible number of solutions is zero, one or infinite. Zero solutions throws a ValueError, whereas infinite solutions are represented parametrically in terms of the given symbols. For unique solution a `FiniteSet` (page 1241) of ordered tuples is returned.

All standard input formats are supported: For the given set of equations, the respective input types are given below:

\[
3x + 2y - z = 1 \\
2x - 2y + 4z = -2 \\
2x - y + 2z = 0
\]

- Augmented matrix form, system given below:

\[
\begin{bmatrix}
3 & 2 & -1 & 1 \\
2 & -2 & 4 & -2 \\
2 & -1 & 2 & 0
\end{bmatrix}
\]

- List of equations form

\[
[3x + 2y - z - 1, 2x - 2y + 4z + 2, 2x - y + 2z]
\]

- Input $A$ and $b$ in matrix form (from $Ax = b$) are given as:

\[
\begin{bmatrix}
3 & 2 & -1 \\
2 & -2 & 4 \\
2 & -1 & 2
\end{bmatrix} \begin{bmatrix}
1 \\
-2 \\
0
\end{bmatrix}
\]

Symbols can always be passed but are actually only needed when 1) a system of equations is being passed and 2) the system is passed as an underdetermined matrix and one wants to control the name of the free variables in the result. An error is raised if no symbols are used for case 1, but if no symbols are provided for case 2, internally generated symbols will be provided. When providing symbols for case 2, there should be at least as many symbols are there are columns in matrix $A$.

The algorithm used here is Gauss-Jordan elimination, which results, after elimination, in a row echelon form matrix.

**Returns**

A `FiniteSet` containing an ordered tuple of values for the unknowns for which the `system` has a solution. (Wrapping the tuple in `FiniteSet` is used to maintain a consistent
output format throughout solveset.)

Returns EmptySet, if the linear system is inconsistent.

Raises

ValueError

The input is not valid. The symbols are not given.

Examples

```python
>>> from sympy import Matrix, linsolve, symbols
>>> x, y, z = symbols("x, y, z")
>>> A = Matrix([[1, 2, 3], [4, 5, 6], [7, 8, 10]])
>>> b = Matrix([3, 6, 9])
>>> A
Matrix([[1, 2, 3],
        [4, 5, 6],
        [7, 8, 10]])
>>> b
Matrix([[3],
        [6],
        [9]])
>>> linsolve((A, b), [x, y, z])
{(-1, 2, 0)}
```

- Parametric Solution: In case the system is underdetermined, the function will return a parametric solution in terms of the given symbols. Those that are free will be returned unchanged. e.g. in the system below, \( z \) is returned as the solution for variable \( z \); it can take on any value.

```python
>>> A = Matrix([[1, 2, 3], [4, 5, 6], [7, 8, 9]])
>>> b = Matrix([3, 6, 9])
>>> linsolve((A, b), x, y, z)
{(z - 1, 2 - 2*z, z)}
```

If no symbols are given, internally generated symbols will be used. The \( \tau_0 \) in the third position indicates (as before) that the third variable – whatever it is named – can take on any value:

```python
>>> linsolve((A, b))
{(-tau0 - 1, 2 - 2*tau0, tau0)}
```

- List of equations as input

```python
>>> Eqns = [3*x + 2*y - z - 1, 2*x - 2*y + 4*z + 2, -x + y/2 - z]
>>> linsolve(Eqns, x, y, z)
{(1, -2, -2)}
```

- Augmented matrix as input
>>> aug = Matrix([[2, 1, 3, 1], [2, 6, 8, 3], [6, 8, 18, 5]])
>>> aug
Matrix([[2, 1, 3, 1],
        [2, 6, 8, 3],
        [6, 8, 18, 5]])
>>> linsolve(aug, x, y, z)
{(3/10, 2/5, 0)}

• Solve for symbolic coefficients

>>> a, b, c, d, e, f = symbols('a, b, c, d, e, f')
>>> eqns = [a*x + b*y - c, d*x + e*y - f]
>>> linsolve(eqns, x, y)
{(-b*f + c*e)/(a*e - b*d), (a*f - c*d)/(a*e - b*d))}

• A degenerate system returns solution as set of given symbols.

>>> system = Matrix(((0, 0, 0), [0, 0, 0], [0, 0, 0]))
>>> linsolve(system, x, y)
{(x, y)}

• For an empty system linsolve returns empty set

>>> linsolve([], x)
EmptySet

• An error is raised if any nonlinearity is detected, even if it could be removed with expansion

>>> linsolve([x*(1/x - 1)], x)
Traceback (most recent call last):
  ...
NonlinearError: nonlinear term: 1/x

>>> linsolve([x*(y + 1)], x, y)
Traceback (most recent call last):
  ...
NonlinearError: nonlinear cross-term: x*(y + 1)

>>> linsolve([x**2 - 1], x)
Traceback (most recent call last):
  ...
NonlinearError: nonlinear term: x**2

SymPy solveset.nonlinsolve(system, *symbols)
Solve system of \( N \) nonlinear equations with \( M \) variables, which means both under and overdetermined systems are supported. Positive dimensional system is also supported (A system with infinitely many solutions is said to be positive-dimensional). In a positive
dimensional system the solution will be dependent on at least one symbol. Returns both real solution and complex solution (if they exist).

**Parameters**

- `system` : list of equations
  The target system of equations
- `symbols` : list of Symbols
  symbols should be given as a sequence eg. list

**Returns**

A `FiniteSet` (page 1241) of ordered tuple of values of `symbols` for which the `system` has solution. Order of values in the tuple is same as symbols present in the parameter `symbols`.

Please note that general `FiniteSet` (page 1241) is unordered, the solution returned here is not simply a `FiniteSet` (page 1241) of solutions, rather it is a `FiniteSet` (page 1241) of ordered tuple, i.e. the first and only argument to `FiniteSet` (page 1241) is a tuple of solutions, which is ordered, and, hence ,the returned solution is ordered.

Also note that solution could also have been returned as an ordered tuple, `FiniteSet` is just a wrapper `{}` around the tuple. It has no other significance except for the fact it is just used to maintain a consistent output format throughout the solveset.

For the given set of equations, the respective input types are given below:

\[
\begin{align*}
xy - 1 & = 0 \\
4x^2 + y^2 - 5 & = 0 \\
\end{align*}
\]

```python
system = [x*y - 1, 4*x**2 + y**2 - 5]
symbols = [x, y]
```

**Raises**

- `ValueError`
  The input is not valid. The symbols are not given.
- `AttributeError`
  The input symbols are not `Symbol` type.
Examples

```python
>>> from sympy import symbols, nonlinsolve
>>> x, y, z = symbols('x, y, z', real=True)
>>> nonlinsolve([x*y - 1, 4*x**2 + y**2 - 5], [x, y])
{(-1, -1), (-1/2, -2), (1/2, 2), (1, 1)}
```

1. Positive dimensional system and complements:

```python
>>> from sympy import pprint
>>> from sympy.polys.polytools import is_zero_dimensional
>>> a, b, c, d = symbols('a, b, c, d', extended_real=True)
>>> eq1 = a + b + c + d
>>> eq2 = a*b + b*c + c*d + d*a
>>> eq3 = a*b*c + b*c*d + c*d*a + d*a*b
>>> eq4 = a*b*c*d - 1
>>> system = [eq1, eq2, eq3, eq4]
>>> is_zero_dimensional(system)
False
>>> pprint(nonlinsolve(system, [a, b, c, d]), use_unicode=False)
(-1, 1, 1, -1)
({(-1, -d, -d, {d} \ {0}), (-, -d, --, {d} \ {0})})
```

2. If some of the equations are non-polynomial then `nonlinsolve` will call the substitution function and return real and complex solutions, if present.

```python
>>> from sympy import exp, sin
>>> nonlinsolve([exp(x) - sin(y), y**2 - 4], [x, y])
{(ImageSet(Lambda(_n, I*(2*_n*pi + pi) + log(sin(2))), Integers), -2),
 (ImageSet(Lambda(_n, 2*_n*I*pi + log(sin(2))), Integers), 2)}
```

3. If system is non-linear polynomial and zero-dimensional then it returns both solution (real and complex solutions, if present) using `solve_poly_system()` (page 903):

```python
>>> from sympy import sqrt
>>> nonlinsolve([x**2 - 2*y**2 - 2, x*y - 2], [x, y])
{(-2, -1), (2, 1), (-sqrt(2)*I, sqrt(2)*I), (sqrt(2)*I, -sqrt(2)*I)}
```

4. `nonlinsolve` can solve some linear (zero or positive dimensional) system (because it uses the `sympy.polys.polytools.groebner()` (page 2451) function to get the groebner basis and then uses the substitution function basis as the new `system`). But it is not recommended to solve linear system using `nonlinsolve`, because `linsolve()` (page 919) is better for general linear systems.

```python
>>> nonlinsolve([x + 2*y - z - 3, x - y - 4*z + 9, y + z - 4], [x, y, z])
{(3*z - 5, 4 - z, z)}
```

5. System having polynomial equations and only real solution is solved using `solve_poly_system()` (page 903):
6. It is better to use symbols instead of trigonometric functions or Function (page 1096). For example, replace \( \sin(x) \) with a symbol, replace \( f(x) \) with a symbol and so on. Get a solution from nonlinsolve and then use solveset() (page 913) to get the value of \( x \).

**How Nonlinsolve Is Better Than Old Solver _solve_system:**

1. A positive dimensional system solver: nonlinsolve can return solution for positive dimensional system. It finds the Groebner Basis of the positive dimensional system(calling it as basis) then we can start solving equation(having least number of variable first in the basis) using solveset and substituting that solved solutions into other equation(of basis) to get solution in terms of minimum variables. Here the important thing is how we are substituting the known values and in which equations.

2. Real and complex solutions: nonlinsolve returns both real and complex solution. If all the equations in the system are polynomial then using solve_poly_system() (page 903) both real and complex solution is returned. If all the equations in the system are not polynomial equation then goes to substitution method with this polynomial and non polynomial equation(s), to solve for unsolved variables. Here to solve for particular variable solveset_real and solveset_complex is used. For both real and complex solution _solve_using_known_values is used inside substitution (substitution will be called when any non-polynomial equation is present). If a solution is valid its general solution is added to the final result.

3. Complement (page 1244) and Intersection (page 1242) will be added: nonlinsolve maintains dict for complements and intersections. If solveset find complements or/and intersections with any interval or set during the execution of substitution function, then complement or/and intersection for that variable is added before returning final solution.

**transolve**

sympy.solvers.solveset._transolve(f, symbol, domain)

Function to solve transcendental equations. It is a helper to solveset and should be used internally. _transolve currently supports the following class of equations:

- Exponential equations
- Logarithmic equations

**Parameters**

- \( f \) : Any transcendental equation that needs to be solved.
  
  This needs to be an expression, which is assumed to be equal to 0.

- \( symbol \) : The variable for which the equation is solved.
This needs to be of class `Symbol`.

**domain**: A set over which the equation is solved.

This needs to be of class `Set`.

**Returns**

Set

A set of values for `symbol` for which `f` is equal to zero. An `EmptySet` is returned if `f` does not have solutions in respective domain. A `ConditionSet` is returned as unsolved object if algorithms to evaluate complete solution are not yet implemented.

**How To Use _transolve**

`_transolve` should not be used as an independent function, because it assumes that the equation (`f`) and the symbol comes from `solveset` and might have undergone a few modification(s). To use `_transolve` as an independent function the equation (`f`) and the symbol should be passed as they would have been by `solveset`.

**Examples**

```python
>>> from sympy.solvers.solveset import _transolve as transolve
>>> from sympy.solvers.solvers import _tsolve as tsolve
>>> from sympy import symbols, S, pprint

>>> x = symbols('x', real=True) # assumption added
>>> transolve(5**(x - 3) - 3**(2*x + 1), x, S.Reals)
{-(log(3) + 3*log(5))/(-log(5) + 2*log(3))}
```

**How _transolve Works**

_transolve uses two types of helper functions to solve equations of a particular class:

- **Identifying helpers**: To determine whether a given equation belongs to a certain class of equation or not. Returns either `True` or `False`.
- **Solving helpers**: Once an equation is identified, a corresponding helper either solves the equation or returns a form of the equation that `solveset` might better be able to handle.

  - **Philosophy behind the module**

The purpose of _transolve is to take equations which are not already polynomial in their generator(s) and to either recast them as such through a valid transformation or to solve them outright. A pair of helper functions for each class of supported transcendental functions are employed for this purpose. One identifies the transcendental form of an equation and the other either solves it or recasts it into a tractable form that can be solved by `solveset`. For example, an equation in the form $a b^{f(x)} - c d^{g(x)} = 0$ can be transformed to $\log(a) + f(x) \log(b) - \log(c) - g(x) \log(d) = 0$ (under certain assumptions) and this can be solved with `solveset` if $f(x)$ and $g(x)$ are in polynomial form.
How _transolve Is Better Than _tsolve

1) Better output

_transolve provides expressions in a more simplified form.

Consider a simple exponential equation

```python
>>> f = 3**(2*x) - 2**(x + 3)
>>> pprint(transolve(f, x, S.Reals), use_unicode=False)
{------------------}
-3*log(2)
-2*log(3) + log(2)
>>> pprint(tsolve(f, x), use_unicode=False)
<table>
<thead>
<tr>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>log(2/9)</td>
</tr>
</tbody>
</table>
[-log\2 /
```

2) Extensible

The API of _transolve is designed such that it is easily extensible, i.e. the code that solves a given class of equations is encapsulated in a helper and not mixed in with the code of _transolve itself.

3) Modular

_transolve is designed to be modular i.e, for every class of equation a separate helper for identification and solving is implemented. This makes it easy to change or modify any of the method implemented directly in the helpers without interfering with the actual structure of the API.

4) Faster Computation

Solving equation via _transolve is much faster as compared to _tsolve. In solve, attempts are made computing every possibility to get the solutions. This series of attempts makes solving a bit slow. In _transolve, computation begins only after a particular type of equation is identified.

How To Add New Class Of Equations

Adding a new class of equation solver is a three-step procedure:

- Identify the type of the equations

Determine the type of the class of equations to which they belong: it could be of Add, Pow, etc. types. Separate internal functions are used for each type. Write identification and solving helpers and use them from within the routine for the given type of equation (after adding it, if necessary). Something like:

```python
def add_type(lhs, rhs, x):
    ....
    if _is_exponential(lhs, x):
        new_eq = _solve_exponential(lhs, rhs, x)
    ....
```

(continues on next page)
• Define the identification helper.
• Define the solving helper.

Apart from this, a few other things needs to be taken care while adding an equation solver:

• Naming conventions: Name of the identification helper should be as _is_class where class will be the name or abbreviation of the class of equation. The solving helper will be named as _solve_class. For example: for exponential equations it becomes _is_exponential and _solve_exp.

• The identifying helpers should take two input parameters, the equation to be checked and the variable for which a solution is being sought, while solving helpers would require an additional domain parameter.

• Be sure to consider corner cases.
• Add tests for each helper.
• Add a docstring to your helper that describes the method implemented. The documentation of the helpers should identify:
  - the purpose of the helper,
  - the method used to identify and solve the equation,
  - a proof of correctness
  - the return values of the helpers

```python
sympy.solvers.solveset._is_exponential(f, symbol)
```
Return True if one or more terms contain symbol only in exponents, else False.

**Parameters**

- **f**: Expr
  The equation to be checked
- **symbol**: Symbol
  The variable in which the equation is checked

**Examples**

```python
>>> from sympy import symbols, cos, exp
>>> from sympy.solvers.solveset import _is_exponential as check
>>> x, y = symbols('x y')
>>> check(y, y)
False
>>> check(x**y - 1, y)
True
>>> check(x**y*2**y - 1, y)
True
```
>>> check(exp(x + 3) + 3**x, x)
True
>>> check(cos(2**x), x)
False

- Philosophy behind the helper

The function extracts each term of the equation and checks if it is of exponential form w.r.t symbol.

**sympy.solvers.solveset._solve_exponential**(lhs, rhs, symbol, domain)

Helper function for solving (supported) exponential equations.

Exponential equations are the sum of (currently) at most two terms with one or both of them having a power with a symbol-dependent exponent.

For example

\[
5^{2x+3} - 5^{3x-1}
\]

\[
4^{5-9x} - e^{2-x}
\]

**Parameters**

- *lhs, rhs*: Expr
  - The exponential equation to be solved, \(lhs = rhs\)
- *symbol*: Symbol
  - The variable in which the equation is solved
- *domain*: Set
  - A set over which the equation is solved.

**Returns**

A set of solutions satisfying the given equation.
A ConditionSet if the equation is unsolvable or if the assumptions are not properly defined, in that case a different style of ConditionSet is returned having the solution(s) of the equation with the desired assumptions.

**Examples**

```python
>>> from sympy.solvers.solveset import _solve_exponential as solve_expo
>>> from sympy import symbols, S
>>> x = symbols('x', real=True)
>>> a, b = symbols('a b')
>>> solve_expo(2**x + 3**x - 5**x, 0, x, S.Reals)  # not solvable
ConditionSet(x, Eq(2**x + 3**x - 5**x, 0), Reals)
>>> solve_expo(a**x - b**x, 0, x, S.Reals)  # solvable but incorrect assumptions
ConditionSet(x, (a > 0) & (b > 0), {0})
```
Proof of correctness of the method

The logarithm function is the inverse of the exponential function. The defining relation between exponentiation and logarithm is:

$$\log_b x = y \text{ if } b^y = x$$

Therefore if we are given an equation with exponent terms, we can convert every term to its corresponding logarithmic form. This is achieved by taking logarithms and expanding the equation using logarithmic identities so that it can easily be handled by solveset.

For example:

$$3^{2x} = 2^{x+3}$$

Taking log both sides will reduce the equation to

$$(2x)\log(3) = (x + 3)\log(2)$$

This form can be easily handled by solveset.

sympy.solvers.solveset._solve_logarithm(lhs, rhs, symbol, domain)
Helper to solve logarithmic equations which are reducible to a single instance of log.

Logarithmic equations are (currently) the equations that contains log terms which can be reduced to a single log term or a constant using various logarithmic identities.

For example:

$$\log(x) + \log(x - 4)$$

can be reduced to:

$$\log(x(x - 4))$$

**Parameters**

- **lhs, rhs**: Expr
  The logarithmic equation to be solved, \(lhs = rhs\)

- **symbol**: Symbol
  The variable in which the equation is solved

- **domain**: Set
  A set over which the equation is solved.

**Returns**

A set of solutions satisfying the given equation.
A ConditionSet if the equation is unsolvable.
Examples

```python
>>> from sympy import symbols, log, S
>>> from sympy.solvers.solveset import _solve_logarithm as solve_log
>>> x = symbols('x')
>>> f = log(x - 3) + log(x + 3)
>>> solve_log(f, 0, x, S.Reals)
{-sqrt(10), sqrt(10)}
```

• Proof of correctness

A logarithm is another way to write exponent and is defined by

\[
\log_b x = y \text{ if } b^y = x
\]

When one side of the equation contains a single logarithm, the equation can be solved by rewriting the equation as an equivalent exponential equation as defined above. But if one side contains more than one logarithm, we need to use the properties of logarithm to condense it into a single logarithm.

Take for example

\[
\log(2x) - 15 = 0
\]

contains single logarithm, therefore we can directly rewrite it to exponential form as

\[
x = \frac{e^{15}}{2}
\]

But if the equation has more than one logarithm as

\[
\log(x - 3) + \log(x + 3) = 0
\]

we use logarithmic identities to convert it into a reduced form

Using,

\[
\log(a) + \log(b) = \log(ab)
\]

the equation becomes,

\[
\log((x - 3)(x + 3))
\]

This equation contains one logarithm and can be solved by rewriting to exponents.

```python
sympy.solvers.solveset._is_logarithmic(f, symbol)
```

Return True if the equation is in the form \(a \log(f(x)) + b \log(g(x)) + \ldots + c\) else False.

**Parameters**

- `f`: Expr
  - The equation to be checked

- `symbol`: Symbol
  - The variable in which the equation is checked

**Returns**

True if the equation is logarithmic otherwise False.
Examples

```python
>>> from sympy import symbols, tan, log
>>> from sympy.solvers.solveset import _is_logarithmic as check
>>> x, y = symbols('x y')
>>> check(log(x + 2) - log(x + 3), x)
True
>>> check(tan(log(2*x)), x)
False
>>> check(x*log(x), x)
False
>>> check(x + log(x), x)
False
>>> check(y + log(x), x)
True
```

- Philosophy behind the helper

The function extracts each term and checks whether it is logarithmic w.r.t symbol.

Diophantine Equations (DEs)

See Diophantine (page 769)

Inequalities

See Inequality Solvers (page 803)

Ordinary Differential equations (ODEs)

See ODE (page 807).

Partial Differential Equations (PDEs)

See PDE (page 872).

abc

This module exports all latin and greek letters as Symbols, so you can conveniently do

```python
>>> from sympy.abc import x, y
```

instead of the slightly more clunky-looking

```python
>>> from sympy import symbols
>>> x, y = symbols('x y')
```
Caveats

1. As of the time of writing this, the names O, S, I, N, E, and Q are colliding with names defined in SymPy. If you import them from both sympy.abc and sympy, the second import will “win”. This is an issue only for * imports, which should only be used for short-lived code such as interactive sessions and throwaway scripts that do not survive until the next SymPy upgrade, where sympy may contain a different set of names.

2. This module does not define symbol names on demand, i.e. from sympy.abc import foo will be reported as an error because sympy.abc does not contain the name foo. To get a symbol named foo, you still need to use Symbol('foo') or symbols('foo'). You can freely mix usage of sympy.abc and Symbol/symbols, though sticking with one and only one way to get the symbols does tend to make the code more readable.

The module also defines some special names to help detect which names clash with the default SymPy namespace.

_clash1 defines all the single letter variables that clash with SymPy objects; _clash2 defines the multi-letter clashing symbols; and _clash is the union of both. These can be passed for locals during symification if one desires Symbols rather than the non-Symbol objects for those names.

Examples

```python
>>> from sympy import S
>>> from sympy.abc import _clash1, _clash2, _clash
>>> S("Q & C", locals=_clash1)
C & Q
>>> S('pi(x)', locals=_clash2)
pi(x)
>>> S('pi(C, Q)', locals=_clash)
pi(C, Q)
```

Algebras

Introduction

The Algebras module for SymPy provides support for basic algebraic operations on Quaternions.

Quaternion Reference

This section lists the classes implemented by the Algebras module.

class sympy.algebras.Quaternion(a=0, b=0, c=0, d=0, real_field=True, norm=None)

Provides basic quaternion operations. Quaternion objects can be instantiated as Quaternion(a, b, c, d) as in (a + b*i + c*j + d*k).

Parameters

- norm : None or number
Pre-defined quaternion norm. If a value is given, Quaternion.norm returns this pre-defined value instead of calculating the norm.

Examples

```python
>>> from sympy import Quaternion
>>> q = Quaternion(1, 2, 3, 4)
>>> q
1 + 2*i + 3*j + 4*k
```

Quaternions over complex fields can be defined as:

```python
>>> from sympy import Quaternion
>>> from sympy import symbols, I
>>> x = symbols('x')
>>> q1 = Quaternion(x, x**3, x, x**2, real_field = False)
>>> q2 = Quaternion(3 + 4*I, 2 + 5*I, 0, 7 + 8*I, real_field = False)
>>> q1
x + x**3*i + x*j + x**2*k
>>> q2
(3 + 4*I) + (2 + 5*I)*i + 0*j + (7 + 8*I)*k
```

Defining symbolic unit quaternions:

```python
>>> from sympy import Quaternion
>>> from sympy.abc import w, x, y, z
>>> q = Quaternion(w, x, y, z, norm=1)
>>> q
w + x*i + y*j + z*k
```

References

[R1], [R2]

add(other)

Adds quaternions.

**Parameters**

other : Quaternion

The quaternion to add to current (self) quaternion.

**Returns**

Quaternion

The resultant quaternion after adding self to other.

Examples

```python
>>> from sympy import Quaternion
>>> from sympy import symbols
>>> q1 = Quaternion(1, 2, 3, 4)
>>> q2 = Quaternion(5, 6, 7, 8)
>>> q1.add(q2)
6 + 8*i + 10*j + 12*k
```

(continues on next page)
Quaternions over complex fields:

```python
>>> from sympy import Quaternion
>>> q3 = Quaternion(3 + 4*I, 2 + 5*I, 0, 7 + 8*I, real_field = False)
>>> q3.add(2 + 3*I)
(5 + 7*I) + (2 + 5*I)*i + 0*j + (7 + 8*I)*k
```

angle()

Returns the angle of the quaternion measured in the real-axis plane.

**Explanation**

Given a quaternion \( q = a + bi + cj + dk \) where \( a, b, c \) and \( d \) are real numbers, returns the angle of the quaternion given by

\[
angle := \text{atan2}(\sqrt{b^2 + c^2 + d^2}, a)
\]

**Examples**

```python
>>> from sympy.algebras.quaternion import Quaternion
>>> q = Quaternion(1, 4, 4, 4)
>>> q.angle()
atan(4*sqrt(3))
```

arc_coplanar(other)

Returns True if the transformation arcs represented by the input quaternions happen in the same plane.

**Parameters**

- **other**: a Quaternion

**Returns**

- **True**: if the planes of the two quaternions are the same, apart from its orientation/sign.
- **False**: if the planes of the two quaternions are not the same, apart from its orientation/sign.
- **None**: if plane of either of the quaternion is unknown.
**Explanation**

Two quaternions are said to be coplanar (in this arc sense) when their axes are parallel. The plane of a quaternion is the one normal to its axis.

**Examples**

```python
>>> from sympy.algebras.quaternion import Quaternion
>>> q1 = Quaternion(1, 4, 4, 4)
>>> q2 = Quaternion(3, 8, 8, 8)
>>> Quaternion.arc_coplanar(q1, q2)
True
```

```python
>>> q1 = Quaternion(2, 8, 13, 12)
>>> Quaternion.arc_coplanar(q1, q2)
False
```

**See also:**

`vector_coplanar` (page 949), `is_pure` (page 939)

**axis()**

Returns the axis $A_x(q)$ of the quaternion.

**Explanation**

Given a quaternion $q = a + b i + c j + d k$, returns $A_x(q)$ i.e., the versor of the vector part of that quaternion equal to $U|V(q)|$. The axis is always an imaginary unit with square equal to $-1 + 0i + 0j + 0k$.

**Examples**

```python
>>> from sympy.algebras.quaternion import Quaternion
>>> q = Quaternion(1, 1, 1, 1)
>>> q.axis()
0 + sqrt(3)/3*im + sqrt(3)/3*jm + sqrt(3)/3*k
```

**See also:**

`vector_part` (page 950)

**exp()**

Returns the exponential of $q$ ($e^q$).

**Returns**

`Quaternion`

Exponential of $q$ ($e^q$).
Examples

```python
>>> from sympy import Quaternion
>>> q = Quaternion(1, 2, 3, 4)
>>> q.exp()
E*cos(sqrt(29))
+ 2*sqrt(29)*E*sin(sqrt(29))/29*i
+ 3*sqrt(29)*E*sin(sqrt(29))/29*j
+ 4*sqrt(29)*E*sin(sqrt(29))/29*k
```

classmethod `from_Matrix`(elements)

Returns quaternion from elements of a column vector. If vector_only is True, returns only imaginary part as a Matrix of length 3.

**Parameters**

- **elements**: Matrix, list or tuple of length 3 or 4. If length is 3, assume real part is zero. Default value: False

**Returns**

Quaternion

A quaternion created from the input elements.

Examples

```python
>>> from sympy import Quaternion
>>> from sympy.abc import a, b, c, d

>>> q = Quaternion.from_Matrix([a, b, c, d])
>>> q
a + b*i + c*j + d*k

>>> q = Quaternion.from_Matrix([b, c, d])
>>> q
0 + b*i + c*j + d*k
```

classmethod `from_axis_angle`(vector, angle)

Returns a rotation quaternion given the axis and the angle of rotation.

**Parameters**

- **vector**: tuple of three numbers
  
The vector representation of the given axis.

- **angle**: number
  
The angle by which axis is rotated (in radians).

**Returns**

Quaternion

The normalized rotation quaternion calculated from the given axis and the angle of rotation.
Examples

```python
>>> from sympy import Quaternion
>>> from sympy import pi, sqrt
>>> q = Quaternion.from_axis_angle((sqrt(3)/3, sqrt(3)/3, sqrt(3)/3),
                                 -2*pi/3)
>>> q
1/2 + 1/2*i + 1/2*j + 1/2*k
```

classmethod `from_euler`(angles, seq)

Returns quaternion equivalent to rotation represented by the Euler angles, in the sequence defined by seq.

**Parameters**

- **angles** : list, tuple or Matrix of 3 numbers
  - The Euler angles (in radians).
- **seq** : string of length 3
  - Represents the sequence of rotations. For intrinsic rotations, seq must be all lowercase and its elements must be from the set {'x', 'y', 'z'} For extrinsic rotations, seq must be all uppercase and its elements must be from the set {'X', 'Y', 'Z'}

**Returns**

- Quaternion
  - The normalized rotation quaternion calculated from the Euler angles in the given sequence.

Examples

```python
>>> from sympy import Quaternion
>>> from sympy import pi
>>> q = Quaternion.from_euler([pi/2, 0, 0], 'xyz')
>>> q
sqrt(2)/2 + sqrt(2)/2*i + 0*j + 0*k

>>> q = Quaternion.from_euler([0, pi/2, pi], 'zyz')
>>> q
0 + (-sqrt(2)/2)*i + 0*j + sqrt(2)/2*k

>>> q = Quaternion.from_euler([0, pi/2, pi], 'ZYZ')
>>> q
0 + sqrt(2)/2*i + 0*j + sqrt(2)/2*k
```

classmethod `from_rotation_matrix`(M)

Returns the equivalent quaternion of a matrix. The quaternion will be normalized only if the matrix is special orthogonal (orthogonal and det(M) = 1).

**Parameters**

- **M** : Matrix
Input matrix to be converted to equivalent quaternion. M must be special orthogonal (orthogonal and det(M) = 1) for the quaternion to be normalized.

**Returns**
Quaternion

The quaternion equivalent to given matrix.

**Examples**

```python
>>> from sympy import Quaternion
>>> from sympy import Matrix, symbols, cos, sin, trigsimp
>>> x = symbols('x')
>>> M = Matrix([[cos(x), -sin(x), 0], [sin(x), cos(x), 0], [0, 0, 1]])
>>> q = trigsimp(Quaternion.from_rotation_matrix(M))
```

```
sqrt(2)*sqrt(cos(x) + 1)/2 + 0*i + 0*j + sqrt(2 - 2*cos(x))*sign(sin(x))/2*k
```

**index_vector()**

Returs the index vector of the quaternion.

**Returns**
Quaternion: representing index vector of the provided quaternion.

**Explanation**

Index vector is given by \( T(q) \) multiplied by \( Ax(q) \) where \( Ax(q) \) is the axis of the quaternion \( q \), and \( \text{mod}(q) \) is the \( T(q) \) (magnitude) of the quaternion.

**Examples**

```python
>>> from sympy.algebras.quaternion import Quaternion
>>> q = Quaternion(2, 4, 2, 4)
>>> q.index_vector()
```

```
0 + 4*sqrt(10)/3*i + 2*sqrt(10)/3*j + 4*sqrt(10)/3*k
```

**See also:**
- `axis` (page 935), `norm` (page 941)

**integrate(*args)**

Computes integration of quaternion.

**Returns**
Quaternion

Integration of the quaternion(self) with the given variable.
Examples

Indefinite Integral of quaternion:

```python
from sympy import Quaternion
from sympy.abc import x
q = Quaternion(1, 2, 3, 4)
q.integrate(x)
x + 2*x*i + 3*x*j + 4*x*k
```

Definite integral of quaternion:

```python
from sympy import Quaternion
from sympy.abc import x
q = Quaternion(1, 2, 3, 4)
q.integrate((x, 1, 5))
4 + 8*i + 12*j + 16*k
```

inverse()

Returns the inverse of the quaternion.

is_pure()

Returns true if the quaternion is pure, false if the quaternion is not pure or returns none if it is unknown.

Explanation

A pure quaternion (also a vector quaternion) is a quaternion with scalar part equal to 0.

Examples

```python
from sympy.algebras.quaternion import Quaternion
q = Quaternion(0, 8, 13, 12)
q.is_pure()
```

See also:

scalar_part (page 945)

is_zero_quaternion()

Returns true if the quaternion is a zero quaternion or false if it is not a zero quaternion and None if the value is unknown.
Explanation

A zero quaternion is a quaternion with both scalar part and vector part equal to 0.

Examples

```python
>>> from sympy.algebras.quaternion import Quaternion
>>> q = Quaternion(1, 0, 0, 0)
>>> q.is_zero_quaternion()
False

>>> q = Quaternion(0, 0, 0, 0)
>>> q.is_zero_quaternion()
True
```

See also:

`scalar_part` (page 945), `vector_part` (page 950)

`mensor()`

Returns the natural logarithm of the norm(magnitude) of the quaternion.

Examples

```python
>>> from sympy.algebras.quaternion import Quaternion
>>> q = Quaternion(2, 4, 2, 4)
>>> q.mensor()
log(2*sqrt(10))
>>> q.norm()
2*sqrt(10)
```

See also:

`norm` (page 941)

`mul(other)`

Multiplies quaternions.

Parameters

other : Quaternion or symbol

The quaternion to multiply to current (self) quaternion.

Returns

Quaternion

The resultant quaternion after multiplying self with other
Examples

```python
>>> from sympy import Quaternion
>>> from sympy import symbols
>>> q1 = Quaternion(1, 2, 3, 4)
>>> q2 = Quaternion(5, 6, 7, 8)
>>> q1.mul(q2)
(-60) + 12*i + 30*j + 24*k
>>> q1.mul(2)
2 + 4*i + 6*j + 8*k
>>> x = symbols('x', real=True)
>>> q1.mul(x)
x + 2*x*i + 3*x*j + 4*x*k
```

Quaternions over complex fields:

```python
>>> from sympy import Quaternion
>>> from sympy import I
>>> q3 = Quaternion(3 + 4*I, 2 + 5*I, 0, 7 + 8*I, real_field=False)
>>> q3.mul(2 + 3*I)
(2 + 3*I)*(3 + 4*I) + (2 + 3*I)*(2 + 5*I)*i + 0*j + (2 + 3*I)*(7 +
-8*I)*k
```

**norm()**

Returns the norm of the quaternion.

**normalize()**

Returns the normalized form of the quaternion.

**orthogonal**(other)

Returns the orthogonality of two quaternions.

Parameters

other : a Quaternion

Returns

**True** : if the two pure quaternions seen as 3D vectors are orthogonal.
**False** : if the two pure quaternions seen as 3D vectors are not orthogonal.
**None** : if the two pure quaternions seen as 3D vectors are orthogonal is unknown.

**Explanation**

Two pure quaternions are called orthogonal when their product is anti-commutative.
Examples

>>> from sympy.algebras.quaternion import Quaternion
>>> q = Quaternion(0, 4, 4, 4)
>>> q1 = Quaternion(0, 8, 8, 8)
>>> q.orthogonal(q1)
False

>>> q1 = Quaternion(0, 2, 2, 0)
>>> q = Quaternion(0, 2, -2, 0)
>>> q.orthogonal(q1)
True

parallel(other)

Returns True if the two pure quaternions seen as 3D vectors are parallel.

Parameters

other : a Quaternion

Returns

True : if the two pure quaternions seen as 3D vectors are parallel.
False : if the two pure quaternions seen as 3D vectors are not parallel.
None : if the two pure quaternions seen as 3D vectors are parallel is unknown.

Explanation

Two pure quaternions are called parallel when their vector product is commutative which implies that the quaternions seen as 3D vectors have same direction.

Examples

>>> from sympy.algebras.quaternion import Quaternion
>>> q = Quaternion(0, 4, 4, 4)
>>> q1 = Quaternion(0, 8, 8, 8)
>>> q.parallel(q1)
True

>>> q1 = Quaternion(0, 8, 13, 12)
>>> q.parallel(q1)
False

pow(p)

Finds the pth power of the quaternion.

Parameters

p : int

Power to be applied on quaternion.

Returns

Quaternion
Returns the p-th power of the current quaternion. Returns the inverse if p = -1.

Examples

```
>>> from sympy import Quaternion
>>> q = Quaternion(1, 2, 3, 4)
>>> q.pow(4)
668 + (-224)*i + (-336)*j + (-448)*k
```

\textbf{pow\_cos\_sin}(p)

Computes the pth power in the cos-sin form.

**Parameters**

\textbf{p} : int

Power to be applied on quaternion.

**Returns**

Quaternion

The p-th power in the cos-sin form.

Examples

```
>>> from sympy import Quaternion
>>> q = Quaternion(1, 2, 3, 4)
>>> q.pow_cos_sin(4)
900*cos(4*acos(sqrt(30)/30))
+ 1800*sqrt(29)*sin(4*acos(sqrt(30)/30))/29*i
+ 2700*sqrt(29)*sin(4*acos(sqrt(30)/30))/29*j
+ 3600*sqrt(29)*sin(4*acos(sqrt(30)/30))/29*k
```

\textbf{property product\_matrix\_left}

Returns 4 x 4 Matrix equivalent to a Hamilton product from the left. This can be useful when treating quaternion elements as column vectors. Given a quaternion \( q = a + bi + cj + dk \) where a, b, c and d are real numbers, the product matrix from the left is:

\[
M = \begin{bmatrix}
a & -b & -c & -d \\
- b & a & -d & c \\
-c & d & a & -b \\
-d & c & b & a \\
\end{bmatrix}
\]
Examples

```python
>>> from sympy import Quaternion
>>> from sympy import a, b, c, d
>>> q1 = Quaternion(1, 0, 0, 1)
>>> q2 = Quaternion(a, b, c, d)
>>> q1.product_matrix_left
Matrix([[1, 0, 0, -1],
    [0, 1, -1, 0],
    [0, 1, 1, 0],
    [1, 0, 0, 1]])
>>> q1.product_matrix_left * q2.to_Matrix()
Matrix([[a - d],
    [b - c],
    [b + c],
    [a + d]])
This is equivalent to:

```python
>>> (q1 * q2).to_Matrix()
Matrix([[a - d],
    [b - c],
    [b + c],
    [a + d]])
```

property `product_matrix_right`

Returns 4 x 4 Matrix equivalent to a Hamilton product from the right. This can be useful when treating quaternion elements as column vectors. Given a quaternion \( q = a + bi + cj + dk \) where \( a, b, c \) and \( d \) are real numbers, the product matrix from the left is:

\[
M = \begin{bmatrix}
a & -b & -c & -d \\
b & a & d & -c \\
c & -d & a & b \\
d & c & -b & a \\
\end{bmatrix}
\]

Examples

```python
>>> from sympy import Quaternion
>>> from sympy import a, b, c, d
>>> q1 = Quaternion(a, b, c, d)
>>> q2 = Quaternion(1, 0, 0, 1)
>>> q2.product_matrix_right
Matrix([[1, 0, 0, -1],
    [0, 1, 1, 0],
    [0, -1, 1, 0],
    [1, 0, 0, 1]])
```
Note the switched arguments: the matrix represents the quaternion on the right, but is still considered as a matrix multiplication from the left.

```
>>> q2.product_matrix_right * q1.to_Matrix()
Matrix([  
    [ a - d],  
    [ b + c],  
    [-b + c],  
    [ a + d]])
```

This is equivalent to:

```
>>> (q1 * q2).to_Matrix()
Matrix([  
    [ a - d],  
    [ b + c],  
    [-b + c],  
    [ a + d]])
```

static rotate_point(pin, r)

Returns the coordinates of the point pin (a 3 tuple) after rotation.

Parameters

- **pin**: tuple
  - A 3-element tuple of coordinates of a point which needs to be rotated.
- **r**: Quaternion or tuple
  - Axis and angle of rotation.

It’s important to note that when r is a tuple, it must be of the form (axis, angle)

Returns

- **tuple**: The coordinates of the point after rotation.

Examples

```
>>> from sympy import Quaternion
>>> from sympy import symbols, trigsimp, cos, sin
>>> x = symbols('x')
>>> q = Quaternion(cos(x/2), 0, 0, sin(x/2))
>>> trigsimp(Quaternion.rotate_point((1, 1, 1), q))
(sqrt(2)*cos(x + pi/4), sqrt(2)*sin(x + pi/4), 1)
>>> (axis, angle) = q.to_axis_angle()
>>> trigsimp(Quaternion.rotate_point((1, 1, 1), (axis, angle)))
(sqrt(2)*cos(x + pi/4), sqrt(2)*sin(x + pi/4), 1)
```

scalar_part()

Returns scalar part($S(q)$) of the quaternion $q$. 

5.8. Topics 945
Explanation

Given a quaternion \( q = a + bi + cj + dk \), returns \( S(q) = a \).

Examples

```
>>> from sympy.algebras.quaternion import Quaternion
>>> q = Quaternion(4, 8, 13, 12)
>>> q.scalar_part()
4
```

`set_norm(norm)`

Sets norm of an already instantiated quaternion.

Parameters

- `norm`: None or number

  Pre-defined quaternion norm. If a value is given, Quaternion.norm returns this pre-defined value instead of calculating the norm.

Examples

```
>>> from sympy import Quaternion
>>> from sympy.abc import a, b, c, d
>>> q = Quaternion(a, b, c, d)
>>> q.norm()
sqrt(a**2 + b**2 + c**2 + d**2)
```

Setting the norm:

```
>>> q.set_norm(1)
>>> q.norm()
1
```

Removing set norm:

```
>>> q.set_norm(None)
>>> q.norm()
sqrt(a**2 + b**2 + c**2 + d**2)
```

to_Matrix(vector_only=False)`

Returns elements of quaternion as a column vector. By default, a Matrix of length 4 is returned, with the real part as the first element. If vector_only is True, returns only imaginary part as a Matrix of length 3.

Parameters

- `vector_only`: bool

  If True, only imaginary part is returned. Default value: False

Returns

Matrix

A column vector constructed by the elements of the quaternion.
Examples

```python
>>> from sympy import Quaternion
>>> from sympy.abc import a, b, c, d
>>> q = Quaternion(a, b, c, d)
>>> q
a + b*i + c*j + d*k

>>> q.to_Matrix()
Matrix([[a], [b], [c], [d]])

>>> q.to_Matrix(vector_only=True)
Matrix([[b], [c], [d]])
```

to_axis_angle()

Returns the axis and angle of rotation of a quaternion.

Returns
tuple
Tuple of (axis, angle)

Examples

```python
>>> from sympy import Quaternion
>>> q = Quaternion(1, 1, 1, 1)
>>> (axis, angle) = q.to_axis_angle()
>>> axis
(sqrt(3)/3, sqrt(3)/3, sqrt(3)/3)
>>> angle
2*pi/3
```

to_euler(seq, angle_addition=True, avoid_square_root=False)

Returns Euler angles representing same rotation as the quaternion, in the sequence
given by seq. This implements the method described in [R3].

For degenerate cases (gymbal lock cases), the third angle is set to zero.

Parameters

seq : string of length 3
    Represents the sequence of rotations. For intrinsic rotations, seq
    must be all lowercase and its elements must be from the set `{x',
    'y', 'z'}. For extrinsic rotations, seq must be all uppercase and its
    elements must be from the set `{X', 'Y', 'Z'}`

angle_addition : bool
When True, first and third angles are given as an addition and subtraction of two simpler \( \text{atan2} \) expressions. When False, the first and third angles are each given by a single more complicated \( \text{atan2} \) expression. This equivalent expression is given by:

\[
\text{atan}_2(b, a) \pm \text{atan}_2(d, c) = \text{atan}_2(bc \pm ad, ac \mp bd)
\]

Default value: True

\textit{avoid\_square\_root} : bool

When True, the second angle is calculated with an expression based on \( \text{acos} \), which is slightly more complicated but avoids a square root. When False, second angle is calculated with \( \text{atan2} \), which is simpler and can be better for numerical reasons (some numerical implementations of \( \text{acos} \) have problems near zero). Default value: False

\textbf{Returns}

Tuple

The Euler angles calculated from the quaternion

\textbf{Examples}

```python
>>> from sympy import Quaternion
>>> from sympy.abc import a, b, c, d
>>> euler = Quaternion(a, b, c, d).to_euler('zyz')
>>> euler
(-atan2(-b, c) + atan2(d, a),
 2*atan2(sqrt(b**2 + c**2), sqrt(a**2 + d**2)),
 atan2(-b, c) + atan2(d, a))
```

\textbf{References}

[R3]

\textit{to\_rotation\_matrix}(v=None, homogeneous=True)

Returns the equivalent rotation transformation matrix of the quaternion which represents rotation about the origin if \( v \) is not passed.

\textbf{Parameters}

\( v \) : tuple or None

Default value: None

\textit{homogeneous} : bool

When True, gives an expression that may be more efficient for symbolic calculations but less so for direct evaluation. Both formulas are mathematically equivalent. Default value: True

\textbf{Returns}

tuple

Returns the equivalent rotation transformation matrix of the quaternion which represents rotation about the origin if \( v \) is not passed.
Examples

```python
>>> from sympy import Quaternion
>>> from sympy import symbols, trigsimp, cos, sin
>>> x = symbols('x')
>>> q = Quaternion(cos(x/2), 0, 0, sin(x/2))
>>> trigsimp(q.to_rotation_matrix())
Matrix([[cos(x), -sin(x), 0],
       [sin(x), cos(x), 0],
       [ 0,     0, 1]])
```

Generates a 4x4 transformation matrix (used for rotation about a point other than the origin) if the point(v) is passed as an argument.

classmethod vector_coplanar(q1, q2, q3)

Returns True if the axis of the pure quaternions seen as 3D vectors q1, q2, and q3 are coplanar.

Parameters

- **q1**
  A pure Quaternion.

- **q2**
  A pure Quaternion.

- **q3**
  A pure Quaternion.

Returns

- **True** : if the axis of the pure quaternions seen as 3D vectors q1, q2, and q3 are coplanar.
- **False** : if the axis of the pure quaternions seen as 3D vectors q1, q2, and q3 are not coplanar.
- **None** : if the axis of the pure quaternions seen as 3D vectors q1, q2, and q3 are coplanar is unknown.

Explanation

Three pure quaternions are vector coplanar if the quaternions seen as 3D vectors are coplanar.
Examples

```python
>>> from sympy.algebras.quaternion import Quaternion
>>> q1 = Quaternion(0, 4, 4, 4)
>>> q2 = Quaternion(0, 8, 8, 8)
>>> q3 = Quaternion(0, 24, 24, 24)
>>> Quaternion.vector_coplanar(q1, q2, q3)
True
```

```python
>>> q1 = Quaternion(0, 8, 16, 8)
>>> q2 = Quaternion(0, 8, 3, 12)
>>> Quaternion.vector_coplanar(q1, q2, q3)
False
```

See also:
- `axis` (page 935), `is_pure` (page 939)

vector_part()

Returns vector part($V(q)$) of the quaternion $q$.

Explanation

Given a quaternion $q = a + bi + cj + dk$, returns $V(q) = bi + cj + dk$.

Examples

```python
>>> from sympy.algebras.quaternion import Quaternion
>>> q = Quaternion(1, 1, 1, 1)
>>> q.vector_part()
0 + 1*i + 1*j + 1*k
```

```python
>>> q = Quaternion(4, 8, 13, 12)
>>> q.vector_part()
0 + 8*i + 13*j + 12*k
```

Concrete

Hypergeometric terms

The center stage, in recurrence solving and summations, play hypergeometric terms. Formally these are sequences annihilated by first order linear recurrence operators. In simple words if we are given term $a(n)$ then it is hypergeometric if its consecutive term ratio is a rational function in $n$.

To check if a sequence is of this type you can use the `is_hypergeometric` method which is available in Basic class. Here is simple example involving a polynomial:
```python
>>> from sympy import *
>>> n, k = symbols('n,k')
>>> (n**2 + 1).is_hypergeometric(n)
True
```

Of course polynomials are hypergeometric but are there any more complicated sequences of this type? Here are some trivial examples:

```python
>>> factorial(n).is_hypergeometric(n)
True
>>> binomial(n, k).is_hypergeometric(n)
True
>>> rf(n, k).is_hypergeometric(n)
True
>>> ff(n, k).is_hypergeometric(n)
True
>>> gamma(n).is_hypergeometric(n)
True
>>> (2**n).is_hypergeometric(n)
True
```

We see that all species used in summations and other parts of concrete mathematics are hypergeometric. Note also that binomial coefficients and both rising and falling factorials are hypergeometric in both their arguments:

```python
>>> binomial(n, k).is_hypergeometric(k)
True
>>> rf(n, k).is_hypergeometric(k)
True
>>> ff(n, k).is_hypergeometric(k)
True
```

To say more, all previously shown examples are valid for integer linear arguments:

```python
>>> factorial(2*n).is_hypergeometric(n)
True
>>> binomial(3*n+1, k).is_hypergeometric(n)
True
>>> rf(n+1, k-1).is_hypergeometric(n)
True
>>> ff(n-1, k+1).is_hypergeometric(n)
True
>>> gamma(5*n).is_hypergeometric(n)
True
>>> (2**(n-7)).is_hypergeometric(n)
True
```

However nonlinear arguments make those sequences fail to be hypergeometric:

```python
>>> factorial(n**2).is_hypergeometric(n)
False
>>> (2**(n**3 + 1)).is_hypergeometric(n)
False
```
If not only the knowledge of being hypergeometric or not is needed, you can use `hypersimp()` function. It will try to simplify combinatorial expression and if the term given is hypergeometric it will return a quotient of polynomials of minimal degree. Otherwise it will return `None` to say that sequence is not hypergeometric:

```python
>>> hypersimp(factorial(2*n), n)
2*(n + 1)*(2*n + 1)
>>> hypersimp(factorial(n**2), n)
```

**Concrete Class Reference**

```python
class sympy.concrete.summations.Sum(function, *symbols, **assumptions)
```

Represents unevaluated summation.

**Explanation**

Sum represents a finite or infinite series, with the first argument being the general form of terms in the series, and the second argument being `(dummy_variable, start, end)`, with `dummy_variable` taking all integer values from `start` through `end`. In accordance with long-standing mathematical convention, the end term is included in the summation.

**Finite Sums**

For finite sums (and sums with symbolic limits assumed to be finite) we follow the summation convention described by Karr [1], especially definition 3 of section 1.4. The sum:

\[
\sum_{m \leq i < n} f(i)
\]

has the obvious meaning for \(m < n\), namely:

\[
\sum_{m \leq i < n} f(i) = f(m) + f(m + 1) + \ldots + f(n - 2) + f(n - 1)
\]

with the upper limit value \(f(n)\) excluded. The sum over an empty set is zero if and only if \(m = n\):

\[
\sum_{m \leq i < n} f(i) = 0 \quad \text{for} \quad m = n
\]

Finally, for all other sums over empty sets we assume the following definition:

\[
\sum_{m \leq i < n} f(i) = -\sum_{n \leq i < m} f(i) \quad \text{for} \quad m > n
\]

It is important to note that Karr defines all sums with the upper limit being exclusive. This is in contrast to the usual mathematical notation, but does not affect the summation convention. Indeed we have:

\[
\sum_{m \leq i < n} f(i) = \sum_{i=m}^{n-1} f(i)
\]

where the difference in notation is intentional to emphasize the meaning, with limits typeset on the top being inclusive.
Examples

```python
>>> from sympy import oo, Sum, factorial, IndexedBase, Function
>>> Sum(k, (k, 1, m)).doit()
m**2/2 + m/2
>>> Sum(k**2, (k, 1, m)).doit()
m**3/3 + m**2/2 + m/6
>>> Sum(x**k, (k, 0, oo)).doit()
piecewise((1/(1 - x), Abs(x) < 1), (Sum(x**k, (k, 0, oo)), True))
exp(x)
```

Here are examples to do summation with symbolic indices. You can use either Function of IndexedBase classes:

```python
>>> f = Function('f')
>>> Sum(f(n), (n, 0, 3)).doit()
f(0) + f(1) + f(2) + f(3)
>>> Sum(f(n), (n, 0, oo)).doit()
Sum(f(n), (n, 0, oo))
>>> f = IndexedBase('f')
>>> Sum(f[n]**2, (n, 0, 3)).doit()
f[0]**2 + f[1]**2 + f[2]**2 + f[3]**2
```

An example showing that the symbolic result of a summation is still valid for seemingly nonsensical values of the limits. Then the Karr convention allows us to give a perfectly valid interpretation to those sums by interchanging the limits according to the above rules:

```python
>>> S = Sum(i, (i, 1, n)).doit()
>>> S
n**2/2 + n/2
>>> S.subs(n, -4)
6
>>> Sum(i, (i, 1, -4)).doit()
6
>>> Sum(-i, (i, -3, 0)).doit()
6
```

An explicit example of the Karr summation convention:

```python
>>> S1 = Sum(i**2, (i, m, m+n-1)).doit()
>>> S1
m**2*n + m*n**2 - m*n + n**3/3 - n**2/2 + n/6
>>> S2 = Sum(i**2, (i, m+n, m-1)).doit()
>>> S2
(continues on next page)
```
(continued from previous page)

\[-m^{**2}n - m\ast n^{**2} + m\ast n - n^{**3}/3 + n^{**2}/2 - n/6\]

```python
>>> S1 + S2
0
>>> S3 = Sum(i, (i, m, m-1)).doit()
>>> S3
0
```

**References**

[R92], [R93], [R94]

euler_maclaurin\((m=0, n=0, eps=0, eval_integral=True)\)

Return an Euler-Maclaurin approximation of self, where \(m\) is the number of leading terms to sum directly and \(n\) is the number of terms in the tail.

With \(m = n = 0\), this is simply the corresponding integral plus a first-order endpoint correction.

Returns \((s, e)\) where \(s\) is the Euler-Maclaurin approximation and \(e\) is the estimated error (taken to be the magnitude of the first omitted term in the tail):

```python
>>> from sympy.abc import k, a, b
>>> from sympy import Sum

>>> Sum(1/k, (k, 2, 5)).doit().evalf()  # Euler-Maclaurin approximation
1.28333333333333

>>> s, e = Sum(1/k, (k, 2, 5)).euler_maclaurin()

>>> s
-log(2) + 7/20 + log(5)

>>> e
Abs(1/(12*b**2) - 1/(12*a**2))

>>> s, e = Sum(1/k, (k, a, b)).euler_maclaurin()

>>> s
-log(a) + log(b) + 1/(2*b) + 1/(2*a)

>>> e
Abs(1/(12*b**2) - 1/(12*a**2))
```

The endpoints may be symbolic:

```python
>>> s, e = Sum(1/k, (k, a, b)).euler_maclaurin()

>>> s
-log(a) + log(b) + 1/(2*b) + 1/(2*a)

>>> e
Abs(1/(12*b**2) - 1/(12*a**2))
```

If the function is a polynomial of degree at most \(2n+1\), the Euler-Maclaurin formula becomes exact (and \(e = 0\) is returned):

```python
>>> Sum(k, (k, 2, b)).euler_maclaurin()
(b**2/2 + b/2 - 1, 0)

>>> Sum(k, (k, 2, b)).doit()

b**2/2 + b/2 - 1
```
With a nonzero eps specified, the summation is ended as soon as the remainder term is less than the epsilon.

**eval_zeta_function**(f, limits)
Check whether the function matches with the zeta function.
If it matches, then return a *Piecewise* expression because zeta function does not converge unless \( s > 1 \) and \( q > 0 \)

**is_absolutely_convergent()**
Checks for the absolute convergence of an infinite series.
Same as checking convergence of absolute value of sequence_term of an infinite series.

**Examples**

```python
>>> from sympy import Sum, Symbol, oo
>>> n = Symbol('n', integer=True)
>>> Sum((-1)**n, (n, 1, oo)).is_absolutely_convergent()
False
>>> Sum((-1)**n/n**2, (n, 1, oo)).is_absolutely_convergent()
True
```

**See also:**
- `Sum.is_convergent` (page 955)

**References**

[R95]

**is_convergent()**
Checks for the convergence of a Sum.

**Explanation**
We divide the study of convergence of infinite sums and products in two parts.
First Part: One part is the question whether all the terms are well defined, i.e., they are finite in a sum and also non-zero in a product. Zero is the analogy of (minus) infinity in products as \( e^{-\infty} = 0 \).
Second Part: The second part is the question of convergence after infinities, and zeros in products, have been omitted assuming that their number is finite. This means that we only consider the tail of the sum or product, starting from some point after which all terms are well defined.
For example, in a sum of the form:

\[
\sum_{1 \leq i < \infty} \frac{1}{n^2 + an + b}
\]
where \(a\) and \(b\) are numbers. The routine will return true, even if there are infinities in the term sequence (at most two). An analogous product would be:

\[
\prod_{1 \leq i < \infty} e^{\frac{1}{n^2 + n + 1}}
\]

This is how convergence is interpreted. It is concerned with what happens at the limit. Finding the bad terms is another independent matter.

Note: It is responsibility of user to see that the sum or product is well defined.

There are various tests employed to check the convergence like divergence test, root test, integral test, alternating series test, comparison tests, Dirichlet tests. It returnstrue if Sum is convergent and false if divergent and NotImplemented if it cannot be checked.

**Examples**

```python
def reverse_order(self, *indices):
    # Reverse the order of a limit in a Sum.
    # reverse_order(self, *indices) reverses some limits in the expression self which can be either a Sum or a Product.
    # The selectors in the argument indices specify some indices whose limits get reversed. These selectors are either variable names or numerical indices counted starting from the inner-most limit tuple.
```

**See also:**

- :func:`sum.is_absolutely_convergent`
- :func:`sympy.concrete.products.Product.is_convergent`

**References**

[R96]
Examples

```python
>>> from sympy import Sum
>>> from sympy.abc import x, y, a, b, c, d

>>> Sum(x, (x, 0, 3)).reverse_order(x)
Sum(-x, (x, 4, -1))
>>> Sum(x*y, (x, 1, 5), (y, 0, 6)).reverse_order(x, y)
Sum(-x*y, (x, 6, 0), (y, 7, -1))
>>> Sum(x, (x, a, b)).reverse_order(x)
Sum(-x, (x, b + 1, a - 1))
>>> Sum(x, (x, a, b)).reverse_order(y)
Sum(-x*y, (x, b + 1, a - 1))

While one should prefer variable names when specifying which limits to reverse, the
index counting notation comes in handy in case there are several symbols with the
same name.

```python
>>> S = Sum(x**2, (x, a, b), (x, c, d))
>>> S
Sum(x**2, (x, a, b), (x, c, d))
>>> S0 = S.reverse_order(0)
>>> S0
Sum(-x**2, (x, b + 1, a - 1), (x, c, d))
>>> S1 = S0.reverse_order(1)
>>> S1
Sum(x**2, (x, b + 1, a - 1), (x, d + 1, c - 1))

Of course we can mix both notations:

```python
>>> Sum(x*y, (x, a, b), (y, 2, 5)).reverse_order(x, 1)
Sum(-x*y, (x, b + 1, a - 1), (y, 6, 1))
>>> Sum(x*y, (x, a, b), (y, 2, 5)).reverse_order(y, x)
Sum(x*y, (x, b + 1, a - 1), (y, 6, 1))
```

References

[R97] sympy.concrete.products.Product(function, *symbols, **assumptions)
Represents unevaluated products.
Explaination

Product represents a finite or infinite product, with the first argument being the general form of terms in the series, and the second argument being \((\text{dummy\_variable}, \text{start}, \text{end})\), with \text{dummy\_variable} taking all integer values from \text{start} through \text{end}. In accordance with long-standing mathematical convention, the end term is included in the product.

Finite Products

For finite products (and products with symbolic limits assumed to be finite) we follow the analogue of the summation convention described by Karr [1], especially definition 3 of section 1.4. The product:

\[
\prod_{m \leq i < n} f(i)
\]

has the obvious meaning for \(m < n\), namely:

\[
\prod_{m \leq i < n} f(i) = f(m)f(m+1) \cdots f(n-2)f(n-1)
\]

with the upper limit value \(f(n)\) excluded. The product over an empty set is one if and only if \(m = n:\)

\[
\prod_{m \leq i < n} f(i) = 1 \text{ for } m = n
\]

Finally, for all other products over empty sets we assume the following definition:

\[
\prod_{m \leq i < n} f(i) = \frac{1}{\prod_{n \leq i < m} f(i)} \text{ for } m > n
\]

It is important to note that above we define all products with the upper limit being exclusive. This is in contrast to the usual mathematical notation, but does not affect the product convention. Indeed we have:

\[
\prod_{m \leq i < n} f(i) = \prod_{i=m}^{n-1} f(i)
\]

where the difference in notation is intentional to emphasize the meaning, with limits typeset on the top being inclusive.

Examples

```python
>>> from sympy.abc import a, b, i, k, m, n, x
>>> from sympy import Product, oo
>>> Product(k, (k, 1, m))
Product(k, (k, 1, m))
>>> Product(k, (k, 1, m)).doit()
factorial(m)
>>> Product(k**2, (k, 1, m))
Product(k**2, (k, 1, m))
>>> Product(k**2, (k, 1, m)).doit()
factorial(m)**2
```
Wallis' product for pi:

```python
>>> W = Product(2*i/(2*i - 1) * 2*i/(2*i + 1), (i, 1, oo))
>>> W
Product(4*i**2/((2*i - 1)*(2*i + 1)), (i, 1, oo))
```

Direct computation currently fails:

```python
>>> W.doit()
Product(4*i**2/((2*i - 1)*(2*i + 1)), (i, 1, oo))
```

But we can approach the infinite product by a limit of finite products:

```python
>>> from sympy import limit
>>> W2 = Product(2*i/(2*i - 1)*2*i/(2*i + 1), (i, 1, n))
>>> W2
Product(4*i**2/((2*i - 1)*(2*i + 1)), (i, 1, n))
>>> W2e = W2.doit()
>>> W2e
4**n*factorial(n)**2/(2**(2*n)*RisingFactorial(1/2, n)*RisingFactorial(3/2, n))
>>> limit(W2e, n, oo)
pi/2
```

By the same formula we can compute \(\sin(\pi/2)\):

```python
>>> from sympy import combsimp, pi, gamma, simplify
>>> P = pi * x * Product(1 - x**2/k**2, (k, 1, n))
>>> P = P.subs(x, pi/2)
>>> P
pi**2*Product(1 - pi**2/(4*k**2), (k, 1, n))/2
>>> Pe = P.doit()
>>> Pe
pi**2*RisingFactorial(1 - pi/2, n)*RisingFactorial(1 + pi/2, n)/((2*factorial(n)**2)
>>> limit(Pe, n, oo).gammasimp()  
sin(pi/2)
>>> Pe rewrite(gamma)
(-1)**n*pi**2*gamma(pi/2)*gamma(n + 1 + pi/2)/(2*gamma(1 + pi/2)*gamma(-n + pi/2)*gamma(n + 1)**2)
```

Products with the lower limit being larger than the upper one:

```python
>>> Product(1/i, (i, 6, 1)).doit()
120
>>> Product(i, (i, 2, 5)).doit()
120
```

The empty product:

```python
>>> Product(i, (i, n, n-1)).doit()
1
```

An example showing that the symbolic result of a product is still valid for seemingly nonsensical values of the limits. Then the Karr convention allows us to give a perfectly
valid interpretation to those products by interchanging the limits according to the above rules:

```python
>>> P = Product(2, (i, 10, n)).doit()
>>> P
2**(n - 9)
>>> P.subs(n, 5)
1/16
>>> Product(2, (i, 10, 5)).doit()
1/16
>>> 1/Product(2, (i, 6, 9)).doit()
1/16
```

An explicit example of the Karr summation convention applied to products:

```python
>>> P1 = Product(x, (i, a, b)).doit()
>>> P1
x**(-a + b + 1)
>>> P2 = Product(x, (i, b+1, a-1)).doit()
>>> P2
x**(a - b - 1)
>>> simplify(P1 * P2)
1
```

And another one:

```python
>>> P1 = Product(i, (i, b, a)).doit()
>>> P1
RisingFactorial(b, a - b + 1)
>>> P2 = Product(i, (i, a+1, b-1)).doit()
>>> P2
RisingFactorial(a + 1, -a + b - 1)
>>> P1 * P2
RisingFactorial(b, a - b + 1)*RisingFactorial(a + 1, -a + b - 1)
>>> combsimp(P1 * P2)
1
```

**References**

[R98], [R99], [R100]

**is_convergent()**

See docs of `Sum.is_convergent()` (page 955) for explanation of convergence in SymPy.
Explaination

The infinite product:

\[
\prod_{1 \leq i < \infty} f(i)
\]

is defined by the sequence of partial products:

\[
\prod_{i=1}^{n} f(i) = f(1)f(2) \cdots f(n)
\]

as \( n \) increases without bound. The product converges to a non-zero value if and only if the sum:

\[
\sum_{1 \leq i < \infty} \log f(n)
\]

cconverges.

Examples

```python
>>> from sympy import Product, Symbol, cos, pi, exp, oo
>>> n = Symbol('n', integer=True)
>>> Product(n/(n + 1), (n, 1, oo)).is_convergent()
False
>>> Product(1/n**2, (n, 1, oo)).is_convergent()
False
>>> Product(cos(pi/n), (n, 1, oo)).is_convergent()
True
>>> Product(exp(-n**2), (n, 1, oo)).is_convergent()
False
```

References

[R101]

`reverse_order(*indices)`

Reverse the order of a limit in a Product.

Explanation

`reverse_order(expr, *indices)` reverses some limits in the expression `expr` which can be either a `Sum` or a `Product`. The selectors in the argument `indices` specify some indices whose limits get reversed. These selectors are either variable names or numerical indices counted starting from the inner-most limit tuple.
Examples

```python
from sympy import gamma, Product, simplify, Sum
from sympy.abc import x, y, a, b, c, d

P = Product(x, (x, a, b))
Pr = P.reverse_order(x)
Pr
Product(1/x, (x, b + 1, a - 1))
Pr = Pr.doit()
Pr
1/RisingFactorial(b + 1, a - b - 1)
simplify(Pr.rewrite(gamma))
Piecewise((gamma(b + 1)/gamma(a), b > -1), ((-1)**(-a + b + 1)*gamma(1 - a)/gamma(-b), True))

P = P.doit()
P
RisingFactorial(a, -a + b + 1)
simplify(P.rewrite(gamma))
Piecewise((gamma(b + 1)/gamma(a), a > 0), ((-1)**(-a + b + 1)*gamma(1 - a)/gamma(-b), True))
```

While one should prefer variable names when specifying which limits to reverse, the index counting notation comes in handy in case there are several symbols with the same name.

```python
S = Sum(x*y, (x, a, b), (y, c, d))
S
S0 = S.reverse_order(0)
S0
Sum(-x*y, (x, b + 1, a - 1), (y, c, d))
S1 = S0.reverse_order(1)
S1
Sum(x*y, (x, b + 1, a - 1), (y, d + 1, c - 1))
```

Of course we can mix both notations:

```python
Sum(x*y, (x, a, b), (y, 2, 5)).reverse_order(x, 1)
Sum(x*y, (x, b + 1, a - 1), (y, 6, 1))
Sum(x*y, (x, a, b), (y, 2, 5)).reverse_order(y, x)
Sum(x*y, (x, b + 1, a - 1), (y, 6, 1))
```

See also:

- `sympy.concrete.expr_with_intlimits.ExprWithIntLimits.index` (page 965), `reorder_limit` (page 966), `sympy.concrete.expr_with_intlimits.ExprWithIntLimits.reorder` (page 966)
### References

[R102]

class sympy.concrete.expr_with_intlimits.ExprWithIntLimits(function, *symbols, **assumptions)

Superclass for Product and Sum.

**See also:**

**change_index**(*var, trafo, newvar=None*)

Change index of a Sum or Product.

Perform a linear transformation \( x \mapsto ax + b \) on the index variable \( x \). For \( a \) the only values allowed are \( \pm 1 \). A new variable to be used after the change of index can also be specified.

**Explanation**

change_index(expr, var, trafo, newvar=None) where var specifies the index variable \( x \) to transform. The transformation trafo must be linear and given in terms of var. If the optional argument newvar is provided then var gets replaced by newvar in the final expression.

**Examples**

```python
>>> from sympy import Sum, Product, simplify
>>> from sympy.abc import x, y, a, b, c, d, u, v, i, j, k, l

>>> S = Sum(x, (x, a, b))
>>> S.doit()
-a**2/2 + a/2 + b**2/2 + b/2

>>> Sn = S.change_index(x, x + 1, y)
>>> Sn
Sum(y - 1, (y, a + 1, b + 1))
>>> Sn.doit()
-a**2/2 + a/2 + b**2/2 + b/2

>>> Sn = S.change_index(x, -x, y)
>>> Sn
Sum(-y, (y, -b, -a))
>>> Sn.doit()
-a**2/2 + a/2 + b**2/2 + b/2

>>> Sn = S.change_index(x, x+u)
>>> Sn
Sum(-u + x, (x, a + u, b + u))
```

(continues on next page)
When dealing with symbols only, we can make a general linear transformation:

```python
>>> Sn = S.change_index(x, u*x+v, y)
>>> Sn
Sum((-v + y)/u, (y, b*u + v, a*u + v))
>>> Sn.doit()
-v*(a*u - b*u + 1)/u + (a**2*u**2/2 + a*u*v + a*u/2 - b**2*u**2/2 - u
   -b*u*v + b*u/2 + v)/u
>>> simplify(Sn.doit())
a**2*u/2 + a/2 - b**2*u/2 + b/2
```

However, the last result can be inconsistent with usual summation where the index increment is always 1. This is obvious as we get back the original value only for \( u \) equal +1 or -1.

**See also:**

**property has_empty_sequence**

Returns True if the Sum or Product is computed for an empty sequence.
Examples

```python
>>> from sympy import Sum, Product, Symbol
>>> m = Symbol('m')
>>> Sum(m, (m, 1, 0)).has_empty_sequence
True

>>> Sum(m, (m, 1, 1)).has_empty_sequence
False

>>> M = Symbol('M', integer=True, positive=True)
>>> Product(m, (m, 1, M)).has_empty_sequence
False

>>> Product(m, (m, 2, M)).has_empty_sequence
True

>>> N = Symbol('N', integer=True, positive=True)
>>> Sum(m, (m, N, M)).has_empty_sequence

>>> N = Symbol('N', integer=True, negative=True)
>>> Sum(m, (m, N, M)).has_empty_sequence
False
```

See also:

`has_reversed_limits` (page 666), `has_finite_limits` (page 666)

`index(x)`

Return the index of a dummy variable in the list of limits.

Explanation

`index(expr, x)` returns the index of the dummy variable `x` in the limits of `expr`. Note that we start counting with 0 at the inner-most limits tuple.

Examples

```python
>>> from sympy.abc import x, y, a, b, c, d
>>> from sympy import Sum, Product
>>> Sum(x*y, (x, a, b), (y, c, d)).index(x)
0

>>> Sum(x*y, (x, a, b), (y, c, d)).index(y)
1

>>> Product(x*y, (x, a, b), (y, c, d)).index(x)
0

>>> Product(x*y, (x, a, b), (y, c, d)).index(y)
1
```
See also: 

`reorder_limit` (page 966), `reorder` (page 966), `sympy.concrete.summations.Sum.reverse_order` (page 956), `sympy.concrete.products.Product.reverse_order` (page 961)

**reorder(***arg***)

Reorder limits in a expression containing a Sum or a Product.

**Explanation**

expr.reorder(**arg**) reorders the limits in the expression expr according to the list of tuples given by arg. These tuples can contain numerical indices or index variable names or involve both.

**Examples**

```python
>>> from sympy import Sum, Product
>>> from sympy.abc import x, y, z, a, b, c, d, e, f

>>> Sum(x*y, (x, a, b), (y, c, d)).reorder((x, y))
Sum(x*y, (y, c, d), (x, a, b))

>>> Sum(x*y*z, (x, a, b), (y, c, d), (z, e, f)).reorder((x, y), (x, z), (y, z))
Sum(x*y*z, (z, e, f), (y, c, d), (x, a, b))

>>> P = Product(x*y*z, (x, a, b), (y, c, d), (z, e, f))
>>> P.reorder((x, y), (x, z), (y, z))
Product(x*y*z, (z, e, f), (y, c, d), (x, a, b))
```

We can also select the index variables by counting them, starting with the inner-most one:

```python
>>> Sum(x**2, (x, a, b), (x, c, d)).reorder((0, 1))
Sum(x**2, (x, c, d), (x, a, b))
```

And of course we can mix both schemes:

```python
>>> Sum(x*y, (x, a, b), (y, c, d)).reorder((y, x))
Sum(x*y, (y, c, d), (x, a, b))
>>> Sum(x*y, (x, a, b), (y, c, d)).reorder((y, 0))
Sum(x*y, (y, c, d), (x, a, b))
```

See also:

`reorder_limit` (page 966), `index` (page 965), `sympy.concrete.summations.Sum.reverse_order` (page 956), `sympy.concrete.products.Product.reverse_order` (page 961)

**reorder_limit**(x, y)

Interchange two limit tuples of a Sum or Product expression.
SymPy Documentation, Release 1.12.1

Explanation

expr.reorder_limit(x, y) interchanges two limit tuples. The arguments x and y are integers corresponding to the index variables of the two limits which are to be interchanged. The expression expr has to be either a Sum or a Product.

Examples

```python
>>> from sympy.abc import x, y, z, a, b, c, d, e, f
>>> from sympy import Sum, Product

>>> Sum(x*y*z, (x, a, b), (y, c, d), (z, e, f)).reorder_limit(0, 2)
Sum(x*y*z, (z, e, f), (y, c, d), (x, a, b))

>>> Sum(x**2, (x, a, b), (x, c, d)).reorder_limit(1, 0)
Sum(x**2, (x, c, d), (x, a, b))

>>> Product(x*y*z, (x, a, b), (y, c, d), (z, e, f)).reorder_limit(0, 2)
Product(x*y*z, (z, e, f), (y, c, d), (x, a, b))
```

index (page 965), reorder (page 966), sympy.concrete.summations.Sum.reverse_order (page 956), sympy.concrete.products.Product.reverse_order (page 961)

Concrete Functions Reference

sympy.concrete.summations.summation(f, *symbols, **kwargs)

Compute the summation of f with respect to symbols.

Explanation

The notation for symbols is similar to the notation used in Integral. summation(f, (i, a, b)) computes the sum of f with respect to i from a to b, i.e.,

\[
\text{summation}(f, (i, a, b)) = \sum_{i=a}^{b} f
\]

If it cannot compute the sum, it returns an unevaluated Sum object. Repeated sums can be computed by introducing additional symbols tuples:

```python
>>> from sympy import summation, oo, symbols, log
>>> i, n, m = symbols('i n m', integer=True)
```
```python
>>> summation(2*i - 1, (i, 1, n))
n**2
>>> summation(1/2**i, (i, 0, oo))
2
>>> summation(1/log(n)**n, (n, 2, oo))
Sum(log(n)**(-n), (n, 2, oo))
>>> summation(i, (i, 0, n), (n, 0, m))
m**3/6 + m**2/2 + m/3
```

```python
>>> from sympy.abc import x
>>> from sympy import factorial
>>> summation(x**n/factorial(n), (n, 0, oo))
exp(x)
```

See also:

```
sympy.concrete.products.product(*args, **kwargs)
```

Compute the product.

**Explanation**

The notation for symbols is similar to the notation used in Sum or Integral. `product(f, (i, a, b))` computes the product of f with respect to i from a to b, i.e.,

\[
\prod_{i=a}^{b} f(n)
\]

If it cannot compute the product, it returns an unevaluated `Product` object. Repeated products can be computed by introducing additional symbols tuples:

```python
>>> from sympy import product, symbols
>>> i, n, m, k = symbols('i n m k', integer=True)
```
Explanation

Given relatively prime univariate polynomials \( f \) and \( g \), rewrite their quotient to a normal form defined as follows:

\[
\frac{f(n)}{g(n)} = Z \cdot \frac{A(n)C(n+1)}{B(n)C(n)}
\]

where \( Z \) is an arbitrary constant and \( A, B, C \) are monic polynomials in \( n \) with the following properties:

1. \( \gcd(A(n), B(n+h)) = 1 \forall h \in \mathbb{N} \)
2. \( \gcd(B(n), C(n+1)) = 1 \)
3. \( \gcd(A(n), C(n)) = 1 \)

This normal form, or rational factorization in other words, is a crucial step in Gosper’s algorithm and in solving of difference equations. It can be also used to decide if two hypergeometric terms are similar or not.

This procedure will return a tuple containing elements of this factorization in the form \((Z*A, B, C)\).

Examples

```python
>>> from sympy.concrete.gosper import gosper_normal
>>> from sympy.abc import n

>>> gosper_normal(4*n+5, 2*(4*n+1)*(2*n+3), n, polys=False)
(1/4, n + 3/2, n + 1/4)
```

```
Compu```
sympy.concrete.gosper.gosper_sum(f, k)
Gosper’s hypergeometric summation algorithm.

Explanation
Given a hypergeometric term $f$ such that:

$$s_n = \sum_{k=0}^{n-1} f_k$$

and $f(n)$ does not depend on $n$, returns $g_n - g(0)$ where $g_{n+1} - g_n = f_n$, or None if $s_n$ cannot be expressed in closed form as a sum of hypergeometric terms.

Examples

```python
>>> from sympy.concrete.gosper import gosper_sum
>>> from sympy import factorial
>>> from sympy.abc import n, k

>>> f = (4*k + 1)*factorial(k)/factorial(2*k + 1)
>>> gosper_sum(f, (k, 0, n))
(-factorial(n) + 2*factorial(2*n + 1))/factorial(2*n + 1)
>>> _.subs(n, 2) == sum(f.subs(k, i) for i in [0, 1, 2])
True
>>> gosper_sum(f, (k, 3, n))
(-60*factorial(n) + factorial(2*n + 1))/(60*factorial(2*n + 1))
>>> _.subs(n, 5) == sum(f.subs(k, i) for i in [3, 4, 5])
True
```

Core

sympify

sympy.core.sympify.sympify(a, locals=None, convert_xor=True, strict=False, rational=False, evaluate=None)

Converts an arbitrary expression to a type that can be used inside SymPy.

Parameters

- a:
  - any object defined in SymPy
  - standard numeric Python types: int, long, float, Decimal
  - strings (like "0.09", "2e-19" or 'sin(x)')
• booleans, including None (will leave None unchanged)
• dicts, lists, sets or tuples containing any of the above

convert_xor : bool, optional

  If true, treats ^ as exponentiation. If False, treats ^ as XOR itself. Used only when input is a string.

locals : any object defined in SymPy, optional

  In order to have strings be recognized it can be imported into a namespace dictionary and passed as locals.

strict : bool, optional

  If the option strict is set to True, only the types for which an explicit conversion has been defined are converted. In the other cases, a SympifyError is raised.

rational : bool, optional

  If True, converts floats into Rational (page 1036). If False, it lets floats remain as it is. Used only when input is a string.

evaluate : bool, optional

  If False, then arithmetic and operators will be converted into their SymPy equivalents. If True the expression will be evaluated and the result will be returned.

Explanation

It will convert Python ints into instances of Integer (page 1038), floats into instances of Float (page 1033), etc. It is also able to coerce symbolic expressions which inherit from Basic (page 979). This can be useful in cooperation with SAGE.

Warning: Note that this function uses eval, and thus shouldn’t be used on unsanitized input.

If the argument is already a type that SymPy understands, it will do nothing but return that value. This can be used at the beginning of a function to ensure you are working with the correct type.

Examples

```python
>>> from sympy import sympify

>>> sympify(2).is_integer
True
>>> sympify(2).is_real
True
```
If the expression could not be converted, a SympifyError is raised.

```python
>>> sympify("x***2")
Traceback (most recent call last):
...  
SympifyError: SympifyError: "could not parse 'x***2'"
```

### Locals

The sympification happens with access to everything that is loaded by `from sympy import *`; anything used in a string that is not defined by that import will be converted to a symbol. In the following, the `bitcount` function is treated as a symbol and the 0 is interpreted as the `Order` (page 686) object (used with series) and it raises an error when used improperly:

```python
>>> s = 'bitcount(42)'
>>> sympify(s)
bitcount(42)
>>> sympify("O(x)")
O(x)
>>> sympify("0 + 1")
Traceback (most recent call last):
...  
TypeError: unbound method...
```

In order to have `bitcount` be recognized it can be imported into a namespace dictionary and passed as `locals`:

```python
>>> ns = {}
>>> exec('from sympy.core.evalf import bitcount', ns)
>>> sympify(s, locals=ns)
6
```

In order to have the 0 interpreted as a Symbol, identify it as such in the namespace dictionary. This can be done in a variety of ways; all three of the following are possibilities:

```python
>>> from sympy import Symbol
>>> ns["0"] = Symbol("0") # method 1
>>> exec('from sympy.abc import O', ns) # method 2
>>> ns.update(dict(O=Symbol("O"))) # method 3
>>> sympify("0 + 1", locals=ns)
O + 1
```

If you want all single-letter and Greek-letter variables to be symbols then you can use the clashing-symbols dictionaries that have been defined there as private variables: `_clash1`
(single-letter variables), _clash2 (the multi-letter Greek names) or _clash (both single
and multi-letter names that are defined in abc).

```python
>>> from sympy.abc import _clash1
>>> set(_clash1)  # if this fails, see issue #23903
{'E', 'I', 'N', 'O', 'Q', 'S'}
>>> sympify('I & Q', _clash1)
I & Q
```

**Strict**

If the option strict is set to True, only the types for which an explicit conversion has
been defined are converted. In the other cases, a SympifyError is raised.

```python
>>> print(sympify(None))
None
>>> sympify(None, strict=True)
Traceback (most recent call last):
... SympifyError: SympifyError: None
```

Deprecated since version 1.6: sympify(obj) automatically falls back to str(obj) when
all other conversion methods fail, but this is deprecated. strict=True will disable this
deprecated behavior. See *The string fallback in sympify()* (page 229).

**Evaluation**

If the option evaluate is set to False, then arithmetic and operators will be converted
into their SymPy equivalents and the evaluate=False option will be added. Nested Add
or Mul will be denested first. This is done via an AST transformation that replaces oper-
ators with their SymPy equivalents, so if an operand redefines any of those operations,
the redefined operators will not be used. If argument a is not a string, the mathematical
expression is evaluated before being passed to sympify, so adding evaluate=False will
still return the evaluated result of expression.

```python
>>> sympify('2**2 / 3 + 5')
19/3
>>> sympify('2**2 / 3 + 5', evaluate=False)
2**2/3 + 5
>>> sympify('4/2+7', evaluate=True)
9
>>> sympify('4/2+7', evaluate=False)
4/2 + 7
>>> sympify(4/2+7, evaluate=False)
9.00000000000000
```
Extending

To extend sympify to convert custom objects (not derived from Basic), just define a _sympy_ method to your class. You can do that even to classes that you do not own by subclassing or adding the method at runtime.

```python
>>> from sympy import Matrix
>>> class MyList1(object):
...     def __iter__(self):
...             yield 1
...             yield 2
...             return
...     def __getitem__(self, i):
...             return list(self)[i]
...     def _sympy_(self):
...             return Matrix(self)

```

```text
sympify(MyList1())
Matrix([[1], [2]])
```

If you do not have control over the class definition you could also use the converter global dictionary. The key is the class and the value is a function that takes a single argument and returns the desired SymPy object, e.g. converter[MyList] = lambda x: Matrix(x).

```python
>>> class MyList2(object):
...     def __iter__(self):
...             yield 1
...             yield 2
...             return
...     def __getitem__(self, i):
...             return list(self)[i]

```

```text
>>> from sympy.core.sympify import converter
>>> converter[MyList2] = lambda x: Matrix(x)

```

```text
sympify(MyList2())
Matrix([[1], [2]])
```

Notes

The keywords rational and convert_xor are only used when the input is a string.
Convert_xor

```python
>>> sympify('x^y',convert_xor=True)
x**y
>>> sympify('x^y',convert_xor=False)
x ^ y
```

Rational

```python
>>> sympify('0.1',rational=False)
0.1
>>> sympify('0.1',rational=True)
1/10
```

Sometimes autosimplification during sympification results in expressions that are very different in structure than what was entered. Until such autosimplification is no longer done, the kernS function might be of some use. In the example below you can see how an expression reduces to \(-1\) by autosimplification, but does not do so when kernS is used.

```python
>>> from sympy.core.sympify import kernS
>>> from sympy.abc import x
>>> -2*(-(-x + 1/x)/(x*(x - 1/x)**2) - 1/(x*(x - 1/x))) - 1
-1
>>> s = '-2*(-(-x + 1/x)/(x*(x - 1/x)**2) - 1/(x*(x - 1/x))) - 1'
>>> sympify(s)
-1
>>> kernS(s)
-2*(-(-x + 1/x)/(x*(x - 1/x)**2) - 1/(x*(x - 1/x))) - 1
```

Assumptions

This module contains the machinery handling assumptions. Do also consider the guide Assumptions (page 71).

All symbolic objects have assumption attributes that can be accessed via `.is_<assumption name>` attribute.

Assumptions determine certain properties of symbolic objects and can have 3 possible values: True, False, None. True is returned if the object has the property and False is returned if it does not or cannot (i.e. does not make sense):

```python
>>> from sympy import I
>>> I.is_algebraic
True
>>> I.is_real
False
>>> I.is_prime
False
```

When the property cannot be determined (or when a method is not implemented) None will be returned. For example, a generic symbol, x, may or may not be positive so a value of None is returned for `x.is_positive`. 

5.8. Topics
By default, all symbolic values are in the largest set in the given context without specifying the property. For example, a symbol that has a property being integer, is also real, complex, etc.

Here follows a list of possible assumption names:

**commtuitive**
- object commutes with any other object with respect to multiplication operation. See\(^\text{12}\).

**complex**
- object can have only values from the set of complex numbers. See\(^\text{13}\).

**imaginary**
- object value is a number that can be written as a real number multiplied by the imaginary unit \(i\). See \([\text{R106}]\). Please note that 0 is not considered to be an imaginary number, see issue \#7649.

**real**
- object can have only values from the set of real numbers.

**extended_real**
- object can have only values from the set of real numbers, oo and -oo.

**integer**
- object can have only values from the set of integers.

**odd**
- object can have only values from the set of odd (even) integers \([\text{R105}]\).

**even**
- object can have only values from the set of odd (even) integers \([\text{R105}]\).

**prime**
- object is a natural number greater than 1 that has no positive divisors other than 1 and itself. See \([\text{R109}]\).

**composite**
- object is a positive integer that has at least one positive divisor other than 1 or the number itself. See \([\text{R107}]\).

**zero**
- object has the value of 0.

**nonzero**
- object is a real number that is not zero.

**rational**
- object can have only values from the set of rationals.

**algebraic**
- object can have only values from the set of algebraic numbers\(^\text{11}\).

**transcendental**
- object can have only values from the set of transcendental numbers\(^\text{10}\).

**irrational**
- object value cannot be represented exactly by \textit{Rational} (page 1036), see \([\text{R108}]\).

\(^{12}\) \url{https://en.wikipedia.org/wiki/Commutative_property}

\(^{13}\) \url{https://en.wikipedia.org/wiki/Complex_number}

\(^{11}\) \url{https://en.wikipedia.org/wiki/Algebraic_number}

\(^{10}\) \url{https://en.wikipedia.org/wiki/Transcendental_number}
finite
infinite
    object absolute value is bounded (arbitrarily large). See [R110], [R111], [R112].

negative
nonnegative
    object can have only negative (nonnegative) values [R104].

positive
nonpositive
    object can have only positive (nonpositive) values.

extended_negative
extended_nonnegative
extended_positive
extended_nonpositive
extended_nonzero
    as without the extended part, but also including infinity with corresponding sign, e.g., extended_positive includes oo

hermitian
antihermitian
    object belongs to the field of Hermitian (antihermitian) operators.

Examples

```python
>>> from sympy import Symbol
>>> x = Symbol('x', real=True); x
x
>>> x.is_real
True
>>> x.is_complex
True
```

See also:

sympy.core.numbers.ImaginaryUnit (page 1050) sympy.core.numbers.Zero (page 1045)
sympy.core.numbers.One (page 1046) sympy.core.numbers.Infinity (page 1048) sympy.
core.numbers.NegativeInfinity (page 1048) sympy.core.numbers.ComplexInfinity (page 1048)
Notes

The fully-resolved assumptions for any SymPy expression can be obtained as follows:

```python
>>> from sympy.core.assumptions import assumptions
>>> x = Symbol('x', positive=True)
>>> assumptions(x + I)
```

Developers Notes

The current (and possibly incomplete) values are stored in the obj.assumptions dictionary; queries to getter methods (with property decorators) or attributes of objects/classes will return values and update the dictionary.

```python
>>> eq = x**2 + I
>>> eq._assumptions
{}
>>> eq.is_finite
True
>>> eq._assumptions
{'finite': True, 'infinite': False}
```

For a `Symbol` (page 1028), there are two locations for assumptions that may be of interest. The assumptions0 attribute gives the full set of assumptions derived from a given set of initial assumptions. The latter assumptions are stored as Symbol._assumptions_orig

```python
>>> Symbol('x', prime=True, even=True)._assumptions_orig
{'even': True, 'prime': True}
```

The _assumptions_orig are not necessarily canonical nor are they filtered in any way: they records the assumptions used to instantiate a Symbol and (for storage purposes) represent a more compact representation of the assumptions needed to recreate the full set in Symbol. assumptions0.
References

cache

sympy.core.cache.__cacheit(maxsize)

caching decorator.

important: the result of cached function must be immutable

Examples

>>> from sympy import cacheit

>>> @cacheit
... def f(a, b):
...     return a+b

>>> @cacheit
... def f(a, b): # noqa: F811
...     return [a, b] # <-- WRONG, returns mutable object

to force cacheit to check returned results mutability and consistency, set environment variable SYMPY_USE_CACHE to 'debug'

basic

class sympy.core.basic.Basic(*args)

Base class for all SymPy objects.

Notes And Conventions

1) Always use .args, when accessing parameters of some instance:

>>> from sympy import cot
>>> from sympy.abc import x, y

>>> cot(x).args
(x,)

>>> cot(x).args[0]
x

>>> (x*y).args
(x, y)

>>> (x*y).args[1]
y

2) Never use internal methods or variables (the ones prefixed with _):
3) By “SymPy object” we mean something that can be returned by sympify. But not all objects one encounters using SymPy are subclasses of Basic. For example, mutable objects are not:

```python
>>> from sympy import Basic, Matrix, sympify
>>> A = Matrix([[1, 2], [3, 4]]).as_mutable()
>>> isinstance(A, Basic)
False

>>> B = sympify(A)
>>> isinstance(B, Basic)
True
```

**property args: tuple**

Returns a tuple of arguments of `self`.

**Examples**

```python
>>> from sympy import cot
>>> from sympy.abc import x, y

>>> cot(x).args
(x,)

>>> cot(x).args[0]
x

>>> (x*y).args
(x, y)

>>> (x*y).args[1]
y
```

**Notes**

Never use `self._args`, always use `self.args`. Only use `_args` in `_new_` when creating a new function. Do not override `.args()` from Basic (so that it is easy to change the interface in the future if needed).

**as_content_primitive** `(radical=False, clear=True)`

A stub to allow Basic args (like Tuple) to be skipped when computing the content and primitive components of an expression.

**See also:**

`sympy.core.expr.Expr.as_content_primitive` (page 1002)
as_dummy()

Return the expression with any objects having structurally bound symbols replaced with unique, canonical symbols within the object in which they appear and having only the default assumption for commutativity being True. When applied to a symbol a new symbol having only the same commutativity will be returned.

Examples

```python
>>> from sympy import Integral, Symbol
>>> from sympy.abc import x
>>> r = Symbol('r', real=True)
>>> Integral(r, (r, x)).as_dummy()
Integral(_0, (_0, x))
>>> _.variables[0].is_real is None
True
>>> r.as_dummy()
_r
```

Notes

Any object that has structurally bound variables should have a property, `bound_symbols` that returns those symbols appearing in the object.

property assumptions0

Return object type assumptions.

For example:

```
Symbol('x', real=True) Symbol('x', integer=True)
```

are different objects. In other words, besides Python type (Symbol in this case), the initial assumptions are also forming their typeinfo.

Examples

```python
>>> from sympy import Symbol
>>> from sympy.abc import x
>>> x.assumptions0
{'}
>>> x = Symbol("x", positive=True)
>>> x.assumptions0
{'}
```

5.8. Topics 981
atoms(*types)

Returns the atoms that form the current object.

By default, only objects that are truly atomic and cannot be divided into smaller pieces are returned: symbols, numbers, and number symbols like \( i \) and \( \pi \). It is possible to request atoms of any type, however, as demonstrated below.

**Examples**

```python
>>> from sympy import I, pi, sin
>>> from sympy import x, y
>>> (1 + x + 2*sin(y + I*pi)).atoms()
{1, 2, I, pi, x, y}
```

If one or more types are given, the results will contain only those types of atoms.

```python
>>> from sympy import Number, NumberSymbol, Symbol
>>> (1 + x + 2*sin(y + I*pi)).atoms(Symbol)
{x, y}
```

```python
>>> (1 + x + 2*sin(y + I*pi)).atoms(Number)
{1, 2}
```

```python
>>> (1 + x + 2*sin(y + I*pi)).atoms(Number, NumberSymbol)
{1, 2, pi}
```

Note that \( i \) (imaginary unit) and \( \text{zoo} \) (complex infinity) are special types of number symbols and are not part of the `NumberSymbol` class.

The type can be given implicitly, too:

```python
>>> (1 + x + 2*sin(y + I*pi)).atoms(x)  # x is a Symbol
{x, y}
```

Be careful to check your assumptions when using the implicit option since `S(1).is_Integer = True` but `type(S(1))` is `One`, a special type of SymPy atom, while `type(S(2))` is `type(Integer)` and will find all integers in an expression:

```python
>>> from sympy import S
>>> (1 + x + 2*sin(y + I*pi)).atoms(S(1))
{1}
```

```python
>>> (1 + x + 2*sin(y + I*pi)).atoms(S(2))
{1, 2}
```

Finally, arguments to `atoms()` can select more than atomic atoms: any SymPy type (loaded in core/_init_.py) can be listed as an argument and those types of “atoms” as found in scanning the arguments of the expression recursively:
>>> from sympy import Function, Mul
>>> f = Function('f')
>>> (1 + f(x) + 2*sin(y + I*pi)).atoms(Function)
{f(x), sin(y + I*pi)}
>>> (1 + f(x) + 2*sin(y + I*pi)).atoms(AppliedUndef)
{f(x)}
>>> (1 + x + 2*sin(y + I*pi)).atoms(Mul)
{I*pi, 2*sin(y + I*pi)}

**property canonical_variables**

Return a dictionary mapping any variable defined in `self.bound_symbols` to Symbols that do not clash with any free symbols in the expression.

**Examples**

```python
>>> from sympy import Lambda
>>> from sympy.abc import x
>>> Lambda(x, 2*x).canonical_variables
{x: _0}
```

**classmethod class_key()**

Nice order of classes.

**compare(other)**

Return -1, 0, 1 if the object is smaller, equal, or greater than other.

Not in the mathematical sense. If the object is of a different type from the “other” then their classes are ordered according to the sorted_classes list.

**Examples**

```python
>>> from sympy.abc import x, y
>>> x.compare(y)
-1
>>> x.compare(x)
0
>>> y.compare(x)
1
```

count(query)

Count the number of matching subexpressions.

count_ops(visual=None)

Wrapper for count_ops that returns the operation count.

doit(**hints)**

Evaluate objects that are not evaluated by default like limits, integrals, sums and products. All objects of this kind will be evaluated recursively, unless some species were excluded via ‘hints’ or unless the ‘deep’ hint was set to ‘False’.
>>> from sympy import Integral
>>> from sympy.abc import x

>>> 2*Integral(x, x)
2*Integral(x, x)

>>> (2*Integral(x, x)).doit()
x**2

>>> (2*Integral(x, x)).doit(deep=False)
2*Integral(x, x)

dummy_eq(other, symbol=None)

Compare two expressions and handle dummy symbols.

Examples

>>> from sympy import Dummy
>>> from sympy.abc import x, y

>>> u = Dummy('u')

>>> (u**2 + 1).dummy_eq(x**2 + 1)
True
>>> (u**2 + 1) == (x**2 + 1)
False

>>> (u**2 + y).dummy_eq(x**2 + y, x)
True
>>> (u**2 + y).dummy_eq(x**2 + y, y)
False

find(query, group=False)

Find all subexpressions matching a query.

property free_symbols: set[

Return from the atoms of self those which are free symbols.

Not all free symbols are Symbol. Eg: IndexedBase('I')[0].free_symbols

For most expressions, all symbols are free symbols. For some classes this is not true. e.g. Integrals use Symbols for the dummy variables which are bound variables, so Integral has a method to return all symbols except those. Derivative keeps track of symbols with respect to which it will perform a derivative; those are bound variables, too, so it has its own free_symbols method.

Any other method that uses bound variables should implement a free_symbols method.

classmethod fromiter(args, **assumptions)

Create a new object from an iterable.
This is a convenience function that allows one to create objects from any iterable, without having to convert to a list or tuple first.

**Examples**

```python
>>> from sympy import Tuple
>>> Tuple.fromiter(i for i in range(5))
(0, 1, 2, 3, 4)
```

**property func**

The top-level function in an expression.

The following should hold for all objects:

```python
>>> x == x.func(*x.args)
```

**Examples**

```python
>>> from sympy import x
>>> a = 2*x
>>> a.func
<class 'sympy.core.mul.Mul'>
>>> a.args
(2, x)
>>> a.func(*a.args)
2*x
>>> a == a.func(*a.args)
True
```

**has(**patterns**)**

Test whether any subexpression matches any of the patterns.

**Examples**

```python
>>> from sympy import sin
>>> from sympy import x, y, z
>>> (x**2 + sin(x*y)).has(z)
False
>>> (x**2 + sin(x*y)).has(x, y, z)
True
>>> x.has(x)
True
```

Note has is a structural algorithm with no knowledge of mathematics. Consider the following half-open interval:

```python
>>> from sympy import Interval
>>> i = Interval.Lopen(0, 5); i
Interval.Lopen(0, 5)
```
>>> i.args
(0, 5, True, False)
>>> i.has(4)  # there is no "4" in the arguments
False
>>> i.has(0)  # there *is* a "0" in the arguments
True

Instead, use contains to determine whether a number is in the interval or not:

>>> i.contains(4)
True
>>> i.contains(0)
False

Note that expr.has(*patterns) is exactly equivalent to any(expr.has(p) for p in patterns). In particular, False is returned when the list of patterns is empty.

>>> x.has()
False

**has_free(*patterns)**

Return True if self has object(s) x as a free expression else False.

**Examples**

```python
>>> from sympy import Integral, Function
>>> from sympy.abc import x, y
>>> f = Function('f')
>>> g = Function('g')
>>> expr = Integral(f(x), (f(x), 1, g(y)))
>>> expr.free_symbols
{y}
>>> expr.has_free(g(y))
True
>>> expr.has_free(*{x, f(x)})
False
```

This works for subexpressions and types, too:

```python
>>> expr.has_free(g)
True
>>> (x + y + 1).has_free(y + 1)
True
```

**has_xfree(s: set[Basic (page 979)])**

Return True if self has any of the patterns in s as a free argument, else False. This is like `Basic.has_free` but this will only report exact argument matches.
Examples

```python
>>> from sympy import Function
>>> from sympy.abc import x, y
>>> f = Function('f')
>>> f(x).has_xfree({f})
False
>>> f(x).has_xfree({f(x)})
True
>>> f(x + 1).has_xfree({x})
True
>>> f(x + 1).has_xfree({x + 1})
True
>>> f(x + y + 1).has_xfree({x + 1})
False
```

property `is_comparable`

Return True if self can be computed to a real number (or already is a real number) with precision, else False.

Examples

```python
>>> from sympy import exp_polar, pi, I
>>> (I*exp_polar(I*pi/2)).is_comparable
True
>>> (I*exp_polar(I*pi*2)).is_comparable
False
```

A False result does not mean that `self` cannot be rewritten into a form that would be comparable. For example, the difference computed below is zero but without simplification it does not evaluate to a zero with precision:

```python
>>> e = 2**pi*(1 + 2**pi)
>>> dif = e - e.expand()
>>> dif.is_comparable
False
>>> dif.n(2)  # prec
1
```

`match(pattern, old=False)`

Pattern matching.

Wild symbols match all.

Return None when expression (self) does not match with pattern. Otherwise return a dictionary such that:

```python
pattern.xreplace(self.match(pattern)) == self
```
Examples

```python
>>> from sympy import Wild, Sum
>>> from sympy.abc import x, y
>>> p = Wild("p")
>>> q = Wild("q")
>>> r = Wild("r")
>>> e = (x+y)**(x+y)
>>> e.match(p**p)
{p_: x + y}
>>> e.match(p**q)
{p_: x + y, q_: x + y}
>>> e = (2*x)**2
>>> e.match(p*q**r)
{p_: 4, q_: x, r_: 2}
>>> (p*q**r).xreplace(e.match(p*q**r))
4*x**2
```

Structurally bound symbols are ignored during matching:

```python
>>> Sum(x, (x, 1, 2)).match(Sum(y, (y, 1, p)))
{p_: 2}
```

But they can be identified if desired:

```python
>>> Sum(x, (x, 1, 2)).match(Sum(q, (q, 1, p)))
{p_: 2, q_: x}
```

The old flag will give the old-style pattern matching where expressions and patterns are essentially solved to give the match. Both of the following give None unless old=True:

```python
>>> (x - 2).match(p - x, old=True)
{p_: 2*x - 2}
>>> (2/x).match(p*x, old=True)
{p_: 2/x**2}
```

`matches(expr, repl_dict=None, old=False)`

Helper method for match() that looks for a match between Wild symbols in self and expressions in expr.

Examples

```python
>>> from sympy import symbols, Wild, Basic
>>> a, b, c = symbols('a b c')
>>> x = Wild('x')
>>> Basic(a + x, x).matches(Basic(a + b, c)) is None
True
>>> Basic(a + x, x).matches(Basic(a + b + c, b + c))
{x_: b + c}
```
rcall(*args)

Apply on the argument recursively through the expression tree.

This method is used to simulate a common abuse of notation for operators. For instance, in SymPy the following will not work:

\[(x + \text{Lambda}(y, 2^y))(z) == x + 2^z,\]

however, you can use:

```
>>> from sympy import Lambda
>>> from sympy.abc import x, y, z
>>> (x + Lambda(y, 2**y)).rcall(z)
x + 2*z
```

refine(assumption=True)

See the refine function in sympy.assumptions

replace(query, value, map=False, simultaneous=True, exact=None)

Replace matching subexpressions of self with value.

If map = True then also return the mapping \{old: new\} where old was a sub-
expression found with query and new is the replacement value for it. If the expression
itself does not match the query, then the returned value will be self.xreplace(map)
otherwise it should be self.subs(ordered(map.items())).

Traverses an expression tree and performs replacement of matching subexpressions
from the bottom to the top of the tree. The default approach is to do the replacement
in a simultaneous fashion so changes made are targeted only once. If this is not
desired or causes problems, simultaneous can be set to False.

In addition, if an expression containing more than one Wild symbol is being used to
match subexpressions and the exact flag is None it will be set to True so the match
will only succeed if all non-zero values are received for each Wild that appears in
the match pattern. Setting this to False accepts a match of 0; while setting it True
accepts all matches that have a 0 in them. See example below for cautions.

The list of possible combinations of queries and replacement values is listed below:

Examples

Initial setup

```
>>> from sympy import log, sin, cos, tan, Wild, Mul, Add
>>> from sympy.abc import x, y
>>> f = log(sin(x)) + tan(sin(x**2))
```

1.1. type -> type

obj.replace(type, newtype)

When object of type type is found, replace it with the result of passing its argu-
ment(s) to newtype.

```
>>> f.replace(sin, cos)
log(cos(x)) + tan(cos(x**2))
>>> sin(x).replace(sin, cos, map=True)
```

(continues on next page)
When object of type type is found, apply func to its argument(s). func must be written to handle the number of arguments of type.

```python
>>> f.replace(sin, lambda arg: sin(2*arg))
log(sin(2*x)) + tan(sin(2*x**2))
```

2.1. pattern -> expr
obj.replace(pattern(wild), expr(wild))
Replace subexpressions matching pattern with the expression written in terms of the Wild symbols in pattern.

```python
>>> a, b = map(Wild, 'ab')
>>> f.replace(sin(a), tan(a))
log(tan(x)) + tan(tan(x**2))
```

Matching is exact by default when more than one Wild symbol is used: matching fails unless the match gives non-zero values for all Wild symbols:

```python
>>> (2*x + y).replace(a*x + b, b - a)
y - 2
```

When set to False, the results may be non-intuitive:

```python
>>> (2*x).replace(a*x + b, b - a, exact=False)
2/x
```

2.2. pattern -> func
obj.replace(pattern(wild), lambda wild: expr(wild))
All behavior is the same as in 2.1 but now a function in terms of pattern variables is used rather than an expression:

```python
>>> f.replace(sin(a), lambda a: sin(2*a))
log(sin(2*x)) + tan(sin(2*x**2))
```
Replace subexpression \( e \) with \( \text{func}(e) \) if \( \text{filter}(e) \) is True.

```python
>>> g = 2*sin(x**3)
>>> g.replace(lambda expr: expr.is_Number, lambda expr: expr**2)
4*sin(x**9)
```

The expression itself is also targeted by the query but is done in such a fashion that changes are not made twice.

```python
>>> e = x*(x*y + 1)
>>> e.replace(lambda x: x.is_Mul, lambda x: 2*x)
2*x*(2*x*y + 1)
```

When matching a single symbol, \( \text{exact} \) will default to True, but this may or may not be the behavior that is desired:

Here, we want \( \text{exact} = \text{False} \):

```python
>>> from sympy import Function
>>> f = Function('f')
>>> e = f(1) + f(0)
>>> q = f(a), lambda a: f(a + 1)
>>> e.replace(*q, exact=False)
f(1) + f(0)
>>> e.replace(*q, exact=True)
f(0) + f(2)
```

But here, the nature of matching makes selecting the right setting tricky:

```python
>>> e = x**(1 + y)
>>> (x**(1 + y)).replace(x**(1 + a), lambda a: x**-a, exact=False)
x
>>> (x**(1 + y)).replace(x**(1 + a), lambda a: x**-a, exact=True)
x**(-x - y + 1)
>>> (x**y).replace(x**(1 + a), lambda a: x**-a, exact=False)
x
>>> (x**y).replace(x**(1 + a), lambda a: x**-a, exact=True)
x**(1 - y)
```

It is probably better to use a different form of the query that describes the target expression more precisely:

```python
>>> (1 + x**(1 + y)).replace(
...     lambda x: x.is_Pow and x.exp.is_Add and x.exp.args[0] == 1,
...     lambda x: x.base**(1 - (x.exp - 1)))
x**(1 - y) + 1
```

See also:

- `subs (page 993)`
  substitution of subexpressions as defined by the objects themselves.
- `xreplace (page 995)`
  exact node replacement in expr tree; also capable of using matching rules
rewrite(*args, deep=True, **hints)

Rewrite self using a defined rule.

Rewriting transforms an expression to another, which is mathematically equivalent but structurally different. For example, you can rewrite trigonometric functions as complex exponentials or combinatorial functions as gamma function.

This method takes a pattern and a rule as positional arguments. pattern is optional parameter which defines the types of expressions that will be transformed. If it is not passed, all possible expressions will be rewritten. rule defines how the expression will be rewritten.

Parameters

- **args**: Expr
  - A rule, or pattern and rule. - pattern is a type or an iterable of types.
  - rule can be any object.

- **deep**: bool, optional
  - If True, subexpressions are recursively transformed. Default is True.

Examples

If pattern is unspecified, all possible expressions are transformed.

```python
>>> from sympy import cos, sin, exp, I
>>> from sympy.abc import x
>>> expr = cos(x) + I*sin(x)
>>> expr.rewrite(exp)
exp(I*x)
```

Pattern can be a type or an iterable of types.

```python
>>> expr.rewrite(sin, exp)
exp(I*x)/2 + cos(x) - exp(-I*x)/2
>>> expr.rewrite([cos,], exp)
exp(I*x)/2 + I*sin(x) + exp(-I*x)/2
>>> expr.rewrite([cos, sin], exp)
exp(I*x)
```

Rewriting behavior can be implemented by defining _eval_rewrite() method.

```python
>>> from sympy import Expr, sqrt, pi
>>> class MySin(Expr):
...     def _eval_rewrite(self, rule, args, **hints):
...         x, = args
...         if rule == cos:
...             return cos(pi/2 - x, evaluate=False)
...         if rule == sqrt:
...             return sqrt(1 - cos(x)**2)
>>> MySin(MySin(x)).rewrite(cos)
cos(-cos(-x + pi/2) + pi/2)
>>> MySin(x).rewrite(sqrt)
sqrt(1 - cos(x)**2)
```
Defining \texttt{\_eval_rewrite_as\[][...\][]()} method is supported for backwards compatibility reason. This may be removed in the future and using it is discouraged.

```python
>>> class MySin(Expr):
...     def \_eval_rewrite_as_cos(self, *args, **hints):
...         x, = args
...         return cos(pi/2 - x, evaluate=False)
>>> MySin(x).rewrite(cos)
cos(-x + pi/2)
```

**simplify(**\*kwargs**)**

See the simplify function in sympy.simplify

**sort_key**(order=\texttt{None})

Return a sort key.

**Examples**

```python
>>> from sympy import S, I

>>> sorted([S(1)/2, I, -I], key=lambda x: x.sort_key())
[1/2, -I, I]

>>> S(“[x, 1/x, 1/x**2, x**2, x**(1/2), x**(1/4), x**(3/2)]”)
[x, 1/x, x**(-2), x**2, sqrt(x), x**(1/4), x**(3/2)]

>>> sorted(x, key=lambda x: x.sort_key())
[x**(-2), 1/x, x**(1/4), sqrt(x), x, x**(3/2), x**2]
```

**subs(**\*args, **\*kwargs**)**

Substitutes old for new in an expression after sympifying \texttt{args}.

**args** is either:

- two arguments, e.g. \texttt{foo.subs(old, new)}
- one iterable argument, e.g. \texttt{foo.subs(iterable)}. The iterable may be
  - an iterable container with (old, new) pairs. In this case the replacements are processed in the order given with successive patterns possibly affecting replacements already made.
  - a dict or set whose key/value items correspond to old/new pairs. In this case the old/new pairs will be sorted by op count and in case of a tie, by number of args and the default_sort_key. The resulting sorted list is then processed as an iterable container (see previous).

If the keyword \texttt{simultaneous} is True, the subexpressions will not be evaluated until all the substitutions have been made.
Examples

```python
>>> from sympy import pi, exp, limit, oo
>>> from sympy.abc import x, y

>>> (1 + x*y).subs(x, pi)
pi*y + 1
>>> (1 + x*y).subs({x:pi, y:2})
1 + 2*pi
>>> (1 + x*y).subs([(x, pi), (y, 2)])
1 + 2*pi
>>> reps = [(y, x**2), (x, 2)]
>>> (x + y).subs(reps)
6
>>> (x + y).subs(reversed(reps))
x**2 + 2

>>> (x**2 + x**4).subs(x**2, y)
y**2 + y

To replace only the x**2 but not the x**4, use xreplace:

>>> (x**2 + x**4).xreplace({x**2: y})
x**4 + y

To delay evaluation until all substitutions have been made, set the keyword simultaneous to True:

>>> (x/y).subs([(x, 0), (y, 0)])
0
>>> (x/y).subs([(x, 0), (y, 0)], simultaneous=True)
nan

This has the added feature of not allowing subsequent substitutions to affect those already made:

>>> ((x + y)/y).subs({x + y: y, y: x + y})
y/(x + y)

>>> ((x + y)/y).subs({x + y: y, y: x + y}, simultaneous=True)
nan
```

In order to obtain a canonical result, unordered iterables are sorted by count_op length, number of arguments and by the default_sort_key to break any ties. All other iterables are left unsorted.

```python
>>> from sympy import sqrt, sin, cos
>>> from sympy.abc import a, b, c, d, e

>>> A = (sqrt(sin(2*x)), a)
>>> B = (sin(2*x), b)
>>> C = (cos(2*x), c)
>>> D = (x, d)
>>> E = (exp(x), e)
```
```python
>>> expr = sqrt(sin(2*x))*sin(exp(x)*x)*cos(2*x) + sin(2*x)
```

```python
>>> expr.subs(dict([A, B, C, D, E]))
a*c*sin(d*e) + b
```

The resulting expression represents a literal replacement of the old arguments with the new arguments. This may not reflect the limiting behavior of the expression:

```python
>>> (x**3 - 3*x).subs({x: oo})
nan
```

```python
>>> limit(x**3 - 3*x, x, oo)

Inf
```

If the substitution will be followed by numerical evaluation, it is better to pass the substitution to `evalf` as

```python
>>> (1/x).evalf(subs={x: 3.0}, n=21)

0.333333333333333333333
```

rather than

```python
>>> (1/x).subs({x: 3.0}).evalf(21)

0.333333333333333314830
```

as the former will ensure that the desired level of precision is obtained.

See also:

- `replace` (page 989)
  - replacement capable of doing wildcard-like matching, parsing of match, and conditional replacements
- `xreplace` (page 995)
  - exact node replacement in expr tree; also capable of using matching rules
- `sympy.core.evalf.EvalfMixin.evalf` (page 1111)
  - calculates the given formula to a desired level of precision

`xreplace(rule)`

Replace occurrences of objects within the expression.

**Parameters**

- `rule`: dict-like
  
  Expresses a replacement rule

**Returns**

- `xreplace`: the result of the replacement
Examples

```python
>>> from sympy import symbols, pi, exp
>>> x, y, z = symbols('x y z')
>>> (1 + x*y).xreplace({x: pi})
pi*y + 1
>>> (1 + x*y).xreplace({x: pi, y: 2})
1 + 2*pi
```

Replacements occur only if an entire node in the expression tree is matched:

```python
>>> (x*y + z).xreplace({x*y: pi})
z + pi
>>> (x*y*z).xreplace({x*y: pi})
x*y*z
>>> (2*x).xreplace({2*x: y, x: z})
y
>>> (2*2*x).xreplace({2*x: y, x: z})
4*z
>>> (x + y + 2).xreplace({x + y: 2})
x + y + 2
>>> (x + 2 + exp(x + 2)).xreplace({x + 2: y})
x + exp(y) + 2
```

xreplace does not differentiate between free and bound symbols. In the following, `subs(x, y)` would not change `x` since it is a bound symbol, but `xreplace` does:

```python
>>> from sympy import Integral
>>> Integral(x, (x, 1, 2*x)).xreplace({x: y})
Integral(y, (y, 1, 2*y))
```

Trying to replace `x` with an expression raises an error:

```python
>>> Integral(x, (x, 1, 2*x)).xreplace({x: 2*y})
ValueError: Invalid limits given: ((2*y, 1, 4*y),)
```

See also:

- `replace` (page 989) replacement capable of doing wildcard-like matching, parsing of match, and conditional replacements
- `subs` (page 993) substitution of subexpressions as defined by the objects themselves.

```python
class sympy.core.basic.Atom(*args)
    A parent class for atomic things. An atom is an expression with no subexpressions.
```
**Examples**

Symbol, Number, Rational, Integer, ... But not: Add, Mul, Pow, ...

**singleton**

```python
class sympy.core.singleton.SingletonRegistry
    The registry for the singleton classes (accessible as S).
```

**Explanation**

This class serves as two separate things.

The first thing it is is the SingletonRegistry. Several classes in SymPy appear so often that they are singletonized, that is, using some metaprogramming they are made so that they can only be instantiated once (see the `sympy.core.singleton.Singleton` (page 998) class for details). For instance, every time you create `Integer(0)`, this will return the same instance, `sympy.core.numbers.Zero` (page 1045). All singleton instances are attributes of the `S` object, so `Integer(0)` can also be accessed as `S.Zero`.

Singletonization offers two advantages: it saves memory, and it allows fast comparison. It saves memory because no matter how many times the singletonized objects appear in expressions in memory, they all point to the same single instance in memory. The fast comparison comes from the fact that you can use `is` to compare exact instances in Python (usually, you need to use `==` to compare things). `is` compares objects by memory address, and is very fast.

**Examples**

```python
>>> from sympy import S, Integer
>>> a = Integer(0)
>>> a is S.Zero
True
```

For the most part, the fact that certain objects are singletonized is an implementation detail that users should not need to worry about. In SymPy library code, `is` comparison is often used for performance purposes. The primary advantage of `S` for end users is the convenient access to certain instances that are otherwise difficult to type, like `S.Half` (instead of `Rational(1, 2)`).

When using `is` comparison, make sure the argument is sympified. For instance,

```python
>>> x = 0
>>> x is S.Zero
False
```

This problem is not an issue when using `==`, which is recommended for most use-cases:

```python
>>> 0 == S.Zero
True
```
The second thing \( S \) is is a shortcut for `sympy.core.sympify.sympify()` (page 970). `sympy.core.sympify.sympify()` (page 970) is the function that converts Python objects such as \( \text{int}(1) \) into SymPy objects such as \( \text{Integer}(1) \). It also converts the string form of an expression into a SymPy expression, like \( \text{sympify(”x**2”)} \rightarrow \text{Symbol(”x”)**2} \). \( S(1) \) is the same thing as \( \text{sympify}(1) \) (basically, \( S._\text{call} \) has been defined to call \( \text{sympify} \)).

This is for convenience, since \( S \) is a single letter. It’s mostly useful for defining rational numbers. Consider an expression like \( x + 1/2 \). If you enter this directly in Python, it will evaluate the \( 1/2 \) and give \( 0.5 \), because both arguments are ints (see also Two Final Notes: ^ and / (page 13)). However, in SymPy, you usually want the quotient of two integers to give an exact rational number. The way Python’s evaluation works, at least one side of an operator needs to be a SymPy object for the SymPy evaluation to take over. You could write this as \( x + \text{Rational(1, 2)} \), but this is a lot more typing. A shorter version is \( x + S(1)/2 \). Since \( S(1) \) returns \( \text{Integer}(1) \), the division will return a Rational type, since it will call \( \text{Integer._truediv} \), which knows how to return a Rational.

```python
class sympy.core.singleton.Singleton(*args, **kwargs)

Metaclass for singleton classes.

Explanation

A singleton class has only one instance which is returned every time the class is instantiated. Additionally, this instance can be accessed through the global registry object \( S \) as \( S.<\text{class name}> \).

Examples

```python
>>> from sympy import S, Basic
>>> from sympy.core.singleton import Singleton

```python
>>> class MySingleton(Basic, metaclass=Singleton):
    pass

```python
>>> Basic() is Basic()
False

```python
>>> MySingleton() is MySingleton()
True

```python
>>> S.MySingleton is MySingleton()
True

Notes

Instance creation is delayed until the first time the value is accessed. (SymPy versions before 1.0 would create the instance during class creation time, which would be prone to import cycles.)
**expr**

**class** sympy.core.expr.Expr(*args)

Base class for algebraic expressions.

**Explanation**

Everything that requires arithmetic operations to be defined should subclass this class, instead of Basic (which should be used only for argument storage and expression manipulation, i.e. pattern matching, substitutions, etc).

If you want to override the comparisons of expressions: Should use \_\_eval\_is\_ge for inequality, or \_\_eval\_is\_eq, with multiple dispatch. \_\_eval\_is\_ge return true if \(x \geq y\), false if \(x < y\), and None if the two types are not comparable or the comparison is indeterminate.

**See also:**

sympy.core.basic.Basic (page 979)

**apart**(x=None, **args)

See the apart function in sympy.polys

**args**\_\_cnc**(cset=False, warn=True, split\_1=True)**

Return \([\text{commutative factors}, \text{non-commutative factors}]\) of self.

**Explanation**

\(\text{self}\) is treated as a Mul and the ordering of the factors is maintained. If \(cset\) is True the commutative factors will be returned in a set. If there were repeated factors (as may happen with an unevaluated Mul) then an error will be raised unless it is explicitly suppressed by setting \(\text{warn}\) to False.

Note: -1 is always separated from a Number unless split\_1 is False.

**Examples**

```python
>>> from sympy import symbols, oo
>>> A, B = symbols('A B', commutative=0)
>>> x, y = symbols('x y')
>>> (-2*x*y).args_cnc()
\([-1, 2, x, y], []\]
>>> (-2.5*x).args_cnc()
\([-1, 2.5, x], []\]
>>> (-2*x*A*B*y).args_cnc()
\([-1, 2, x, y], [A, B]\]
>>> (-2*x*A*B*y).args_cnc(split\_1=False)
\([-2, x, y], [A, B]\]
>>> (-2*x*y).args_cnc(cset=True)
\([-1, 2, x, y], []\]
```

The arg is always treated as a Mul:
as_coeff_Add(rational=False) → tuple[Number (page 1033), Expr (page 999)]
Efficiently extract the coefficient of a summation.

as_coeff_Mul(rational: bool = False) → tuple[Number (page 1033), Expr (page 999)]
Efficiently extract the coefficient of a product.

as_coeff_add(*deps) → tuple[Expr (page 999), tuple[Expr (page 999), ...]]
Return the tuple (c, args) where self is written as an Add, a.

c should be a Rational added to any terms of the Add that are independent of deps.
args should be a tuple of all other terms of a; args is empty if self is a Number or if self is independent of deps (when given).

This should be used when you do not know if self is an Add or not but you want to treat self as an Add or if you want to process the individual arguments of the tail of self as an Add.

• if you know self is an Add and want only the head, use self.args[0];
• if you do not want to process the arguments of the tail but need the tail then use self.as_two_terms() which gives the head and tail.
• if you want to split self into an independent and dependent parts use self.as_independent(*deps)

as_coeff_exponent(x) → tuple[Expr (page 999), Expr (page 999)]
c*x**e -> c, e where x can be any symbolic expression.

as_coeff_mul(*deps, **kwargs) → tuple[Expr (page 999), tuple[Expr (page 999), ...]]
Return the tuple (c, args) where self is written as a Mul, m.

c should be a Rational multiplied by any factors of the Mul that are independent of deps.
args should be a tuple of all other factors of m; args is empty if self is a Number or if self is independent ofdeps (when given).

This should be used when you do not know if self is a Mul or not but you want to treat self as a Mul or if you want to process the individual arguments of the tail of self as a Mul.

• if you know self is a Mul and want only the head, use self.args[0];
• if you do not want to process the arguments of the tail but need the tail then use `self.as_two_terms()` which gives the head and tail;
• if you want to split `self` into an independent and dependent parts use `self.as_independent(*deps)`

```python
>>> from sympy import S
>>> from sympy.abc import x, y
>>> (S(3)).as_coeff_mul()
(3, ())
>>> (3*x*y).as_coeff_mul()
(3, (x, y))
>>> (3*x*y).as_coeff_mul(x)
(3*y, (x,))
>>> (3*y).as_coeff_mul(x)
(3*y, ())
```

`as_coefficient(expr)`

Extracts symbolic coefficient at the given expression. In other words, this function separates 'self' into the product of 'expr' and 'expr'-free coefficient. If such separation is not possible it will return None.

**Examples**

```python
>>> from sympy import E, pi, sin, I, Poly
>>> from sympy.abc import x

>>> E.as_coefficient(E)
1
>>> (2*E).as_coefficient(E)
2
>>> (2*sin(E)*E).as_coefficient(E)
```

Two terms have E in them so a sum is returned. (If one were desiring the coefficient of the term exactly matching E then the constant from the returned expression could be selected. Or, for greater precision, a method of Poly can be used to indicate the desired term from which the coefficient is desired.)

```python
>>> (2*E + x*E).as_coefficient(E)
x + 2
>>> _.args[0]  # just want the exact match
2
>>> p = Poly(2*E + x*E); p
Poly(x*E + 2*E, x, E, domain='ZZ')
>>> p.coeff_monomial(E)
2
>>> p.nth(0, 1)
2
```

Since the following cannot be written as a product containing E as a factor, None is returned. (If the coefficient 2*x is desired then the `coeff` method should be used.)
>>> (2*E*x + x).as_coefficient(E)
>>> (2*E*x + x).coeff(E)
2*x

>>> (E*(x + 1) + x).as_coefficient(E)

>>> (2*pi*I).as_coefficient(pi*I)
2
>>> (2*I).as_coefficient(pi*I)

See also:

coeff (page 1010)
return sum of terms have a given factor

as_coeff_Add (page 1000)
separate the additive constant from an expression

as_coeff_Mul (page 1000)
separate the multiplicative constant from an expression

as_independent (page 1004)
separate x-dependent terms/factors from others

sympy.polys.polytools.Poly.coeff_monomial (page 2459)
efficiently find the single coefficient of a monomial in Poly

sympy.polys.polytools.Poly.nth (page 2483)
like coeff_monomial but powers of monomial terms are used

as_coefficients_dict(*syms)
Return a dictionary mapping terms to their Rational coefficient. Since the dictionary is a defaultdict, inquiries about terms which were not present will return a coefficient of 0.

If symbols syms are provided, any multiplicative terms independent of them will be considered a coefficient and a regular dictionary of syms-dependent generators as keys and their corresponding coefficients as values will be returned.

Examples

```python
>>> from sympy.abc import a, x, y
>>> (3*x + a*x + 4).as_coefficients_dict()
{1: 4, x: 3, a*x: 1}
>>> [a]
0
>>> (3*a*x).as_coefficients_dict()
{a*x: 3}
>>> (3*a*x).as_coefficients_dict(x)
{x: 3*a}
>>> (3*a*x).as_coefficients_dict(y)
{1: 3*a*x}
```
**as_content_primitive** (*radical=False, clear=True*)

This method should recursively remove a Rational from all arguments and return that (content) and the new self (primitive). The content should always be positive and Mul(*foo.as_content_primitive()) == foo. The primitive need not be in canonical form and should try to preserve the underlying structure if possible (i.e. expand_mul should not be applied to self).

### Examples

```python
def example():
    from sympy import sqrt
    from sympy.abc import x, y, z

    eq = 2 + 2*x + 2*y*(3 + 3*y)

    # The as_content_primitive function is recursive and retains structure:
    print(eq.as_content_primitive())
    # Output: (2, x + 3*y*(y + 1) + 1)

    # Integer powers will have Rationals extracted from the base:
    print((2 + 6*x)**2).as_content_primitive())
    # Output: (4, (3*x + 1)**2)

    # Terms may end up joining once their as_content_primitives are added:
    print((x*(1 + y) + 2*x*(3 + 3*y)).as_content_primitive())
    # Output: (11, x*(y + 1))
    print((x*(1 + y) + 2*x*(3 + 3*y)).as_content_primitive())
    # Output: (9, x*(y + 1))
    print((z*(1 + y) + 2.0*x*(3 + 3*y)).as_content_primitive())
    # Output: (1, 6.0*x*(y + 1) + 3*z*(y + 1))
    print((x*(1 + y) + 0.4*x*(3 + 3*y)).as_content_primitive())
    # Output: (1, 4.84*x**2*(y + 1)**2)

    # Radical content can also be factored out of the primitive:
    print(2*sqrt(2) + 4*sqrt(10)).as_content_primitive(radical=True)
    # Output: (2, sqrt(2)*(1 + 2*sqrt(5)))

    # If clear=False (default is True) then content will not be removed from an Add if it can be distributed to leave one or more terms with integer coefficients.
    print((x/2 + y).as_content_primitive())
    # Output: (1/2, x + 2*y)
    print((x/2 + y).as_content_primitive(clear=False)
    # Output: (1, x/2 + y)
```

5.8. Topics 1003
as_expr(*gens)
Convert a polynomial to a SymPy expression.

Examples

```python
>>> from sympy import sin
>>> from sympy.abc import x, y

>>> f = (x**2 + x*y).as_poly(x, y)
>>> f.as_expr()
```
```
x**2 + x*y
```
```python

>>> sin(x).as_expr()
```
```
sin(x)
```

as_independent(*deps, **hint) → tuple[Expr (page 999), Expr (page 999)]
A mostly naive separation of a Mul or Add into arguments that are not are dependent on deps. To obtain as complete a separation of variables as possible, use a separation method first, e.g.:

- separatevars() to change Mul, Add and Pow (including exp) into Mul
- .expand(mul=True) to change Add or Mul into Add
- .expand(log=True) to change log expr into an Add

The only non-naive thing that is done here is to respect noncommutative ordering of variables and to always return (0, 0) for self of zero regardless of hints.

For nonzero self, the returned tuple (i, d) has the following interpretation:

- i will have no variable that appears in deps
- d will either have terms that contain variables that are in deps, or be equal to 0 (when self is an Add) or 1 (when self is a Mul)

- if self is an Add then self = i + d
- if self is a Mul then self = i*d
- otherwise (self, S.One) or (S.One, self) is returned.

To force the expression to be treated as an Add, use the hint as_Add=True

Examples

- self is an Add

```python
>>> from sympy import sin, cos, exp
>>> from sympy.abc import x, y, z

>>> (x + x*y).as_independent(x)
```
```
(0, x*y + x)
```
```python

>>> (x + x*y).as_independent(y)
```
```
(x, x*y)
```
```
```python
>>> (2*x*sin(x) + y + x + z).as_independent(x)
(y + z, 2*x*sin(x) + x)
>>> (2*x*sin(x) + y + x + z).as_independent(x, y)
(z, 2*x*sin(x) + x + y)

- self is a Mul

>>> (x*sin(x)*cos(y)).as_independent(x)
(cos(y), x*sin(x))

non-commutative terms cannot always be separated out when self is a Mul

```from sympy import symbols
>>> n1, n2, n3 = symbols('n1 n2 n3', commutative=False)
>>> (n1 + n1*n2).as_independent(n2)
(n1, n1*n2)
>>> (n2*n1 + n1*n2).as_independent(n2)
(0, n1*n2 + n2*n1)
>>> (n1*n2*n3).as_independent(n1)
(1, n1*n2*n3)
>>> (n1*n2*n3).as_independent(n2)
(n1, n2*n3)
>>> ((x-n1)*(x-y)).as_independent(x)
(1, (x - y)*(x - n1))

- self is anything else:

```from sympy import symbols
>>> n1, n2, n3 = symbols('n1 n2 n3', commutative=False)
>>> (sin(x)).as_independent(x)
(1, sin(x))
>>> (sin(x)).as_independent(y)
(sinx, 1)
>>> exp(x+y).as_independent(x)
(1, exp(x + y))
```

- force self to be treated as an Add:

```python
>>> (3*x).as_independent(x, as_Add=True)
(0, 3*x)
```

- force self to be treated as a Mul:

```python
>>> (3+x).as_independent(x, as_Add=False)
(1, x + 3)
>>> (-3+x).as_independent(x, as_Add=False)
(1, x - 3)
```

Note how the below differs from the above in making the constant on the dep term positive.

```python
>>> (y*(-3+x)).as_independent(x)
(y, x - 3)
```

- use .as_independent() for true independence testing instead
of \texttt{.has()}. The former considers only symbols in the free symbols while the latter considers all symbols

defining an integral and checking properties:

```python
>>> from sympy import Integral
>>> I = Integral(x, (x, 1, 2))
>>> I.has(x)
True
>>> x in I.free_symbols
False
>>> I.as_independent(x) == (I, 1)
True
>>> (I + x).as_independent(x) == (I, x)
True
```

Note: when trying to get independent terms, a separation method might need to be used first. In this case, it is important to keep track of what you send to this routine so you know how to interpret the returned values

```python
>>> from sympy import separatevars, log
>>> separatevars(exp(x+y)).as_independent(x)
(exp(y), exp(x))
>>> (x + x*y).as_independent(y)
(x, x*y)
>>> separatevars(x + x*y).as_independent(y)
(x, y + 1)
>>> (x*(1 + y)).as_independent(y)
(x, y + 1)
>>> (x*(1 + y)).expand(mul=True).as_independent(y)
(x, x*y)
>>> a, b=symbols('a b', positive=True)
>>> (log(a*b).expand(log=True)).as_independent(b)
(log(a), log(b))
```

See also:

- \texttt{separatevars} (page 722), \texttt{expand_log} (page 1107), \texttt{sympy.core.add.Add.as_two_terms} (page 1065), \texttt{sympy.core.mul.Mul.as_two_terms} (page 1060), \texttt{as_coeff_mul} (page 1000)
- \texttt{as_leading_term}(*symbols, logx=None, cdir=0)
  Returns the leading (nonzero) term of the series expansion of self.

The _eval_as_leading_term routines are used to do this, and they must always return a non-zero value.
Examples

```python
>>> from sympy import x
>>> (1 + x + x**2).as_leading_term(x)
1
>>> (1/x**2 + x + x**2).as_leading_term(x)
x**(-2)
```

`as_numer_denom()`

Return the numerator and the denominator of an expression.
expression -> a/b -> a, b
This is just a stub that should be defined by an object’s class methods to get anything else.

See also:

`normal` (page 1023)

```
return a/b instead of (a, b)
```

`as_ordered_factors(order=None)`

Return list of ordered factors (if Mul) else [self].

`as_ordered_terms(order=None, data=False)`

Transform an expression to an ordered list of terms.

Examples

```
>>> from sympy import sin, cos

>>> from sympy import x

>>> (sin(x)**2*cos(x) + sin(x)**2 + 1).as_ordered_terms()
[sin(x)**2*cos(x), sin(x)**2, 1]
```

`as_poly(*gens, **args)`

Converts self to a polynomial or returns None.

Explanation

```
>>> from sympy import sin

>>> from sympy import x, y

>>> print((x**2 + x*y).as_poly())
Poly(x**2 + x*y, x, y, domain='ZZ')

>>> print((x**2 + x*y).as_poly(x, y))
Poly(x**2 + x*y, x, y, domain='ZZ')
```
```python
>>> print((x**2 + sin(y)).as_poly(x, y))
None
```

**as_powers_dict()**

Return self as a dictionary of factors with each factor being treated as a power. The keys are the bases of the factors and the values, the corresponding exponents. The resulting dictionary should be used with caution if the expression is a Mul and contains non-commutative factors since the order that they appeared will be lost in the dictionary.

**See also:**

*as_ordered_factors* (page 1007)

An alternative for noncommutative applications, returning an ordered list of factors.

*args_cnc* (page 999)

Similar to as_ordered_factors, but guarantees separation of commutative and noncommutative factors.

**as_real_imag** (deep=True, **hints)**

Performs complex expansion on ‘self’ and returns a tuple containing collected both real and imaginary parts. This method cannot be confused with re() and im() functions, which does not perform complex expansion at evaluation. However it is possible to expand both re() and im() functions and get exactly the same results as with a single call to this function.

```python
>>> from sympy import symbols, I

>>> x, y = symbols('x,y', real=True)

>>> (x + y*I).as_real_imag()
(x, y)

>>> from sympy.abc import z, w

>>> (z + w*I).as_real_imag()
(re(z) - im(w), re(w) + im(z))
```

**as_terms()**

Transform an expression to a list of terms.

**aseries** (x=None, n=6, bound=0, hir=False)

Asymptotic Series expansion of self. This is equivalent to `self.series(x, oo, n)`.

**Parameters**

- **self**: Expression
  - The expression whose series is to be expanded.
- **x**: Symbol
  - It is the variable of the expression to be calculated.
- **n**: Value
The value used to represent the order in terms of $x^n$, up to which the series is to be expanded.

**h**ir : Boolean

Set this parameter to be True to produce hierarchical series. It stops
the recursion at an early level and may provide nicer and more useful
results.

**bound** : Value, Integer

Use the bound parameter to give limit on rewriting coefficients in its
normalised form.

Returns

Expr

Asymptotic series expansion of the expression.

**Examples**

```python
>>> from sympy import sin, exp
>>> from sympy.abc import x

>>> e = sin(1/x + exp(-x)) - sin(1/x)

>>> e.assoces(x)
(1/(24*x**4) - 1/(2*x**2) + 1 + O(x**(-6), (x, oo)))*exp(-x)

>>> e.assoces(x, n=3, hir=True)
-exp(-2*x)*sin(1/x)/2 + exp(-x)*cos(1/x) + 0(exp(-3*x), (x, oo))

>>> e = exp(exp(x)/(1 - 1/x))

>>> e.assoces(x)
exp(exp(x)/(1 - 1/x))

>>> e.assoces(x, bound=3)
exp(exp(x)/x**2)*exp(exp(x)/x)*exp(-exp(x) + exp(x)/(1 - 1/x) -
-exp(x)/x - exp(x)/x**2)*exp(exp(x))
```

For rational expressions this method may return original expression without the
Order term. >>> (1/x).assoces(x, n=8) 1/x
Notes

This algorithm is directly induced from the limit computational algorithm provided by Gruntz. It majorly uses the mrv and rewrite sub-routines. The overall idea of this algorithm is first to look for the most rapidly varying subexpression $w$ of a given expression $f$ and then expands $f$ in a series in $w$. Then same thing is recursively done on the leading coefficient till we get constant coefficients.

If the most rapidly varying subexpression of a given expression $f$ is $f$ itself, the algorithm tries to find a normalised representation of the mrv set and rewrites $f$ using this normalised representation.

If the expansion contains an order term, it will be either $O(x^{-n})$ or $O(w^{-n})$ where $w$ belongs to the most rapidly varying expression of $self$.

See also:

Expr.aseries (page 1008)

See the docstring of this function for complete details of this wrapper.

References

[R113], [R114], [R115]

cancel(*gens, **args)

See the cancel function in sympy.polys

coeff(x, n=1, right=False, _first=True)

Returns the coefficient from the term(s) containing $x^n$. If $n$ is zero then all terms independent of $x$ will be returned.

Explanation

When $x$ is noncommutative, the coefficient to the left (default) or right of $x$ can be returned. The keyword ‘right’ is ignored when $x$ is commutative.

Examples

```python
>>> from sympy import symbols
>>> from sympy.abc import x, y, z
```

You can select terms that have an explicit negative in front of them:

```python
>>> (-x + 2*y).coeff(-1)
x
>>> (x - 2*y).coeff(-1)
2*y
```

You can select terms with no Rational coefficient:
```python
>>> (x + 2*y).coeff(1)
x
>>> (3 + 2*x + 4*x**2).coeff(1)
0
```
You can select terms independent of `x` by making `n=0`; in this case `Expr.as_independent(x)[0]` is returned (and 0 will be returned instead of `None`):

```python
>>> (3 + 2*x + 4*x**2).coeff(x, 0)
3
>>> eq = ((x + 1)**3).expand() + 1
>>> eq
x**3 + 3*x**2 + 3*x + 2
>>> [eq.coeff(x, i) for i in reversed(range(4))]
[1, 3, 3, 2]
>>> eq -= 2
>>> [eq.coeff(x, i) for i in reversed(range(4))]
[1, 3, 3, 0]
```
You can select terms that have a numerical term in front of them:

```python
>>> (-x - 2*y).coeff(2)
-y
>>> from sympy import sqrt
>>> (x + sqrt(2)*x).coeff(sqrt(2))
x
```
The matching is exact:

```python
>>> (3 + 2*x + 4*x**2).coeff(x)
2
>>> (3 + 2*x + 4*x**2).coeff(x**2)
4
>>> (3 + 2*x + 4*x**2).coeff(x**3)
0
>>> (z*(x + y)**2).coeff((x + y)**2)
z
>>> (z*(x + y)**2).coeff(x + y)
0
```
In addition, no factoring is done, so `1 + z*(1 + y)` is not obtained from the following:

```python
>>> (x + z*(x + x*y)).coeff(x)
1
```
If such factoring is desired, `factor_terms` can be used first:

```python
>>> from sympy import factor_terms
>>> factor_terms(x + z*(x + x*y)).coeff(x)
z*(y + 1) + 1
```
```python
>>> n, m, o = symbols('n m o', commutative=False)
>>> n.coeff(n)
```
(continues on next page)
If there is more than one possible coefficient 0 is returned:

```python
>>> (n*m + m*n).coeff(n)
0
```

If there is only one possible coefficient, it is returned:

```python
>>> (n*m + x*m*n).coeff(m*n)
x
>>> (n*m + x*m*n).coeff(m*n, right=1)
1
```

See also:

- `as_coefficient` (page 1001)
  separate the expression into a coefficient and factor
- `as_coeff_Add` (page 1000)
  separate the additive constant from an expression
- `as_coeff_Mul` (page 1000)
  separate the multiplicative constant from an expression
- `as_independent` (page 1004)
  separate x-dependent terms/factors from others
- `sympy.polys.polytools.Poly.coeff_monomial` (page 2459)
  efficiently find the single coefficient of a monomial in Poly
- `sympy.polys.polytools.Poly.nth` (page 2483)
  like coeff_monomial but powers of monomial terms are used

`collect(syms, func=None, evaluate=True, exact=False, distribute_order_term=True)`

See the collect function in sympy.simplify

`combsimp()`

See the combsimp function in sympy.simplify

`compute_leading_term(x, logx=None)`

Deprecated function to compute the leading term of a series.

as leading_term is only allowed for results of .series() This is a wrapper to compute a series first.

`conjugate()`

Returns the complex conjugate of ‘self’.
could_extract_minus_sign()
Return True if self has -1 as a leading factor or has more literal negative signs than positive signs in a sum, otherwise False.

Examples

```python
>>> from sympy import x, y
>>> e = x - y
>>> {i.could_extract_minus_sign() for i in (e, -e)}
{False, True}
```

Though the y - x is considered like -(x - y), since it is in a product without a leading factor of -1, the result is false below:

```python
>>> (x*(y - x)).could_extract_minus_sign()
False
```

To put something in canonical form wrt to sign, use `signsimp`:

```python
>>> from sympy import signsimp
>>> signsimp(x*(y - x))
-x*(x - y)
>>> _.could_extract_minus_sign()
True
```

equals(other, failing_expression=False)
Return True if self == other, False if it does not, or None. If failing_expression is True then the expression which did not simplify to a 0 will be returned instead of None.

Explanation

If self is a Number (or complex number) that is not zero, then the result is False.

If self is a number and has not evaluated to zero, evalf will be used to test whether the expression evaluates to zero. If it does so and the result has significance (i.e. the precision is either -1, for a Rational result, or is greater than 1) then the evalf value will be used to return True or False.

expand(deep=True, modulus=None, power_base=True, power_exp=True, mul=True, log=True, multinomial=True, basic=True, **hints)
Expand an expression using hints.

See the docstring of the expand() function in sympy.core.function for more information.

property expr_free_symbols
Like free_symbols, but returns the free symbols only if they are contained in an expression node.
Examples

```python
>>> from sympy.abc import x, y
>>> (x + y).expr_free_symbols
{x, y}
```

If the expression is contained in a non-expression object, do not return the free symbols. Compare:

```python
>>> from sympy import Tuple

>>> t = Tuple(x + y)
>>> t.expr_free_symbols
set()
>>> t.free_symbols
{x, y}
```

eextract_additively(c)

Return self - c if it’s possible to subtract c from self and make all matching coefficients move towards zero, else return None.

Examples

```python
>>> from sympy.abc import x, y

>>> e = 2*x + 3
>>> e.extract_additively(x + 1)  
x + 2
>>> e.extract_additively(3*x)
>>> e.extract_additively(4)
>>> (y*(x + 1)).extract_additively(x + 1)
>>> ((x + 1)*(x + 2*y + 1) + 3).extract_additively(x + 1)
(x + 1)*(x + 2*y) + 3
```

See also:

extract_multiplicatively (page 1015), coeff (page 1010), as_coefficient (page 1001)

eextract_branch_factor(allow_half=False)

Try to write self as exp_polar(2*pi*I*n)*z in a nice way. Return (z, n).

```python
>>> from sympy import exp_polar, I, pi

>>> exp_polar(I*pi).extract_branch_factor()
(exp_polar(I*pi), 0)
>>> exp_polar(2*I*pi).extract_branch_factor()
(1, 1)
>>> exp_polar(-pi*I).extract_branch_factor()
(exp_polar(I*pi), -1)
>>> exp_polar(3*pi*I + x).extract_branch_factor()
(exp_polar(x + I*pi), 1)
>>> (y*exp_polar(-5*pi*I)*exp_polar(3*pi*I + 2*pi*x)).extract_branch_factor()
```

(continues on next page)
extract_multiplicatively\( (c) \)
Return None if it’s not possible to make self in the form \( c \ast \) something in a nice way, i.e. preserving the properties of arguments of self.

Examples

```python
>>> from sympy import symbols, Rational

>>> x, y = symbols('x,y', real=True)

>>> ((x*y)**3).extract_multiplicatively(x**2 * y)
x*y**2

>>> ((x*y)**3).extract_multiplicatively(x**4 * y)

>>> (2*x).extract_multiplicatively(2)
x

>>> (2*x).extract_multiplicatively(3)

>>> (Rational(1, 2)*x).extract_multiplicatively(3)
x/6
```

factor\( (*gens, **args) \)
See the factor() function in sympy.polys.polytools

fourier_series\( (limits=None) \)
Compute fourier sine/cosine series of self.
See the docstring of the fourier_series() (page 1015) in sympy.series.fourier for more information.

fps\( (x=None, x0=0, dir=1, hyper=True, order=4, rational=True, full=False) \)
Compute formal power power series of self.
See the docstring of the `fps()` function in `sympy.series.formal` for more information.

**gammassimp()**

See the gammassimp function in `sympy.simplify`.

**getO()**

Returns the additive `O(..)` symbol if there is one, else None.

**getn()**

Returns the order of the expression.

**Explanation**

The order is determined either from the `O(...)` term. If there is no `O(...)` term, it returns None.

**Examples**

```python
>>> from sympy import O
>>> from sympy.abc import x
>>> (1 + x + O(x**2)).getn()
2
>>> (1 + x).getn()
```

**integrate(**args**, **kwargs**)**

See the integrate function in `sympy.integrals`.

**invert(g, **gens**, **args**)**

Return the multiplicative inverse of self mod g where self (and g) may be symbolic expressions).

**See also:**

`sympy.core.numbers.mod_inverse` (page 1053), `sympy.polys.polytools.invert` (page 2439)

**is_algebraic_expr(**syms**)**

This tests whether a given expression is algebraic or not, in the given symbols, syms. When syms is not given, all free symbols will be used. The rational function does not have to be in expanded or in any kind of canonical form.

This function returns False for expressions that are “algebraic expressions” with symbolic exponents. This is a simple extension to the is_rational_function, including rational exponentiation.
Examples

```python
>>> from sympy import Symbol, sqrt
>>> x = Symbol('x', real=True)
>>> sqrt(1 + x).is_rational_function()
False
>>> sqrt(1 + x).is_algebraic_expr()
True
```

This function does not attempt any nontrivial simplifications that may result in an expression that does not appear to be an algebraic expression to become one.

```python
>>> from sympy import exp, factor
>>> a = sqrt(exp(x)**2 + 2*exp(x) + 1)/(exp(x) + 1)
>>> a.is_algebraic_expr(x)
False
>>> factor(a).is_algebraic_expr()
True
```

See also:

`is_rational_function` (page 1021)

References

[R116]

`is_constant(*wrt, **flags)`

Return True if self is constant, False if not, or None if the constancy could not be determined conclusively.

Explanation

If an expression has no free symbols then it is a constant. If there are free symbols it is possible that the expression is a constant, perhaps (but not necessarily) zero. To test such expressions, a few strategies are tried:

1) numerical evaluation at two random points. If two such evaluations give two different values and the values have a precision greater than 1 then self is not constant. If the evaluations agree or could not be obtained with any precision, no decision is made. The numerical testing is done only if wrt is different than the free symbols.

2) differentiation with respect to variables in ‘wrt’ (or all free symbols if omitted) to see if the expression is constant or not. This will not always lead to an expression that is zero even though an expression is constant (see added test in test_expr.py). If all derivatives are zero then self is constant with respect to the given symbols.

3) finding out zeros of denominator expression with free_symbols. It will not be constant if there are zeros. It gives more negative answers for expression that are not constant.

If neither evaluation nor differentiation can prove the expression is constant, None is returned unless two numerical values happened to be the same and the flag failing_number is True – in that case the numerical value will be returned.
If flag simplify=False is passed, self will not be simplified; the default is True since self should be simplified before testing.

Examples

```python
>>> from sympy import cos, sin, Sum, S, pi
>>> from sympy.abc import a, n, x, y
>>> x.is_constant()
False
>>> S(2).is_constant()
True
>>> Sum(x, (x, 1, 10)).is_constant()
True
>>> Sum(x, (x, 1, n)).is_constant()
False
>>> Sum(x, (x, 1, n)).is_constant(y)
True
>>> Sum(x, (x, 1, n)).is_constant(n)
False
>>> Sum(x, (x, 1, n)).is_constant(x)
True
>>> eq = a*cos(x)**2 + a*sin(x)**2 - a
>>> eq.is_constant()
True
>>> eq.subs({x: pi, a: 2}) == eq.subs({x: pi, a: 3}) == 0
True
```

```python
>>> (0**x).is_constant()
False
>>> x.is_constant()
False
>>> (x**x).is_constant()
False
>>> one = cos(x)**2 + sin(x)**2
>>> one.is_constant()
True
>>> ((one - 1)**(x + 1)).is_constant() in (True, False) # could be 0, or 1
True
```

`is_meromorphic(x, a)`

This tests whether an expression is meromorphic as a function of the given symbol x at the point a.

This method is intended as a quick test that will return None if no decision can be made without simplification or more detailed analysis.
Examples

```python
>>> from sympy import zoo, log, sin, sqrt
>>> from sympy.abc import x

>>> f = 1/x**2 + 1 - 2*x**3
>>> f.is_meromorphic(x, 0)
True
>>> f.is_meromorphic(x, 1)
True
>>> f.is_meromorphic(x, zoo)
True

>>> g = x**log(3)
>>> g.is_meromorphic(x, 0)
False
>>> g.is_meromorphic(x, 1)
True
>>> g.is_meromorphic(x, zoo)
False

>>> h = sin(1/x)*x**2
>>> h.is_meromorphic(x, 0)
False
>>> h.is_meromorphic(x, 1)
True
>>> h.is_meromorphic(x, zoo)
True

Multivalued functions are considered meromorphic when their branches are meromorphic. Thus most functions are meromorphic everywhere except at essential singularities and branch points. In particular, they will be meromorphic also on branch cuts except at their endpoints.

```python
>>> log(x).is_meromorphic(x, -1)
True
>>> log(x).is_meromorphic(x, 0)
False
>>> sqrt(x).is_meromorphic(x, -1)
True
>>> sqrt(x).is_meromorphic(x, 0)
False
```

**property is_number**

Returns True if self has no free symbols and no undefined functions (AppliedUndef, to be precise). It will be faster than if not self.free_symbols, however, since is_number will fail as soon as it hits a free symbol or undefined function.
Examples

```python
>>> from sympy import Function, Integral, cos, sin, pi
>>> from sympy.abc import x
>>> f = Function('f')

>>> x.is_number
False
>>> f(1).is_number
False
>>> (2*x).is_number
False
>>> (2 + Integral(2, x)).is_number
False
>>> (2 + Integral(2, (x, 1, 2))).is_number
True
```

Not all numbers are Numbers in the SymPy sense:

```python
>>> pi.is_number, pi.is_Number
(True, False)
```

If something is a number it should evaluate to a number with real and imaginary parts that are Numbers; the result may not be comparable, however, since the real and/or imaginary part of the result may not have precision.

```python
>>> cos(1).is_number and cos(1).is_comparable
True
>>> z = cos(1)**2 + sin(1)**2 - 1
>>> z.is_number
True
>>> z.is_comparable
False
```

See also:

`sympy.core.basic.Basic.is_comparable` (page 987)

`is_polynomial(*syms)`

Return True if self is a polynomial in syms and False otherwise.

This checks if self is an exact polynomial in syms. This function returns False for expressions that are "polynomials" with symbolic exponents. Thus, you should be able to apply polynomial algorithms to expressions for which this returns True, and Poly(expr,*syms) should work if and only if expr.is_polynomial(*syms) returns True. The polynomial does not have to be in expanded form. If no symbols are given, all free symbols in the expression will be used.

This is not part of the assumptions system. You cannot do Symbol('z', polynomial=True).
Examples

```python
>>> from sympy import Symbol, Function
>>> x = Symbol('x')
>>> ((x**2 + 1)**4).is_polynomial(x)
True
>>> ((x**2 + 1)**4).is_polynomial()
True
>>> (2**x + 1).is_polynomial(x)
False
>>> (2**x + 1).is_polynomial(2**x)
True
>>> f = Function('f')
>>> (f(x) + 1).is_polynomial(x)
False
>>> (f(x) + 1).is_polynomial(f(x))
True
>>> (1/f(x) + 1).is_polynomial(f(x))
False

>>> n = Symbol('n', nonnegative=True, integer=True)
>>> (x**n + 1).is_polynomial(x)
False
```

This function does not attempt any nontrivial simplifications that may result in an expression that does not appear to be a polynomial to become one.

```python
>>> from sympy import sqrt, factor, cancel
>>> y = Symbol('y', positive=True)
>>> a = sqrt(y**2 + 2*y + 1)
>>> a.is_polynomial(y)
False
>>> factor(a)
y + 1
>>> factor(a).is_polynomial(y)
True

>>> b = (y**2 + 2*y + 1)/(y + 1)
>>> b.is_polynomial(y)
False
>>> cancel(b)
y + 1
>>> cancel(b).is_polynomial(y)
True
```

See also `.is_rational_function()`

`.is_rational_function(*syms)`

Test whether function is a ratio of two polynomials in the given symbols, syms. When syms is not given, all free symbols will be used. The rational function does not have to be in expanded or in any kind of canonical form.

This function returns False for expressions that are “rational functions” with symbolic exponents. Thus, you should be able to call `.as_numer_denom()` and apply
polynomial algorithms to the result for expressions for which this returns True. This is not part of the assumptions system. You cannot do Symbol('z', rational_function=True).

**Examples**

```python
>>> from sympy import Symbol, sin
>>> from sympy.abc import x, y

>>> (x/y).is_rational_function()
True

>>> (x**2).is_rational_function()
True

>>> (x/sin(y)).is_rational_function(y)
False

>>> n = Symbol('n', integer=True)
>>> (x**n + 1).is_rational_function(x)
False

This function does not attempt any nontrivial simplifications that may result in an expression that does not appear to be a rational function to become one.

```python
>>> from sympy import sqrt, factor
>>> y = Symbol('y', positive=True)
>>> a = sqrt(y**2 + 2*y + 1)/y
>>> a.is_rational_function(y)
False
>>> factor(a)
(y + 1)/y
>>> factor(a).is_rational_function(y)
True
```

See also is_algebraic_expr().

**leadterm** *(x, logx=None, cdir=0)*

Returns the leading term a*x**b as a tuple (a, b).

**Examples**

```python
>>> from sympy.abc import x

>>> (1+x+x**2).leadterm(x)
(1, 0)

>>> (1/x**2+x+x**2).leadterm(x)
(1, -2)
```

**limit** *(x, xlim, dir='+')*

Compute limit x->xlim.
\texttt{lseries}(x=\texttt{None}, x0=0, dir='+', logx=\texttt{None}, cdir=0)

Wrapper for series yielding an iterator of the terms of the series.

Note: an infinite series will yield an infinite iterator. The following, for example, will never terminate. It will just keep printing terms of the \texttt{sin(x)} series:

\begin{verbatim}
for \texttt{term} in \texttt{sin(x).lseries(x)}:
    \texttt{print term}
\end{verbatim}

The advantage of \texttt{lseries()} over \texttt{nseries()} is that many times you are just interested in the next term in the series (i.e. the first term for example), but you do not know how many you should ask for in \texttt{nseries()} using the “n” parameter.

See also \texttt{nseries()}.

\textbf{normal()}

Return the expression as a fraction.

\texttt{expression -> a/b}

\textbf{See also:}

\texttt{as_numer_denom (page 1007)}

return (a, b) instead of \texttt{a/b}

\texttt{nseries}(x=\texttt{None}, x0=0, n=6, dir='+', logx=\texttt{None}, cdir=0)

Wrapper to \texttt{_eval_nseries} if assumptions allow, else to \texttt{series}.

If \texttt{x} is given, \texttt{x0} is 0, \texttt{dir='+'}, and \texttt{self} has \texttt{x}, then \texttt{_eval_nseries} is called. This calculates “n” terms in the innermost expressions and then builds up the final series just by “cross-multiplying” everything out.

The optional \texttt{logx} parameter can be used to replace any \texttt{log(x)} in the returned series with a symbolic value to avoid evaluating \texttt{log(x)} at 0. A symbol to use in place of \texttt{log(x)} should be provided.

Advantage – it’s fast, because we do not have to determine how many terms we need to calculate in advance.

Disadvantage – you may end up with less terms than you may have expected, but the \texttt{O(x**n)} term appended will always be correct and so the result, though perhaps shorter, will also be correct.

If any of those assumptions is not met, this is treated like a wrapper to \texttt{series} which will try harder to return the correct number of terms.

See also \texttt{lseries()}.

\textbf{Examples}

\begin{verbatim}
>>> \texttt{from sympy import sin, log, Symbol}
>>> \texttt{from sympy.abc import x, y}
>>> \texttt{sin(x).nseries(x, 0, 6)}
\texttt{x} - \texttt{x**3/6 + x**5/120 + 0(x**6)}
>>> \texttt{log(x+1).nseries(x, 0, 5)}
\texttt{x} - \texttt{x**2/2 + x**3/3 - x**4/4 + 0(x**5)}
\end{verbatim}
Handling of the logx parameter — in the following example the expansion fails since sin does not have an asymptotic expansion at -oo (the limit of log(x) as x approaches 0):

```python
>>> e = sin(log(x))
>>> e.nseries(x, 0, 6)
Traceback (most recent call last):
...  PoleError: ...
...
>>> logx = Symbol('logx')
>>> e.nseries(x, 0, 6, logx=logx)
sin(logx)
```

In the following example, the expansion works but only returns self unless the logx parameter is used:

```python
>>> e = x**y
>>> e.nseries(x, 0, 2)
x**y
>>> e.nseries(x, 0, 2, logx=logx)
exp(logx*y)
```

`nsimplify(constants=(), tolerance=None, full=False)`
See the nsimplify function in sympy.simplify

`powsimp(*args, **kwargs)`
See the powsimp function in sympy.simplify

`primitive()`
Return the positive Rational that can be extracted non-recursively from every term of self (i.e., self is treated like an Add). This is like the as_coeff_Mul() method but primitive always extracts a positive Rational (never a negative or a Float).

**Examples**

```python
>>> from sympy.abc import x
>>> (3*(x + 1)**2).primitive()
(3, (x + 1)**2)
>>> a = (6*x + 2); a.primitive()
(2, 3*x + 1)
>>> b = (x/2 + 3); b.primitive()
(1/2, x + 6)
>>> (a*b).primitive() == (1, a*b)
True
```

`radsimp(**kwargs)`
See the radsimp function in sympy.simplify

`ratsimp()`
See the ratsimp function in sympy.simplify
removeO()
Remove the additive O(..) symbol if there is one

round(n=None)
Return x rounded to the given decimal place.
If a complex number would results, apply round to the real and imaginary components of the number.

Examples

```python
>>> from sympy import pi, E, I, S, Number
>>> pi.round()
3
>>> pi.round(2)
3.14
>>> (2*pi + E*I).round()
6 + 3*I
```

The round method has a chopping effect:

```python
>>> (2*pi + I/10).round()
6
>>> (pi/10 + 2*I).round()
2*I
>>> (pi/10 + E*I).round(2)
0.31 + 2.72*I
```

Notes
The Python round function uses the SymPy round method so it will always return a SymPy number (not a Python float or int):

```python
>>> isinstance(round(S(123), -2), Number)
True
```

separate(deep=False, force=False)
See the separate function in sympy.simplify

series(x=None, x0=0, n=6, dir='+', logx=None, cdir=0)
Series expansion of “self” around x = x0 yielding either terms of the series one by one (the lazy series given when n=None), else all the terms at once when n != None.
Returns the series expansion of “self” around the point x = x0 with respect to x up to O((x - x0)**n, x, x0) (default n is 6).
If x=None and self is univariate, the univariate symbol will be supplied, otherwise an error will be raised.

Parameters
expr : Expression
The expression whose series is to be expanded.
x : Symbol
It is the variable of the expression to be calculated.

$x_0$ : Value

The value around which $x$ is calculated. Can be any value from $-\infty$ to $\infty$.

$n$ : Value

The value used to represent the order in terms of $x^n$, up to which the series is to be expanded.

dir : String, optional

The series-expansion can be bi-directional. If dir="+", then $(x->x_0+)$. If dir="-", then $(x->x_0-)$. For infinite `\`x0 (oo or -oo), the dir argument is determined from the direction of the infinity (i.e., dir="-" for oo).

$logx$ : optional

It is used to replace any log(x) in the returned series with a symbolic value rather than evaluating the actual value.

cdir : optional

It stands for complex direction, and indicates the direction from which the expansion needs to be evaluated.

Returns

Expr : Expression

Series expansion of the expression about $x_0$

Raises

TypeError

If "n" and "x0" are infinity objects

PoleError

If "x0" is an infinity object

Examples

```python
>>> from sympy import cos, exp, tan
>>> from sympy.abc import x, y

>>> cos(x).series()
1 - x**2/2 + x**4/24 + O(x**6)

>>> cos(x).series(n=4)
1 - x**2/2 + O(x**4)

>>> cos(x).series(x, x0=1, n=2)
cos(1) - (x - 1)*sin(1) + O((x - 1)**2, (x, 1))

>>> e = cos(x + exp(y))

>>> e.series(y, n=2)
cos(x + 1) - y*sin(x + 1) + O(y**2)

>>> e.series(x, n=2)
cos(exp(y)) - x*sin(exp(y)) + O(x**2)
```

If n=None then a generator of the series terms will be returned.
>>> term = cos(x).series(n=None)
>>> [next(term) for i in range(2)]
[1, -x**2/2]

For dir=+ (default) the series is calculated from the right and for dir=- the series from the left. For smooth functions this flag will not alter the results.

>>> abs(x).series(dir="+")
1
>>> abs(x).series(dir="-")
-x
>>> f = tan(x)
>>> f.series(x, 2, 6, "+")
tan(2) + (1 + tan(2)**2)*(x - 2) + (x - 2)**2*(tan(2)**3 + tan(2)) + (x - 2)**3*(1/3 + 4*tan(2)**2/3 + tan(2)**4) + (x - 2)**4*(tan(2)**5 + 5*tan(2)**3/3 + 2*tan(2)/3) + (x - 2)**5*(2/15 + 17*tan(2)**2/15 + 2*tan(2)**4 + tan(2)**6) + O((x - 2)**6, (x, 2))

>>> f.series(x, 2, 3, "-")
tan(2) + (2 - x)*(-tan(2)**2 - 1) + (2 - x)**2*(tan(2)**3 + tan(2)) + O((x - 2)**3, (x, 2))

For rational expressions this method may return original expression without the Order term. >>> (1/x).series(x, n=8) 1/x

taylor_term(n, x, *previous_terms)
General method for the taylor term.
This method is slow, because it differentiates n-times. Subclasses can redefine it to make it faster by using the “previous_terms”.

together(*args, **kwargs)
See the together function in sympy.polys

trigsimp(**args)
See the trigsimp function in sympy.simplify

class sympy.core.expr.UnevaluatedExpr(arg, **kwargs)
Expression that is not evaluated unless released.

Examples

>>> from sympy import UnevaluatedExpr
>>> from sympy.abc import x
>>> x*(1/x)
1
>>> x*UnevaluatedExpr(1/x)
x*1/x

class sympy.core.expr.AtomicExpr(*args)
A parent class for object which are both atoms and Exprs.
For example: Symbol, Number, Rational, Integer, ... But not: Add, Mul, Pow, ...
symbol

class sympy.core.symbol.Symbol(name, **assumptions)

 Assumptions:
    commutative = True

You can override the default assumptions in the constructor.

Examples

```python
>>> from sympy import symbols
>>> A, B = symbols('A,B', commutative=False)
>>> bool(A*B != B*A)
True
>>> bool(A*B*2 == 2*A*B) == True  # multiplication by scalars is commutative
True
```

class sympy.core.symbol.Wild(name, exclude=(), properties=(), **assumptions)

A Wild symbol matches anything, or anything without whatever is explicitly excluded.

Parameters

- **name**: str
  Name of the Wild instance.

- **exclude**: iterable, optional
  Instances in exclude will not be matched.

- **properties**: iterable of functions, optional
  Functions, each taking an expressions as input and returns a bool.
  All functions in properties need to return True in order for the Wild instance to match the expression.

Examples

```python
>>> from sympy import Wild, WildFunction, cos, pi
>>> from sympy.abc import x, y, z
>>> a = Wild('a')
>>> x.match(a)
{a_: x}
>>> pi.match(a)
{a_: pi}
>>> (3*x**2).match(a*x)
{a_: 3*x}
>>> cos(x).match(a)
{a_: cos(x)}
>>> b = Wild('b', exclude=[x])
>>> (3*x**2).match(b*x)
{a_: b_}
```
Tips

When using Wild, be sure to use the exclude keyword to make the pattern more precise. Without the exclude pattern, you may get matches that are technically correct, but not what you wanted. For example, using the above without exclude:

```python
>>> from sympy import symbols
>>> a, b = symbols('a b', cls=Wild)
>>> (2 + 3*y).match(a*x + b*y)
{a_: 2/x, b_: 3}
```

This is technically correct, because \((2/x)*x + 3*y = 2 + 3*y\), but you probably wanted it to not match at all. The issue is that you really did not want \(a\) and \(b\) to include \(x\) and \(y\), and the exclude parameter lets you specify exactly this. With the exclude parameter, the pattern will not match.

```python
>>> a = Wild('a', exclude=[x, y])
>>> b = Wild('b', exclude=[x, y])
>>> (2 + 3*y).match(a*x + b*y)
```

Exclude also helps remove ambiguity from matches.

```python
>>> E = 2*x**3*y*z
>>> a, b = symbols('a b', cls=Wild)
>>> E.match(a*b)
{a_: 2*y*z, b_: x**3}
>>> a = Wild('a', exclude=[x, y])
>>> E.match(a*b)
{a_: z, b_: 2*x**3*y}
>>> a = Wild('a', exclude=[x, y, z])
>>> E.match(a*b)
{a_: 2, b_: x**3*y*z}
```

Wild also accepts a properties parameter:

```python
>>> a = Wild('a', properties=[lambda k: k.is_Integer])
>>> E.match(a*b)
{a_: 2, b_: x**3*y*z}
```

**class** *sympy.core.symbol.Dummy*(name=None, dummy_index=None, **assumptions)*

Dummy symbols are each unique, even if they have the same name:
Examples

```python
>>> from sympy import Dummy
>>> Dummy("x") == Dummy("x")
False
```

If a name is not supplied then a string value of an internal count will be used. This is useful when a temporary variable is needed and the name of the variable used in the expression is not important.

```python
>>> Dummy()
_Dummy_10
```

`sympy.core.symbol.symbols(names, *, cls=<class 'sympy.core.symbol.Symbol'>, **args)`

→ Any

Transform strings into instances of `Symbol` (page 1028) class.

`symbols()` (page 1030) function returns a sequence of symbols with names taken from names argument, which can be a comma or whitespace delimited string, or a sequence of strings:

```python
>>> from sympy import symbols, Function
>>> x, y, z = symbols('x,y,z')
>>> a, b, c = symbols('a b c')
```

The type of output is dependent on the properties of input arguments:

```python
>>> symbols('x')
x
>>> symbols('x,')
(x,)
>>> symbols('x,y')
(x, y)
```

If an iterable container is needed for a single symbol, set the seq argument to True or terminate the symbol name with a comma:

```python
>>> symbols('x', seq=True)
(x,)
```

To reduce typing, range syntax is supported to create indexed symbols. Ranges are indicated by a colon and the type of range is determined by the character to the right of the colon. If the character is a digit then all contiguous digits to the left are taken as the nonnegative starting value (or 0 if there is no digit left of the colon) and all contiguous digits to the right are taken as 1 greater than the ending value:
>>> symbols('x:10')
(x0, x1, x2, x3, x4, x5, x6, x7, x8, x9)

>>> symbols('x5:10')
(x5, x6, x7, x8, x9)

>>> symbols('x5:2')
(x50, x51)

>>> symbols('x5:10, y:5')
((x5, x6, x7, x8, x9), (y0, y1, y2, y3, y4))

If the character to the right of the colon is a letter, then the single letter to the left (or 'a' if there is none) is taken as the start and all characters in the lexicographic range through the letter to the right are used as the range:

>>> symbols('x:z')
(x, y, z)

>>> symbols('x:c')  # null range
()

>>> symbols('x(:c)')
(xa, xb, xc)

>>> symbols(':c')
(a, b, c)

>>> symbols('a:d, x:z')
(a, b, c, d, x, y, z)

>>> symbols(['a:d', 'x:z'])
((a, b, c, d), (x, y, z))

Multiple ranges are supported; contiguous numerical ranges should be separated by parentheses to disambiguate the ending number of one range from the starting number of the next:

>>> symbols('x:2(1:3)')
(x01, x02, x11, x12)

>>> symbols('3:2')  # parsing is from left to right
(00, 01, 10, 11, 20, 21)

Only one pair of parentheses surrounding ranges are removed, so to include parentheses around ranges, double them. And to include spaces, commas, or colons, escape them with a backslash:

>>> symbols('x((a:b))')
(x(a), x(b))

>>> symbols(r'x(1\,:,2)')  # or r'x((1),(2))'
(x(0,0), x(0,1))

All newly created symbols have assumptions set according to args:
Despite its name, `symbols()` (page 1030) can create symbol-like objects like instances of Function or Wild classes. To achieve this, set `cls` keyword argument to the desired type:

```python
>>> symbols('f,g,h', cls=Function)
(f, g, h)
>>> type([0])
<class 'sympy.core.function.UndefinedFunction'>
```

```python
sympy.core.symbol.var(names, **args)

Create symbols and inject them into the global namespace.
```

**Explanation**

This calls `symbols()` (page 1030) with the same arguments and puts the results into the global namespace. It’s recommended not to use `var()` (page 1032) in library code, where `symbols()` (page 1030) has to be used:

```
.. rubric:: Examples

```python
>>> from sympy import var
```

```python
>>> var('x')
x
>>> x # noqa: F821
x
```

```python
>>> var('a,ab,abc')
(a, ab, abc)
>>> abc # noqa: F821
abc
```

```python
>>> var('x,y', real=True)
(x, y)
>>> x.is_real and y.is_real # noqa: F821
True
```

See `symbols()` (page 1030) documentation for more details on what kinds of arguments can be passed to `var()` (page 1032).
numbers

class sympy.core.numbers.Number(*obj)
    Represents atomic numbers in SymPy.

Explanation

Floating point numbers are represented by the Float class. Rational numbers (of any size) are represented by the Rational class. Integer numbers (of any size) are represented by the Integer class. Float and Rational are subclasses of Number; Integer is a subclass of Rational.

For example, 2/3 is represented as Rational(2, 3) which is a different object from the floating point number obtained with Python division 2/3. Even for numbers that are exactly represented in binary, there is a difference between how two forms, such as Rational(1, 2) and Float(0.5), are used in SymPy. The rational form is to be preferred in symbolic computations.

Other kinds of numbers, such as algebraic numbers sqrt(2) or complex numbers 3 + 4*I, are not instances of Number class as they are not atomic.

See also:
Float (page 1033), Integer (page 1038), Rational (page 1036)

as_coeff_Add(rational=False)
    Efficiently extract the coefficient of a summation.

as_coeff_Mul(rational=False)
    Efficiently extract the coefficient of a product.

cofactors(other)
    Compute GCD and cofactors of self and other.

gcd(other)
    Compute GCD of self and other.

lcm(other)
    Compute LCM of self and other.

class sympy.core.numbers.Float(num, dps=None, precision=None)
    Represent a floating-point number of arbitrary precision.

Examples

>>> from sympy import Float
>>> Float(3.5)
3.50000000000000
>>> Float(3)
3.00000000000000

Creating Floats from strings (and Python int and long types) will give a minimum precision of 15 digits, but the precision will automatically increase to capture all digits entered.
However, `floating-point` numbers (Python float types) retain only 15 digits of precision:

```
>>> Float(1e20)
1.00000000000000e+20
>>> Float('1e20')
1.23456789123457
```

It may be preferable to enter high-precision decimal numbers as strings:

```
>>> Float('1.23456789123456789')
1.23456789123457
```

The desired number of digits can also be specified:

```
>>> Float('1e-3', 3)
0.00100
>>> Float(100, 4)
100.0
```

Float can automatically count significant figures if a null string is sent for the precision; spaces or underscores are also allowed. (Auto-counting is only allowed for strings, ints and longs).

```
>>> Float('123 456 789.123_456', '')
123456789.123456
>>> Float('12e-3', '')
0.012
>>> Float(3, '')
3.
```

If a number is written in scientific notation, only the digits before the exponent are considered significant if a decimal appears, otherwise the “e” signifies only how to move the decimal:

```
>>> Float('60.e2', '') # 2 digits significant
6.0e+3
>>> Float('60e2', '') # 4 digits significant
6000.
>>> Float('600e-2', '') # 3 digits significant
6.00
```
## Notes

Floats are inexact by their nature unless their value is a binary-exact value.

```python
>>> approx, exact = Float(.1, 1), Float(.125, 1)
```

For calculation purposes, `evalf` needs to be able to change the precision but this will not increase the accuracy of the inexact value. The following is the most accurate 5-digit approximation of a value of 0.1 that had only 1 digit of precision:

```python
>>> approx.evalf(5)
0.099609
```

By contrast, 0.125 is exact in binary (as it is in base 10) and so it can be passed to `Float` or `evalf` to obtain an arbitrary precision with matching accuracy:

```python
>>> Float(exact, 5)
0.12500
>>> exact.evalf(20)
0.12500000000000000000
```

Trying to make a high-precision `Float` from a float is not disallowed, but one must keep in mind that the underlying float (not the apparent decimal value) is being obtained with high precision. For example, 0.3 does not have a finite binary representation. The closest rational is the fraction $5404319552844595/2^{54}$. So if you try to obtain a Float of 0.3 to 20 digits of precision you will not see the same thing as 0.3 followed by 19 zeros:

```python
>>> Float(0.3, 20)
0.29999999999999998890
```

If you want a 20-digit value of the decimal 0.3 (not the floating point approximation of 0.3) you should send the 0.3 as a string. The underlying representation is still binary but a higher precision than Python’s float is used:

```python
>>> Float('0.3', 20)
0.30000000000000000000
```

Although you can increase the precision of an existing `Float` using `Float` it will not increase the accuracy – the underlying value is not changed:

```python
>>> def show(f): # binary rep of Float...
...     from sympy import Mul, Pow...
...     s, m, e, b = f._mpf_...
...     v = Mul(int(m), Pow(2, int(e), evaluate=False), evaluate=False)
...     print('%s at prec=%s' % (v, f._prec))...
>>> t = Float('0.3', 3)
>>> show(t)
4915/2**14 at prec=13
>>> show(Float(t, 20)) # higher prec, not higher accuracy
4915/2**14 at prec=70
>>> show(Float(t, 2)) # lower prec
307/2**10 at prec=10
```

The same thing happens when `evalf` is used on a `Float`:
Finally, Floats can be instantiated with an mpf tuple \((n, c, p)\) to produce the number \((-1)^n c \times 2^p\):

```python
>>> n, c, p = 1, 5, 0
>>> (-1)**n * c * 2**p
-5
>>> Float((1, 5, 0))
-5.00000000000000
```

An actual mpf tuple also contains the number of bits in \(c\) as the last element of the tuple:

```python
>>> _.mpf_
(1, 5, 0, 3)
```

This is not needed for instantiation and is not the same thing as the precision. The mpf tuple and the precision are two separate quantities that Float tracks.

In SymPy, a Float is a number that can be computed with arbitrary precision. Although floating point ‘inf’ and ‘nan’ are not such numbers, Float can create these numbers:

```python
>>> Float('-inf')
-inf
>>> _.is_Float
False
```

Zero in Float only has a single value. Values are not separate for positive and negative zeroes.

class sympy.core.numbers.Rational\((p, q=\text{None}, \text{gcd=\text{None}})\)

Represents rational numbers \((p/q)\) of any size.

**Examples**

```python
>>> from sympy import Rational, nsimplify, S, pi
>>> Rational(1, 2)
1/2
```

Rational is unprejudiced in accepting input. If a float is passed, the underlying value of the binary representation will be returned:

```python
>>> Rational(.5)
1/2
>>> Rational(.2)
3602879701896397/18014398509481984
```

If the simpler representation of the float is desired then consider limiting the denominator to the desired value or convert the float to a string (which is roughly equivalent to limiting the denominator to \(10^{\times12}\)):
An arbitrarily precise Rational is obtained when a string literal is passed:

```python
>>> Rational("1.23")
123/100
>>> Rational('1e-2')
1/100
>>> Rational(".1")
1/10
>>> Rational('1e-2/3.2')
1/320
```

The conversion of other types of strings can be handled by the `sympify()` function, and conversion of floats to expressions or simple fractions can be handled with `nsimplify`:

```python
>>> S('.[3]')  # repeating digits in brackets
1/3
>>> S('3**2/10')  # general expressions
9/10
>>> nsimplify(.3)  # numbers that have a simple form
3/10
```

But if the input does not reduce to a literal Rational, an error will be raised:

```python
>>> Rational(pi)
Traceback (most recent call last):
  ... TypeError: invalid input: pi
```

### Low-level

Access numerator and denominator as `.p` and `.q`:

```python
>>> r = Rational(3, 4)
>>> r
3/4
>>> r.p
3
>>> r.q
4
```

Note that `p` and `q` return integers (not SymPy Integers) so some care is needed when using them in expressions:

```python
>>> r.p/r.q
0.75
```

If an unevaluated Rational is desired, `gcd=1` can be passed and this will keep common divisors of the numerator and denominator from being eliminated. It is not possible,
however, to leave a negative value in the denominator.

```python
>>> Rational(2, 4, gcd=1)
2/4
>>> Rational(2, -4, gcd=1).q
4
```

**See also:**

`sympy.core.sympify.sympify` (page 970), `sympy.simplify.simplify.njsimplify` (page 725)

- `as_coeff_Add(rational=False)`
  Efficiently extract the coefficient of a summation.

- `as_coeff_Mul(rational=False)`
  Efficiently extract the coefficient of a product.

- `as_content_primitive(radical=False, clear=True)`
  Return the tuple (R, self/R) where R is the positive Rational extracted from self.

**Examples**

```python
>>> from sympy import S
>>> (S(-3)/2).as_content_primitive()
(3/2, -1)
```

See docstring of Expr.as_content_primitive for more examples.

- `factors(limit=None, use_trial=True, use_rho=False, use_pm1=False, verbose=False, visual=False)`
  A wrapper to factorint which return factors of self that are smaller than limit (or cheap to compute). Special methods of factoring are disabled by default so that only trial division is used.

- `limit_denominator(max_denominator=1000000)`
  Closest Rational to self with denominator at most max_denominator.

**Examples**

```python
>>> from sympy import Rational
>>> Rational('3.141592653589793').limit_denominator(10)
22/7
>>> Rational('3.141592653589793').limit_denominator(100)
311/99
```

class sympy.core.numbers.Integer(i)

Represents integer numbers of any size.
Examples

```python
>>> from sympy import Integer
>>> Integer(3)
3
```

If a float or a rational is passed to `Integer`, the fractional part will be discarded; the effect is of rounding toward zero.

```python
>>> Integer(3.8)
3
>>> Integer(-3.8)
-3
```

A string is acceptable input if it can be parsed as an integer:

```python
>>> Integer("9" * 20)
99999999999999999999
```

It is rarely needed to explicitly instantiate an `Integer`, because Python integers are automatically converted to `Integer` when they are used in SymPy expressions.

```python
class sympy.core.numbers.AlgebraicNumber(expr, coeffs=None, alias=None, **args)
```

Class for representing algebraic numbers in SymPy.

Symbolically, an instance of this class represents an element \( \alpha \in \mathbb{Q}(\theta) \hookrightarrow \mathbb{C} \). That is, the algebraic number \( \alpha \) is represented as an element of a particular number field \( \mathbb{Q}(\theta) \), with a particular embedding of this field into the complex numbers.

Formally, the primitive element \( \theta \) is given by two data points: (1) its minimal polynomial (which defines \( \mathbb{Q}(\theta) \)), and (2) a particular complex number that is a root of this polynomial (which defines the embedding \( \mathbb{Q}(\theta) \hookrightarrow \mathbb{C} \)). Finally, the algebraic number \( \alpha \) which we represent is then given by the coefficients of a polynomial in \( \theta \).

```python
static __new__(cls, expr, coeffs=None, alias=None, **args)
```

Construct a new algebraic number \( \alpha \) belonging to a number field \( k = \mathbb{Q}(\theta) \).

There are four instance attributes to be determined:

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Type/meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>root</td>
<td><code>Expr</code> (page 999) for ( \theta ) as a complex number</td>
</tr>
<tr>
<td>minpoly</td>
<td><code>Poly</code> (page 2453), the minimal polynomial of ( \theta )</td>
</tr>
<tr>
<td>rep</td>
<td><code>DMP</code> (page 2643) giving ( \alpha ) as poly in ( \theta )</td>
</tr>
<tr>
<td>alias</td>
<td><code>Symbol</code> (page 1028) for ( \theta ), or None</td>
</tr>
</tbody>
</table>

See Parameters section for how they are determined.

Parameters

- **expr**: `Expr` (page 999), or pair \((m, r)\)

There are three distinct modes of construction, depending on what is passed as `expr`.

1. **expr** is an `AlgebraicNumber` (page 1039): In this case we begin by copying all four instance attributes from `expr`. If `coeffs` were also
given, we compose the two coeff polynomials (see below). If an alias was given, it overrides.

(2) \textit{expr} is any other type of \textit{Expr} (page 999): Then root will equal \textit{expr}. Therefore it must express an algebraic quantity, and we will compute its \textit{minpoly}.

(3) \textit{expr} is an ordered pair \((m, r)\) giving the \textit{minpoly} \(m\), and a root \(r\) thereof, which together define \(\theta\). In this case \(m\) may be either a univariate \textit{Poly} (page 2453) or any \textit{Expr} (page 999) representing the same, while \(r\) must be some \textit{Expr} (page 999) representing a complex number that is a root of \(m\), including both explicit expressions in radicals, and instances of \textit{ComplexRootOf} (page 2507) or \textit{AlgebraicNumber} (page 1039).

coeffs : list, \textit{ANP} (page 2650), None, optional (default=None)

This defines \textit{rep}, giving the algebraic number \(\alpha\) as a polynomial in \(\theta\). If a list, the elements should be integers or rational numbers. If an \textit{ANP} (page 2650), we take its coefficients, using \textit{its \textit{to_list}()} (page 2650) method). If None, then the list of coefficients defaults to \([1, 0]\), meaning that \(\alpha = \theta\) is the primitive element of the field.

If \textit{expr} was an \textit{AlgebraicNumber} (page 1039), let \(g(x)\) be its \textit{rep} polynomial, and let \(f(x)\) be the polynomial defined by \textit{coeffs}. Then self. \textit{rep} will represent the composition \((f \circ g)(x)\).

alias : str, \textit{Symbol} (page 1028), None, optional (default=None)

This is a way to provide a name for the primitive element. We described several ways in which \textit{the \textit{expr} argument can define the value of the primitive element, but none of these methods gave it a name. Here, for example, \textit{alias} could be set as \textit{Symbol}('theta'), in order to make this symbol appear when \(\alpha\) is printed, or rendered as a polynomial, using the \textit{as_poly()} (page 1042) method.

\section*{Examples}

Recall that we are constructing an algebraic number as a field element \(\alpha \in \mathbb{Q}(\theta)\).

\begin{verbatim}
>>> from sympy import AlgebraicNumber, sqrt, CRootOf, S
>>> from sympy.abc import x

Example (1): \(\alpha = \theta = \sqrt{2}\)

>>> a1 = AlgebraicNumber(sqrt(2))
>>> a1.minpoly_of_element().as_expr(x)
1.414213562

Example (2): \(\alpha = 3\sqrt{2} - 5, \theta = \sqrt{2}\). We can either build on the last example:

>>> a2 = AlgebraicNumber(a1, [3, -5])
>>> a2.as_expr()
-5 + 3*sqrt(2)
\end{verbatim}
or start from scratch:

```python
>>> a2 = AlgebraicNumber(sqrt(2), [3, -5])
>>> a2.as_expr()
-5 + 3*sqrt(2)
```

Example (3): $\alpha = 6\sqrt{2} - 11, \theta = \sqrt{2}$. Again we can build on the previous example, and we see that the coeff polys are composed:

```python
>>> a3 = AlgebraicNumber(a2, [2, -1])
>>> a3.as_expr()
-11 + 6*sqrt(2)
```

reflecting the fact that $(2x - 1) \circ (3x - 5) = 6x - 11$.

Example (4): $\alpha = \sqrt{2}, \theta = \sqrt{2} + \sqrt{3}$. The easiest way is to use the `to_number_field()` function:

```python
>>> from sympy import to_number_field
>>> a4 = to_number_field(sqrt(2), sqrt(2) + sqrt(3))
>>> a4.minpoly_of_element().as_expr(x)
x**2 - 2
>>> a4.to_root()
sqrt(2)
>>> a4.primitive_element()
sqrt(2) + sqrt(3)
>>> a4.coeffs()
[1/2, 0, -9/2, 0]
```

but if you already knew the right coefficients, you could construct it directly:

```python
>>> a4 = AlgebraicNumber(sqrt(2) + sqrt(3), [S(1)/2, 0, S(-9)/2, 0])
>>> a4.to_root()
sqrt(2)
>>> a4.primitive_element()
sqrt(2) + sqrt(3)
```

Example (5): Construct the Golden Ratio as an element of the 5th cyclotomic field, supposing we already know its coefficients. This time we introduce the alias $\zeta$ for the primitive element of the field:

```python
>>> from sympy import cyclotomic_poly
>>> from sympy.abc import zeta
>>> a5 = AlgebraicNumber(CRootOf(cyclotomic_poly(5), -1), ...
... [-1, -1, 0, 0], alias=zeta)
>>> a5.as_poly().as_expr()
-zeta**3 - zeta**2
>>> a5.evalf()
1.61803398874989
```

(The index -1 to `CRootOf` selects the complex root with the largest real and imaginary parts, which in this case is $e^{2i\pi/5}$. See `ComplexRootOf` (page 2507).)

Example (6): Building on the last example, construct the number $2\phi \in \mathbb{Q}(\phi)$, where $\phi$ is the Golden Ratio:
```
>>> from sympy import phi
>>> a6 = AlgebraicNumber(a5.to_root(), coeffs=[2, 0], alias=phi)
>>> a6.as_poly().as_expr()
2*phi
>>> a6.primitive_element().evalf()
1.61803398874989
```

Note that we needed to use `a5.to_root()`, since passing `a5` as the first argument would have constructed the number `2\phi` as an element of the field \( \mathbb{Q}(\phi) \):

```
>>> a6_wrong = AlgebraicNumber(a5, coeffs=[2, 0])
>>> a6_wrong.as_poly().as_expr()
-2*zeta**3 - 2*zeta**2
>>> a6_wrong.primitive_element().evalf()
0.309016994374947 + 0.951056516295154*I
```

**as_expr**

Create a Basic expression from self.

**as_poly**

Create a Poly instance from self.

**coeffs()**

Returns all SymPy coefficients of an algebraic number.

**field_element(coeffs)**

Form another element of the same number field.

**Parameters**

- **coeffs**: list, \( \text{ANP} \) (page 2650)
  
  Like the `coeffs` arg to the class constructor (page 1039), defines the new element as a polynomial in the primitive element.

  If a list, the elements should be integers or rational numbers. If an \( \text{ANP} \) (page 2650), we take its coefficients (using its `to_list()` (page 2650) method).

**Explanation**

If we represent \( \alpha \in \mathbb{Q}(\theta) \), form another element \( \beta \in \mathbb{Q}(\theta) \) of the same number field.

**Examples**

```
>>> from sympy import AlgebraicNumber, sqrt
>>> a = AlgebraicNumber(sqrt(5), [-1, 1])
>>> b = a.field_element([3, 2])
>>> print(a)
1 - sqrt(5)
>>> print(b)
2 + 3*sqrt(5)
>>> print(b.primitive_element() == a.primitive_element())
True
```
See also:

AlgebraicNumber (page 1039)

**property is_aliened**

Returns True if alias was set.

**property is_primitive_element**

Say whether this algebraic number \( \alpha \in \mathbb{Q}(\theta) \) is equal to the primitive element \( \theta \) for its field.

**minpoly_of_element()**

Compute the minimal polynomial for this algebraic number.

**Explanation**

Recall that we represent an element \( \alpha \in \mathbb{Q}(\theta) \). Our instance attribute self.minpoly is the minimal polynomial for our primitive element \( \theta \). This method computes the minimal polynomial for \( \alpha \).

**native_coeffs()**

Returns all native coefficients of an algebraic number.

**primitive_element()**

Get the primitive element \( \theta \) for the number field \( \mathbb{Q}(\theta) \) to which this algebraic number \( \alpha \) belongs.

**Returns**

AlgebraicNumber

**to_algebraic_integer()**

Convert self to an algebraic integer.

**to_primitive_element(radiicals=True)**

Convert self to an AlgebraicNumber (page 1039) instance that is equal to its own primitive element.

**Parameters**

radiicals : boolean, optional (default=True)

If True, then we will try to return an AlgebraicNumber (page 1039) whose root is an expression in radicals. If that is not possible (or if radicals is False), root will be a ComplexRootOf (page 2507).

**Returns**

AlgebraicNumber
Explanation

If we represent $\alpha \in \mathbb{Q}(\theta)$, $\alpha \neq \theta$, construct a new *AlgebraicNumber* (page 1039) that represents $\alpha \in \mathbb{Q}(\alpha)$.

Examples

```python
>>> from sympy import sqrt, to_number_field
>>> from sympy.abc import x
>>> a = to_number_field(sqrt(2), sqrt(2) + sqrt(3))

The *AlgebraicNumber* (page 1039) $a$ represents the number $\sqrt{2}$ in the field $\mathbb{Q}(\sqrt{2} + \sqrt{3})$. Rendering $a$ as a polynomial,

```python
>>> a.as_poly().as_expr(x)
```
x**3/2 - 9*x/2
```

reflects the fact that $\sqrt{2} = \theta^3/2 - 9\theta/2$, where $\theta = \sqrt{2} + \sqrt{3}$. $a$ is not equal to its own primitive element. Its minpoly

```python
>>> a.minpoly.as_poly().as_expr(x)
```
x**4 - 10*x**2 + 1
```

is that of $\theta$.

Converting to a primitive element,

```python
>>> a_prim = a.to_primitive_element()
>>> a_prim.minpoly.as_poly().as_expr(x)
```
x**2 - 2
```

we obtain an *AlgebraicNumber* (page 1039) whose minpoly is that of the number itself.

See also:

* is_primitive_element (page 1043)

**to_root**(radicals=True, minpoly=None)

Convert to an *Expr* (page 999) that is not an *AlgebraicNumber* (page 1039), specifically, either a *ComplexRootOf* (page 2507), or, optionally and where possible, an expression in radicals.

Parameters

- **radicals** : boolean, optional (default=True)
  - If True, then we will try to return the root as an expression in radicals.
  - If that is not possible, we will return a *ComplexRootOf* (page 2507).

- **minpoly** : *Poly* (page 2453)
  - If the minimal polynomial for *self* has been pre-computed, it can be passed in order to save time.
approximation(number_cls)
Return an interval with number_cls endpoints that contains the value of NumberSymbol. If not implemented, then return None.

sympy.core.numbers.RealNumber
alias of Float (page 1033)

sympy.core.numbers.igcd(*args)
Computes nonnegative integer greatest common divisor:

Explanation
The algorithm is based on the well known Euclid’s algorithm [R117]. To improve speed, igcd() has its own caching mechanism.

Examples

```python
>>> from sympy import igcd
>>> igcd(2, 4)
2
>>> igcd(5, 10, 15)
5
```

References

[R117]
sympy.core.numbers.ilcm(*args)
Computes integer least common multiple.

Examples

```python
>>> from sympy import ilcm
>>> ilcm(5, 10)
10
>>> ilcm(7, 3)
21
>>> ilcm(5, 10, 15)
30
```
sympy.core.numbers.seterr(divide=False)
Should SymPy raise an exception on 0/0 or return a nan?
divide == True .... raise an exception divide == False ... return nan
class sympy.core.numbers.Zero
The number zero.
Zero is a singleton, and can be accessed by S.Zero
Examples

```python
>>> from sympy import S, Integer
>>> Integer(0) is S.Zero
True
>>> 1/S.Zero
zoo
```

References

[R118]

class sympy.core.numbers.One
The number one.
One is a singleton, and can be accessed by S.One.

Examples

```python
>>> from sympy import S, Integer
>>> Integer(1) is S.One
True
```

References

[R119]

class sympy.core.numbers.NegativeOne
The number negative one.
NegativeOne is a singleton, and can be accessed by S.NegativeOne.

Examples

```python
>>> from sympy import S, Integer
>>> Integer(-1) is S.NegativeOne
True
```

See also:

One (page 1046)
References

[R120]

class sympy.core.numbers.Half

The rational number 1/2.

Half is a singleton, and can be accessed by S.Half.

Examples

>>> from sympy import S, Rational
>>> Rational(1, 2) is S.Half
True

References

[R121]

class sympy.core.numbers.NaN

Not a Number.

Explanation

This serves as a place holder for numeric values that are indeterminate. Most operations on NaN, produce another NaN. Most indeterminate forms, such as 0/0 or oo - oo` produce NaN. Two exceptions are `0**0 and oo**0, which all produce 1 (this is consistent with Python’s float).

NaN is loosely related to floating point nan, which is defined in the IEEE 754 floating point standard, and corresponds to the Python float('nan'). Differences are noted below.

NaN is mathematically not equal to anything else, even NaN itself. This explains the initially counter-intuitive results with Eq and == in the examples below.

NaN is not comparable so inequalities raise a TypeError. This is in contrast with floating point nan where all inequalities are false.

NaN is a singleton, and can be accessed by S.NaN, or can be imported as nan.

Examples

>>> from sympy import nan, S, oo, Eq
>>> nan is S.NaN
True
>>> oo - oo
nan
>>> nan + 1
nan
>>> Eq(nan, nan) # mathematical equality

(continues on next page)
False

>>> nan == nan  # structural equality
True

References

[R122]

```
class sympy.core.numbers.Infinity

Positive infinite quantity.
```

Explanation

In real analysis the symbol $\infty$ denotes an unbounded limit: $x \to \infty$ means that $x$ grows without bound.

Infinity is often used not only to define a limit but as a value in the affinely extended real number system. Points labeled $+\infty$ and $-\infty$ can be added to the topological space of the real numbers, producing the two-point compactification of the real numbers. Adding algebraic properties to this gives us the extended real numbers. Infinity is a singleton, and can be accessed by `S.Infinity`, or can be imported as `oo`.

Examples

```python
>>> from sympy import oo, exp, limit, Symbol
>>> 1 + oo
oo
>>> 42/oo
0
>>> x = Symbol('x')
>>> limit(exp(x), x, oo)
oo
```

See also:

```
NegativeInfinity (page 1048), NaN (page 1047)
```

References

[R123]

```
class sympy.core.numbers.NegativeInfinity

Negative infinite quantity.
```

NegativeInfinity is a singleton, and can be accessed by `S.NegativeInfinity`.

See also:

```
Infinity (page 1048)
```
class sympy.core.numbers.ComplexInfinity
Complex infinity.

Explanation

In complex analysis the symbol \( \infty \), called “complex infinity”, represents a quantity with infinite magnitude, but undetermined complex phase.

ComplexInfinity is a singleton, and can be accessed by \( S.\text{ComplexInfinity} \), or can be imported as \( \text{zoo} \).

Examples

```python
>>> from sympy import zoo
>>> zoo + 42
zoo
>>> 42/zoo
\( 0 \)
>>> zoo + zoo
\( \text{nan} \)
>>> zoo*zoo
zoo
```

See also:

Infinity (page 1048)

---

class sympy.core.numbers.Exp1
The \( e \) constant.

Explanation

The transcendental number \( e = 2.718281828 \cdots \) is the base of the natural logarithm and of the exponential function, \( e = \exp(1) \). Sometimes called Euler’s number or Napier’s constant.

Exp1 is a singleton, and can be accessed by \( S.\text{Exp1} \), or can be imported as \( E \).

Examples

```python
>>> from sympy import exp, log, E
>>> E is exp(1)
True
>>> log(E)
1
```
References

[R124]
class sympy.core.numbers.ImaginaryUnit

The imaginary unit, \( i = \sqrt{-1} \).

I is a singleton, and can be accessed by S.I, or can be imported as I.

Examples

```python
>>> from sympy import I, sqrt
>>> sqrt(-1)
I
>>> I*I
-1
>>> 1/I
-I
```

References

[R125]
class sympy.core.numbers.Pi

The \( \pi \) constant.

Explanation

The transcendental number \( \pi = 3.141592654 \ldots \) represents the ratio of a circle’s circumference to its diameter, the area of the unit circle, the half-period of trigonometric functions, and many other things in mathematics.

Pi is a singleton, and can be accessed by S.Pi, or can be imported as pi.

Examples

```python
>>> from sympy import S, pi, oo, sin, exp, integrate, Symbol
>>> S.Pi
pi
>>> pi > 3
True
>>> pi.is_irrational
True
>>> x = Symbol('x')
>>> sin(x + 2*pi)
sin(x)
>>> integrate(exp(-x**2), (x, -oo, oo))
sqrt(pi)
```
class sympy.core.numbers.EulerGamma
The Euler-Mascheroni constant.

Explanation

\( \gamma = 0.5772157\ldots \) (also called Euler’s constant) is a mathematical constant recurring in analysis and number theory. It is defined as the limiting difference between the harmonic series and the natural logarithm:

\[
\gamma = \lim_{n \to \infty} \left( \sum_{k=1}^{n} \frac{1}{k} - \ln n \right)
\]

EulerGamma is a singleton, and can be accessed by `S.EulerGamma`.

Examples

```python
>>> from sympy import S
>>> S.EulerGamma.is_irrational
True
>>> S.EulerGamma > 0
True
>>> S.EulerGamma > 1
False
```

References

[R126]

class sympy.core.numbers.Catalan
Catalan’s constant.

Explanation

\( G = 0.91596559\ldots \) is given by the infinite series

\[
G = \sum_{k=0}^{\infty} \frac{(-1)^k}{(2k+1)^2}
\]

Catalan is a singleton, and can be accessed by `S.Catalan`.

References

[R127]
Examples

```python
>>> from sympy import S
>>> S.Catalan.is_irrational
True
>>> S.Catalan > 0
True
>>> S.Catalan > 1
False
```

References

[R128]

```python
class sympy.core.numbers.GoldenRatio
The golden ratio, \( \phi \).
```

Explanation

\( \phi = \frac{1 + \sqrt{5}}{2} \) is an algebraic number. Two quantities are in the golden ratio if their ratio is the same as the ratio of their sum to the larger of the two quantities, i.e. their maximum. GoldenRatio is a singleton, and can be accessed by `S.GoldenRatio`.

Examples

```python
>>> from sympy import S
>>> S.GoldenRatio > 1
True
>>> S.GoldenRatio.expand(func=True)
1/2 + sqrt(5)/2
>>> S.GoldenRatio.is_irrational
True
```

References

[R129]

```python
class sympy.core.numbers.TribonacciConstant
The tribonacci constant.
```
Explanation

The tribonacci numbers are like the Fibonacci numbers, but instead of starting with two predetermined terms, the sequence starts with three predetermined terms and each term afterwards is the sum of the preceding three terms.

The tribonacci constant is the ratio toward which adjacent tribonacci numbers tend. It is a root of the polynomial $x^3 - x^2 - x - 1 = 0$, and also satisfies the equation $x + x^{-3} = 2$. TribonacciConstant is a singleton, and can be accessed by `S.TribonacciConstant`.

Examples

```python
>>> from sympy import S
>>> S.TribonacciConstant > 1
True
>>> S.TribonacciConstant.expand(func=True)
1/3 + (19 - 3*sqrt(33))**(1/3)/3 + (3*sqrt(33) + 19)**(1/3)/3
>>> S.TribonacciConstant.is_irrational
True
>>> S.TribonacciConstant.n(20)
1.8392867552141611326
```

References

[R130] sympy.core.numbers.mod_inverse(a, m)

Return the number $c$ such that, $a \times c = 1 \pmod{m}$ where $c$ has the same sign as $m$. If no such value exists, a ValueError is raised.

Examples

```python
>>> from sympy import mod_inverse, S

Suppose we wish to find multiplicative inverse $x$ of 3 modulo 11. This is the same as finding $x$ such that $3x = 1 \pmod{11}$. One value of $x$ that satisfies this congruence is 4. Because $3 \times 4 = 12$ and $12 = 1 \pmod{11}$. This is the value returned by `mod_inverse`:

```python
>>> mod_inverse(3, 11)
4
>>> mod_inverse(-3, 11)
7
```

When there is a common factor between the numerators of $a$ and $m$ the inverse does not exist:

```python
>>> mod_inverse(2, 4)
Traceback (most recent call last):
...
ValueError: inverse of 2 mod 4 does not exist
```
>>> mod_inverse(S(2)/7, S(5)/2)
7/2

References

[R131], [R132]
sympy.core.numbers.equal_valued(x, y)

Compare expressions treating plain floats as rationals.

Examples

```python
>>> from sympy import S, symbols, Rational, Float
>>> from sympy.core.numbers import equal_valued
>>> equal_valued(1, 2)
False
>>> equal_valued(1, 1)
True
```

In SymPy expressions with Floats compare unequal to corresponding expressions with rationals:

```python
>>> x = symbols('x')
>>> x**2 == x**2.0
False
```

However an individual Float compares equal to a Rational:

```python
>>> Rational(1, 2) == Float(0.5)
True
```

In a future version of SymPy this might change so that Rational and Float compare unequal. This function provides the behavior currently expected of == so that it could still be used if the behavior of == were to change in future.

```python
>>> equal_valued(1, 1.0) # Float vs Rational
True
>>> equal_valued(S(1).n(3), S(1).n(5)) # Floats of different precision
True
```

Explanation

In future SymPy versions Float and Rational might compare unequal and floats with different precisions might compare unequal. In that context a function is needed that can check if a number is equal to 1 or 0 etc. The idea is that instead of testing if \( x == 1 \): if we want to accept floats like \( 1.0 \) as well then the test can be written as if equal_valued(x, 1): or if equal_valued(x, 2):. Since this function is intended to be used in situations where one or both operands are expected to be concrete numbers like 1 or 0 the function does not recurse through the args of any compound expression to compare any nested floats.
References

[R133]

power

class sympy.core.power.Pow(b, e, evaluate=None)

Defines the expression x**y as “x raised to a power y”

Deprecated since version 1.7: Using arguments that aren’t subclasses of Expr (page 999) in core operators (Mul (page 1058), Add (page 1062), and Pow (page 1055)) is deprecated. See Core operators no longer accept non-Expr args (page 226) for details.

Singleton definitions involving (0, 1, -1, oo, -oo, I, -I):

</tr>
</tbody>
</table>
Because symbolic computations are more flexible than floating point calculations and we prefer to never return an incorrect answer, we choose not to conform to all IEEE 754 conventions. This helps us avoid extra test-case code in the calculation of limits.

**References**

[R134], [R135], [R136]

**as_base_exp()**

Return base and exp of self.

**Explanation**

If base a Rational less than 1, then return 1/Rational, -exp. If this extra processing is not needed, the base and exp properties will give the raw arguments.

**Examples**

```python
>>> from sympy import Pow, S
>>> p = Pow(S.Half, 2, evaluate=False)
>>> p.as_base_exp()
(2, -2)
>>> p.args
(1/2, 2)
>>> p.base, p.exp
(1/2, 2)
```

**as_content_primitive** *(radical=False, clear=True)*

Return the tuple (R, self/R) where R is the positive Rational extracted from self.

**Examples**

```python
>>> from sympy import sqrt
>>> sqrt(4 + 4*sqrt(2)).as_content_primitive()
(2, sqrt(1 + sqrt(2)))
>>> sqrt(3 + 3*sqrt(2)).as_content_primitive()
(1, sqrt(3)*sqrt(1 + sqrt(2)))
```

```python
>>> from sympy import expand_power_base, powsimp, Mul
>>> from sympy.abc import x, y
```
```python
>>> ((2*x + 2)**2).as_content_primitive()
(4, (x + 1)**2)
>>> (4**(1 + y)/2).as_content_primitive()
(2, 4**(y/2))
>>> (3**(1 + y)/2).as_content_primitive()
(1, 3**(y + 1)/2))
>>> (3**(5 + y)/2).as_content_primitive()
(9, 3**(y + 1)/2)
>>> eq = 3**(2 + 2*x)
>>> powsimp(eq) == eq
True
>>> eq.as_content_primitive()
(9, 3**(2*x))
>>> powsimp(Mul(*_))
3**(2*x + 2)
```

See docstring of Expr.as_content_primitive for more examples.

```python
>>> eq = (2 + 2*x)**y
>>> s = expand_power_base(eq); s.is_Mul, s
(False, (2*x + 2)**y)
>>> eq.as_content_primitive()
(1, (2*(x + 1))**y)
>>> s = expand_power_base(_[1]); s.is_Mul, s
(True, 2**y*(x + 1)**y)
```

```python
>>> from sympy import integer_nthroot
>>> integer_nthroot(16, 2)
(4, True)
>>> integer_nthroot(26, 2)
(5, False)
```

To simply determine if a number is a perfect square, the is_square function should be used:

```python
>>> from sympy.ntheory.primetest import is_square
>>> is_square(26)
False
```

See also:

- `sympy.ntheory.primetest.is_square` (page 1559), `integer_log` (page 1057)

```python
>>> from sympy import integer_log
>>> integer_log(y, x)
```

Returns \((e, \text{bool})\) where \(e\) is the largest nonnegative integer such that \(|y| \geq |x^e|\) and \(\text{bool}\) is True if \(y = x^e\).
Examples

```python
>>> from sympy import integer_log
>>> integer_log(125, 5)
(3, True)
>>> integer_log(17, 9)
(1, False)
>>> integer_log(4, -2)
(2, True)
>>> integer_log(-125, -5)
(3, True)
```

See also:

integer_nthroot (page 1057), sympy.ntheory.primetest.is_square (page 1559), sympy.ntheory.factor_.multiplicity (page 1533), sympy.ntheory.factor_.perfect_power (page 1534)

mul

class sympy.core.mul.Mul(*args, evaluate=None, _sympify=True)

Expression representing multiplication operation for algebraic field.

Deprecated since version 1.7: Using arguments that aren’t subclasses of Expr (page 999) in core operators (Mul (page 1058), Add (page 1062), and Pow (page 1055)) is deprecated. See Core operators no longer accept non-Expr args (page 226) for details.

Every argument of Mul() must be Expr. Infix operator * on most scalar objects in SymPy calls this class.

Another use of Mul() is to represent the structure of abstract multiplication so that its arguments can be substituted to return different class. Refer to examples section for this.

Mul() evaluates the argument unless evaluate=False is passed. The evaluation logic includes:

1. **Flattening**
   
   Mul(x, Mul(y, z)) -> Mul(x, y, z)

2. **Identity removing**
   
   Mul(x, 1, y) -> Mul(x, y)

3. **Exponent collecting by .as_base_exp()**
   
   Mul(x, x**2) -> Pow(x, 3)

4. **Term sorting**
   
   Mul(y, x, 2) -> Mul(2, x, y)

Since multiplication can be vector space operation, arguments may have the different sympy.core.kind.Kind() (page 1118). Kind of the resulting object is automatically inferred.
Examples

```python
>>> from sympy import Mul
>>> from sympy import x, y
>>> Mul(x, 1)
x
>>> Mul(x, x)
x**2
```

If `evaluate=False` is passed, result is not evaluated.

```python
>>> Mul(1, 2, evaluate=False)
1*2
>>> Mul(x, x, evaluate=False)
x*x
```

`Mul()` also represents the general structure of multiplication operation.

```python
>>> from sympy import MatrixSymbol
>>> A = MatrixSymbol('A', 2, 2)
>>> expr = Mul(x, y).subs({y:A})
>>> expr
x*A
>>> type(expr)
<class 'sympy.matrices.expressions.matmul.MatMul'>
```

See also:

- `MatMul` (page 1417)
- `as_coeff_Mul(rational=False)`
  Efficiently extract the coefficient of a product.
- `as_content_primitive(radical=False, clear=True)`
  Return the tuple (R, self/R) where R is the positive Rational extracted from self.

Examples

```python
>>> from sympy import sqrt
>>> (-3*sqrt(2)*(2 - 2*sqrt(2))).as_content_primitive()
(6, -sqrt(2)*(1 - sqrt(2)))
```

See docstring of Expr.as_content_primitive for more examples.

- `as_ordered_factors(order=None)`
  Transform an expression into an ordered list of factors.
**Examples**

```python
>>> from sympy import sin, cos
>>> from sympy.abc import x, y

>>> (2*x*y*sin(x)*cos(x)).as_ordered_factors()
[2, x, y, sin(x), cos(x)]
```

**as_two_terms()**

Return head and tail of self.

This is the most efficient way to get the head and tail of an expression.

- if you want only the head, use `self.args[0]`;
- if you want to process the arguments of the tail then use `self.as_coeff_mul()` which gives the head and a tuple containing the arguments of the tail when treated as a `Mul`.
- if you want the coefficient when self is treated as an `Add` then use `self.as_coeff_add()[0]`

**Examples**

```python
>>> from sympy import Mul, sqrt
>>> from sympy.abc import x, y, z

>>> 2*(x + 1) # this is the 2-arg Mul behavior
2*x + 2
>>> y*(x + 1)*2
2*y*(x + 1)
>>> 2*(x + 1)*y # 2-arg result will be obtained first
y*(2*x + 2)
>>> Mul(2, x + 1, y) # all 3 args simultaneously processed
2*y*(x + 1)
>>> 2*((x + 1)*y) # parentheses can control this behavior
2*y*(x + 1)
```

**classmethod flatten(seq)**

Return commutative, noncommutative and order arguments by combining related terms.

**Notes**

- In an expression like `a*b*c`, Python process this through SymPy as `Mul(Mul(a, b), c)`. This can have undesirable consequences.
  - Sometimes terms are not combined as one would like: {c.f. https://github.com/sympy/sympy/issues/4596}
Powers with compound bases may not find a single base to combine with unless all arguments are processed at once. Post-processing may be necessary in such cases. {c.f. https://github.com/sympy/sympy/issues/5728}

```python
>>> a = sqrt(x*sqrt(y))
>>> a**3
(x*sqrt(y))**(3/2)
>>> Mul(a, a, a)
(x*sqrt(y))**(3/2)
>>> a*a*a
x*sqrt(y)*sqrt(x*sqrt(y))
>>> _.subs(a.base, z).subs(z, a.base)
(x*sqrt(y))**(3/2)
```

- If more than two terms are being multiplied then all the previous terms will be re-processed for each new argument. So if each of a, b and c were `Mul` (page 1058) expression, then `a*b*c` (or building up the product with `*=`) will process all the arguments of a and b twice: once when `a*b` is computed and again when c is multiplied.

Using `Mul(a, b, c)` will process all arguments once.

- The results of `Mul` are cached according to arguments, so flatten will only be called once for `Mul(a, b, c)`. If you can structure a calculation so the arguments are most likely to be repeats then this can save time in computing the answer. For example, say you had a `Mul`, M, that you wished to divide by `d[i]` and multiply by `n[i]` and you suspect there are many repeats in `n`. It would be better to compute `M*n[i]/d[i]` rather than `M/d[i]*n[i]` since every time `n[i]` is a repeat, the product, `M*n[i]` will be returned without flattening - the cached value will be returned. If you divide by the `d[i]` first (and those are more unique than the `n[i]`) then that will create a new `Mul`, `M/d[i]` the args of which will be traversed again when it is multiplied by `n[i]`.

{c.f. https://github.com/sympy/sympy/issues/5706}

This consideration is moot if the cache is turned off.

**Nb**

The validity of the above notes depends on the implementation details of `Mul` and flatten which may change at any time. Therefore, you should only consider them when your code is highly performance sensitive.

Removal of 1 from the sequence is already handled by `AssocOp.__new__`.

```python
sympy.core.mul.prod(a, start=1)
```

**Return product of elements of a. Start with int 1 so if only**

ints are included then an int result is returned.
Examples

```python
>>> from sympy import prod, S
>>> prod(range(3))
0
>>> type(_) is int
True
>>> prod([S(2), 3])
6
>>> _.is_Integer
True
```

You can start the product at something other than 1:

```python
>>> prod([1, 2], 3)
6
```

**add**

```
class sympy.core.add.Add(*args, evaluate=None, _sympify=True)
```

Expression representing addition operation for algebraic group.

Deprecated since version 1.7: Using arguments that aren’t subclasses of `Expr` (page 999) in core operators (`Mul` (page 1058), `Add` (page 1062), and `Pow` (page 1055)) is deprecated. See `Core operators no longer accept non-Expr args` (page 226) for details.

Every argument of `Add()` must be `Expr`. Infix operator + on most scalar objects in SymPy calls this class.

Another use of `Add()` is to represent the structure of abstract addition so that its arguments can be substituted to return different class. Refer to examples section for this.

`Add()` evaluates the argument unless `evaluate=False` is passed. The evaluation logic includes:

1. **Flattening**
   
   `Add(x, Add(y, z)) -> Add(x, y, z)`

2. **Identity removing**
   
   `Add(x, 0, y) -> Add(x, y)`

3. **Coefficient collecting by \texttt{as\_coeff\_Mul()}**
   
   `Add(x, 2*x) -> Mul(3, x)`

4. **Term sorting**
   
   `Add(y, x, 2) -> Add(2, x, y)`

If no argument is passed, identity element 0 is returned. If single element is passed, that element is returned.

Note that `Add(*args)` is more efficient than `sum(args)` because it flattens the arguments. `sum(a, b, c, ...)` recursively adds the arguments as `a + (b + (c + ...))`, which has quadratic complexity. On the other hand, `Add(a, b, c, d)` does not assume nested structure, making the complexity linear.

Since addition is group operation, every argument should have the same `sympy.core.kind.Kind()` (page 1118).
Examples

```python
>>> from sympy import Add, I
>>> from sympy.abc import x, y
>>> Add(x, 1)
x + 1
>>> Add(x, x)
2*x
>>> 2*x**2 + 3*x + I*y + 2*y + 2*x/5 + 1.0*y + 1
2*x**2 + 17*x/5 + 3.0*y + I*y + 1
```

If evaluate=False is passed, result is not evaluated.

```python
>>> Add(1, 2, evaluate=False)
1 + 2
>>> Add(x, x, evaluate=False)
x + x
```

Add() also represents the general structure of addition operation.

```python
>>> from sympy import MatrixSymbol
>>> A, B = MatrixSymbol('A', 2, 2), MatrixSymbol('B', 2, 2)
>>> expr = Add(x, y).subs({x:A, y:B})
>>> expr
A + B
>>> type(expr)
<class 'sympy.matrices.expressions.matadd.MatAdd'>
```

Note that the printers do not display in args order.

```python
>>> Add(x, 1)
x + 1
>>> Add(x, 1).args
(1, x)
```

See also:

- `MatAdd` (page 1417)
- `as_coeff_Add(rational=False, deps=None)`
  Efficiently extract the coefficient of a summation.
- `as_coeff_add(*deps)`
  Returns a tuple (coeff, args) where self is treated as an Add and coeff is the Number term and args is a tuple of all other terms.
Examples

```python
>>> from sympy.abc import x
>>> (7 + 3*x).as_coeff_add()
(7, (3*x,))
>>> (7*x).as_coeff_add()
(0, (7*x,))
```

**as_content_primitive**(radical=False, clear=True)

Return the tuple (R, self/R) where R is the positive Rational extracted from self. If radical is True (default is False) then common radicals will be removed and included as a factor of the primitive expression.

Examples

```python
>>> from sympy import sqrt
>>> (3 + 3*sqrt(2)).as_content_primitive()
(3, 1 + sqrt(2))
```

Radical content can also be factored out of the primitive:

```python
>>> (2*sqrt(2) + 4*sqrt(10)).as_content_primitive(radical=True)
(2, sqrt(2)*(1 + 2*sqrt(5)))
```

See docstring of Expr.as_content_primitive for more examples.

**as_numer_denom()**

Decomposes an expression to its numerator part and its denominator part.

Examples

```python
>>> from sympy.abc import x, y, z
>>> (x*y/z).as_numer_denom()
(x*y, z)
>>> (x*(y + 1)/y**7).as_numer_denom()
(x*(y + 1), y**7)
```

See also:

```
sympy.core.expr.Expr.as_numer_denom (page 1007)
```

**as_real_imag**(deep=True, **hints)**

Return a tuple representing a complex number.
Examples

```python
>>> from sympy import I
>>> (7 + 9*I).as_real_imag()
(7, 9)
>>> ((1 + I)/(1 - I)).as_real_imag()
(0, 1)
>>> ((1 + 2*I)*(1 + 3*I)).as_real_imag()
(-5, 5)
```

**as_two_terms()**

Return head and tail of self.

This is the most efficient way to get the head and tail of an expression.

- if you want only the head, use self.args[0];
- if you want to process the arguments of the tail then use self.as_coef_add() which gives the head and a tuple containing the arguments of the tail when treated as an Add.
- if you want the coefficient when self is treated as a Mul then use self.as_coeff_mul()[0]

```python
>>> from sympy.abc import x, y
>>> (3*x - 2*y + 5).as_two_terms()
(5, 3*x - 2*y)
```

**extract_leading_order(symbols, point=None)**

Returns the leading term and its order.

Examples

```python
>>> from sympy.abc import x
>>> (x + 1 + 1/x**5).extract_leading_order(x)
((x**(-5), 0(x**(1))),)
>>> (1 + x).extract_leading_order(x)
((1, 0(1)),)
>>> (x + x**2).extract_leading_order(x)
((x, 0(x)),)
```

**classmethod flatten(seq)**

Takes the sequence “seq” of nested Adds and returns a flatten list.

Returns: (commutative_part, noncommutative_part, order_symbols)

Applies associativity, all terms are commutable with respect to addition.

NB: the removal of 0 is already handled by AssocOp.__new__

See also:

sympy.core.mul.Mul.flatten (page 1060)
**primitive()**

Return $(R, \text{self}/R)$ where $R$ is the Rational GCD of $\text{self}$.

$R$ is collected only from the leading coefficient of each term.

**Examples**

```python
>>> from sympy.abc import x, y

>>> (2*x + 4*y).primitive()
(2, x + 2*y)

>>> (2*x/3 + 4*y/9).primitive()
(2/9, 3*x + 2*y)

>>> (2*x/3 + 4.2*y).primitive()
(1/3, 2*x + 12.6*y)
```

No subprocessing of term factors is performed:

```python
>>> ((2 + 2*x)*x + 2).primitive()
(1, x*(2*x + 2) + 2)
```

Recursive processing can be done with the `as_content_primitive()` method:

```python
>>> ((2 + 2*x)*x + 2).as_content_primitive()
(2, x*(x + 1) + 1)
```

See also: primitive() function in polytools.py

**mod**

**class** sympy.core.mod.Mod\((p, q)\)

Represents a modulo operation on symbolic expressions.

**Parameters**

\(p\) : Expr
- Dividend.

\(q\) : Expr
- Divisor.
Notes

The convention used is the same as Python’s: the remainder always has the same sign as the divisor.

Examples

```python
>>> from sympy.abc import x, y
>>> x**2 % y
Mod(x**2, y)
>>> _.subs({x: 5, y: 6})
1
```

relational

class sympy.core.relational.Relational(lhs, rhs, rop=None, **assumptions)

Base class for all relation types.

Parameters

- **rop**: str or None
  
  Indicates what subclass to instantiate. Valid values can be found in the keys of Relational.ValidRelationOperator.

Explanation

Subclasses of Relational should generally be instantiated directly, but Relational can be instantiated with a valid rop value to dispatch to the appropriate subclass.

Examples

```python
>>> from sympy import Rel
>>> from sympy.abc import x, y
>>> Rel(y, x + x**2, '==')
Eq(y, x**2 + x)
```

A relation’s type can be defined upon creation using rop. The relation type of an existing expression can be obtained using its rel_op property. Here is a table of all the relation types, along with their rop and rel_op values:

<table>
<thead>
<tr>
<th>Relation</th>
<th>rop</th>
<th>rel_op</th>
</tr>
</thead>
<tbody>
<tr>
<td>Equality</td>
<td>== or eq or None</td>
<td>==</td>
</tr>
<tr>
<td>Unequality</td>
<td>!= or ne</td>
<td>!=</td>
</tr>
<tr>
<td>GreaterThan</td>
<td>&gt;= or ge</td>
<td>&gt;=</td>
</tr>
<tr>
<td>LessThan</td>
<td>&lt;= or le</td>
<td>&lt;=</td>
</tr>
<tr>
<td>StrictGreaterThan</td>
<td>&gt; or gt</td>
<td>&gt;</td>
</tr>
<tr>
<td>StrictLessThan</td>
<td>&lt; or lt</td>
<td>&lt;</td>
</tr>
</tbody>
</table>
For example, setting rop to == produces an Equality relation, Eq(). So does setting rop to eq, or leaving rop unspecified. That is, the first three Rel() below all produce the same result. Using a rop from a different row in the table produces a different relation type. For example, the fourth Rel() below using lt for rop produces a StrictLessThan inequality:

```python
>>> from sympy import Rel
>>> from sympy.abc import x, y
>>> Rel(y, x + x**2, '==')
Eq(y, x**2 + x)
>>> Rel(y, x + x**2, 'eq')
Eq(y, x**2 + x)
>>> Rel(y, x + x**2)
Eq(y, x**2 + x)
>>> Rel(y, x + x**2, 'lt')
y < x**2 + x
```

To obtain the relation type of an existing expression, get its rel_op property. For example, rel_op is == for the Equality relation above, and < for the strict less than inequality above:

```python
>>> from sympy import Rel
>>> from sympy.abc import x, y
>>> my_equality = Rel(y, x + x**2, '==')
>>> my_equality.rel_op
'=='
>>> my_inequality = Rel(y, x + x**2, 'lt')
>>> my_inequality.rel_op
'<'
```

**property canonical**

Return a canonical form of the relational by putting a number on the rhs, canonically removing a sign or else ordering the args canonically. No other simplification is attempted.

**Examples**

```python
>>> from sympy.abc import x, y
>>> x < 2
x < 2
>>> _.reversed.canonical
x < 2
>>> (-y < x).canonical
x > -y
>>> (-y > x).canonical
x < -y
>>> (-y < -x).canonical
x < y
```

The canonicalization is recursively applied:
equals(other, failing_expression=False)

Return True if the sides of the relationship are mathematically identical and the type of relationship is the same. If failing_expression is True, return the expression whose truth value was unknown.

property lhs
The left-hand side of the relation.

property negated
Return the negated relationship.

Examples

```python
>>> from sympy import Eq
>>> Eq(x < y, y > x).canonical
True
```

```python
>>> from sympy import Eq
>>> from sympy.abc import x

>>> Eq(x, 1)
Eq(x, 1)

>>> _.negated
Ne(x, 1)

>>> x < 1
x < 1

>>> _.negated
x >= 1
```

Notes

This works more or less identical to ~/Not. The difference is that negated returns the relationship even if evaluate=False. Hence, this is useful in code when checking for e.g. negated relations to existing ones as it will not be affected by the `evaluate` flag.

property reversed
Return the relationship with sides reversed.

Examples

```python
>>> from sympy import Eq
>>> from sympy.abc import x

>>> Eq(x, 1)
Eq(x, 1)

>>> _.reversed
Eq(1, x)

>>> x < 1
x < 1

>>> _.reversed
1 > x
```
property `reversedsign`  
Return the relationship with signs reversed.

**Examples**

```python
>>> from sympy import Eq
>>> from sympy.abc import x
>>> Eq(x, 1)
Eq(x, 1)
>>> _.reversedsign
Eq(-x, -1)
>>> x < 1
x < 1
>>> _.reversedsign
-x > -1
```

property `rhs`  
The right-hand side of the relation.

property `strict`  
return the strict version of the inequality or self

**Examples**

```python
>>> from sympy.abc import x
>>> (x <= 1).strict
x < 1
>>> _.strict
x < 1
```

property `weak`  
return the non-strict version of the inequality or self

**Examples**

```python
>>> from sympy.abc import x
>>> (x < 1).weak
x <= 1
>>> _.weak
x <= 1
```
class sympy.core.relational.Equality(lhs, rhs, **options)

An equal relation between two objects.

**Explanation**

Represents that two objects are equal. If they can be easily shown to be definitively equal (or unequal), this will reduce to True (or False). Otherwise, the relation is maintained as an unevaluated Equality object. Use the `simplify` function on this object for more nontrivial evaluation of the equality relation.

As usual, the keyword argument `evaluate=False` can be used to prevent any evaluation.

**Examples**

```python
>>> from sympy import Eq, simplify, exp, cos
>>> from sympy.abc import x, y
>>> Eq(y, x + x**2)
Eq(y, x**2 + x)
>>> Eq(2, 5)
False
>>> Eq(2, 5, evaluate=False)
Eq(2, 5)
>>> _.doit()
False
>>> Eq(exp(x), exp(x).rewrite(cos))
Eq(exp(x), sinh(x) + cosh(x))
>>> simplify(_)
True
```

**Notes**

Python treats 1 and True (and 0 and False) as being equal; SymPy does not. And integer will always compare as unequal to a Boolean:

```python
>>> Eq(True, 1), True == 1
(False, True)
```

This class is not the same as the `==` operator. The `==` operator tests for exact structural equality between two expressions; this class compares expressions mathematically.
If either object defines an _eval_Eq method, it can be used in place of the default algorithm. If \( \text{lhs]._\text{eval}_\text{Eq}(\text{rhs}) \) or \( \text{rhs}.\_\text{eval}_\text{Eq}(\text{lhs}) \) returns anything other than None, that return value will be substituted for the Equality. If None is returned by _eval_Eq, an Equality object will be created as usual.

Since this object is already an expression, it does not respond to the method as_expr if one tries to create \( x-y \) from Eq(\( x \), \( y \)). This can be done with the rewrite(Add) method.

Deprecated since version 1.5: Eq(expr) with a single argument is a shorthand for Eq(expr, 0), but this behavior is deprecated and will be removed in a future version of SymPy.

**sympy.logic.boolalg.Equivalent** (page 1215)
for representing equality between two boolean expressions

```
\text{as\_poly}(\ast\text{gens}, \ast\text{kwargs})
\text{Returns lhsh rhs as a Poly}
```

Examples

```
>>> \text{from \text{sympy} import Eq}
>>> \text{from \text{sympy.abc} import \text{x}}
>>> \text{Eq(\text{x}\ast\ast2, 1).\text{as\_poly(\text{x})}}
\text{Poly(\text{x}\ast\ast2 - 1, \text{x}, \text{domain='ZZ'}))}
```

```
\text{integrate}(\ast\text{args}, \ast\text{kwargs})
\text{See the integrate function in sympy.integrals}
```

```
\text{class sympy.core.relational.GreaterThan(lhs, rhs, **options)}
\text{Class representations of inequalities.}
```

Explanation

The *Than classes represent inequal relationships, where the left-hand side is generally bigger or smaller than the right-hand side. For example, the GreaterThan class represents an inequal relationship where the left-hand side is at least as big as the right side, if not bigger. In mathematical notation:

\( \text{lhs} \geq \text{rhs} \)

In total, there are four *Than classes, to represent the four inequalities:

```
\begin{array}{|l|l|}
\hline
\text{Class Name} & \text{Symbol} \\
\hline
\text{GreaterThan} & \geq \\
\text{LessThan} & \leq \\
\text{StrictGreaterThan} & > \\
\text{StrictLessThan} & < \\
\hline
\end{array}
```

All classes take two arguments, lhs and rhs.
In addition to the normal .lhs and .rhs of Relations, *Than inequality objects also have the .lts and .gts properties, which represent the “less than side” and “greater than side” of the operator. Use of .lts and .gts in an algorithm rather than .lhs and .rhs as an assumption of inequality direction will make more explicit the intent of a certain section of code, and will make it similarly more robust to client code changes:

```python
>>> from sympy import GreaterThan, StrictGreaterThan
>>> from sympy import LessThan, StrictLessThan
>>> from sympy import And, Ge, Gt, Le, Lt, Rel, S
>>> from sympy.abc import x, y, z
>>> from sympy.core.relational import Relational

>>> e = GreaterThan(x, 1)
>>> e
x >= 1
>>> '%s >= %s is the same as %s <= %s' % (e.gts, e.lts, e.lts, e.gts)
'x >= 1 is the same as 1 <= x'
```

### Examples

One generally does not instantiate these classes directly, but uses various convenience methods:

```python
>>> for f in [Ge, Gt, Le, Lt]:  # convenience wrappers
...     print(f(x, 2))
  x >= 2
  x > 2
  x <= 2
  x < 2
```

Another option is to use the Python inequality operators (>=, >, <=, <) directly. Their main advantage over the Ge, Gt, Le, and Lt counterparts, is that one can write a more “mathematical looking” statement rather than littering the math with oddball function calls. However there are certain (minor) caveats of which to be aware (search for ‘gotcha’, below).

```python
>>> x >= 2
x >= 2
>>> _ == Ge(x, 2)
True
```

However, it is also perfectly valid to instantiate a *Than class less succinctly and less conveniently:

<table>

<tr>
<td>GreaterThan(lhs, rhs)</td>
<td>lhs \geq rhs</td>
</tr>
<tr>
<td>LessThan(lhs, rhs)</td>
<td>lhs \leq rhs</td>
</tr>
<tr>
<td>StrictGreaterThan(lhs, rhs)</td>
<td>lhs &gt; rhs</td>
</tr>
<tr>
<td>StrictLessThan(lhs, rhs)</td>
<td>lhs &lt; rhs</td>
</tr>
</tbody>
</table>
SymPy Documentation, Release 1.12.1

>>> Rel(x, 1, ">")
 x > 1
>>> Relational(x, 1, ">")
 x > 1

>>> StrictGreaterThan(x, 1)
 x > 1
>>> GreaterThan(x, 1)
 x >= 1
>>> LessThan(x, 1)
 x <= 1
>>> StrictLessThan(x, 1)
 x < 1

Notes

There are a couple of “gotchas” to be aware of when using Python’s operators. The first is that what your write is not always what you get:

```python
>>> 1 < x
 x > 1
```

Due to the order that Python parses a statement, it may not immediately find two objects comparable. When `1 < x` is evaluated, Python recognizes that the number 1 is a native number and that x is not. Because a native Python number does not know how to compare itself with a SymPy object Python will try the reflective operation, `x > 1` and that is the form that gets evaluated, hence returned.

If the order of the statement is important (for visual output to the console, perhaps), one can work around this annoyance in a couple ways:

(1) “sympify” the literal before comparison

```python
>>> S(1) < x
 1 < x
```

(2) use one of the wrappers or less succinct methods described above

```python
>>> Lt(1, x)
 1 < x
>>> Relational(1, x, "<")
 1 < x
```

The second gotcha involves writing equality tests between relationals when one or both sides of the test involve a literal relational:

```python
>>> e = x < 1; e
 x < 1
>>> e == e # neither side is a literal
 True
>>> e == x < 1 # expecting True, too
```

(continues on next page)
The solution for this case is to wrap literal relationals in parentheses:

```python
>>> e == (x < 1)
True
>>> e != (x < 1)
False
>>> (x < 1) != (x < 1)
False
```

The third gotcha involves chained inequalities not involving == or !=. Occasionally, one may be tempted to write:

```python
>>> e = x < y < z
Traceback (most recent call last):
...
TypeError: symbolic boolean expression has no truth value.
```

Due to an implementation detail or decision of Python [R137], there is no way for SymPy to create a chained inequality with that syntax so one must use And:

```python
>>> e = And(x < y, y < z)
>>> type(e)
And
>>> e
(x < y) & (y < z)
```

Although this can also be done with the ‘&’ operator, it cannot be done with the ‘and’ operator:

```python
>>> (x < y) & (y < z)
(x < y) & (y < z)
>>> (x < y) and (y < z)
Traceback (most recent call last):
...
TypeError: cannot determine truth value of Relational
```

```python
class sympy.core.relational.LessThan(lhs, rhs, **options)
```

Class representations of inequalities.
Explanation

The *Than classes represent inequal relationships, where the left-hand side is generally bigger or smaller than the right-hand side. For example, the GreaterThan class represents an inequal relationship where the left-hand side is at least as big as the right side, if not bigger. In mathematical notation:

\[ \text{lhs} \geq \text{rhs} \]

In total, there are four *Than classes, to represent the four inequalities:

<table>
<thead>
<tr>
<th>Class Name</th>
<th>Symbol</th>
</tr>
</thead>
<tbody>
<tr>
<td>GreaterThan</td>
<td>&gt;=</td>
</tr>
<tr>
<td>LessThan</td>
<td>&lt;=</td>
</tr>
<tr>
<td>StrictGreaterThan</td>
<td>&gt;</td>
</tr>
<tr>
<td>StrictLessThan</td>
<td>&lt;</td>
</tr>
</tbody>
</table>

All classes take two arguments, lhs and rhs.

<table>
<thead>
<tr>
<th>Signature Example</th>
<th>Math Equivalent</th>
</tr>
</thead>
<tbody>
<tr>
<td>GreaterThan(lhs, rhs)</td>
<td>lhs \geq rhs</td>
</tr>
<tr>
<td>LessThan(lhs, rhs)</td>
<td>lhs \leq rhs</td>
</tr>
<tr>
<td>StrictGreaterThan(lhs, rhs)</td>
<td>lhs &gt; rhs</td>
</tr>
<tr>
<td>StrictLessThan(lhs, rhs)</td>
<td>lhs &lt; rhs</td>
</tr>
</tbody>
</table>

In addition to the normal .lhs and .rhs of Relations, *Than inequality objects also have the .lts and .gts properties, which represent the “less than side” and “greater than side” of the operator. Use of .lts and .gts in an algorithm rather than .lhs and .rhs as an assumption of inequality direction will make more explicit the intent of a certain section of code, and will make it similarly more robust to client code changes:

```python
>>> from sympy import GreaterThan, StrictGreaterThan
>>> from sympy import LessThan, StrictLessThan
>>> from sympy import And, Ge, Gt, Le, Lt, Rel, S
>>> from sympy.abc import x, y, z
>>> from sympy.core.relation import Relational

>>> e = GreaterThan(x, 1)
>>> e
x >= 1
>>> '%s >= %s is the same as %s <= %s' % (e.gts, e.lts, e.lts, e.gts)
'x >= 1 is the same as 1 <= x'
```
Examples

One generally does not instantiate these classes directly, but uses various convenience methods:

```
>>> for f in [Ge, Gt, Le, Lt]:    # convenience wrappers
...     print(f(x, 2))
```

```
x >= 2
x > 2
x <= 2
x < 2
```

Another option is to use the Python inequality operators (>=, >, <=, <) directly. Their main advantage over the Ge, Gt, Le, and Lt counterparts, is that one can write a more “mathematical looking” statement rather than littering the math with oddball function calls. However there are certain (minor) caveats of which to be aware (search for ‘gotcha’, below).

```
>>> x >= 2
x >= 2
>>> _ == Ge(x, 2)
True
```

However, it is also perfectly valid to instantiate a *Than class less succintly and less conveniently:

```
>>> Rel(x, 1, ">")
x > 1
>>> Relational(x, 1, ">")
x > 1
```

```
>>> StrictGreaterThan(x, 1)
x > 1
>>> GreaterThan(x, 1)
x >= 1
>>> LessThan(x, 1)
x <= 1
>>> StrictLessThan(x, 1)
x < 1
```

Notes

There are a couple of “gotchas” to be aware of when using Python’s operators. The first is that what you write is not always what you get:

```
>>> 1 < x
x > 1
```

Due to the order that Python parses a statement, it may not immediately find two objects comparable. When 1 < x is evaluated, Python recognizes that the number 1 is a native number and that x is not. Because a native Python number does not know how to compare itself with a SymPy object Python will try
the reflective operation, \( x > 1 \) and that is the form that gets evaluated, hence returned.

If the order of the statement is important (for visual output to the console, perhaps), one can work around this annoyance in a couple ways:

(1) “sympify” the literal before comparison

```python
>>> S(1) < x
1 < x
```

(2) use one of the wrappers or less succinct methods described above

```python
>>> Lt(1, x)
1 < x
>>> Relational(1, x, "<")
1 < x
```

The second gotcha involves writing equality tests between relationals when one or both sides of the test involve a literal relational:

```python
>>> e = x < 1; e
x < 1
>>> e == e  # neither side is a literal
True
>>> e == x < 1  # expecting True, too
False
>>> e != x < 1  # expecting False
x < 1
>>> x < 1 != x < 1  # expecting False or the same thing as before
Traceback (most recent call last):
  ...
TypeError: cannot determine truth value of Relational
```

The solution for this case is to wrap literal relationals in parentheses:

```python
>>> e == (x < 1)
True
>>> e != (x < 1)
False
>>> (x < 1) != (x < 1)
False
```

The third gotcha involves chained inequalities not involving \( == \) or \( != \). Occasionally, one may be tempted to write:

```python
>>> e = x < y < z
Traceback (most recent call last):
  ...
TypeError: symbolic boolean expression has no truth value.
```

Due to an implementation detail or decision of Python [R138], there is no way for SymPy to create a chained inequality with that syntax so one must use \( \text{And} \):
Although this can also be done with the ‘&’ operator, it cannot be done with the ‘and’ operator:

```python
>>> (x < y) & (y < z)
(x < y) & (y < z)
>>> (x < y) and (y < z)
Traceback (most recent call last):
...  
TypeError: cannot determine truth value of Relational
```

```python
class sympy.core.relational.Unequality(lhs, rhs, **options)

An unequal relation between two objects.

Explanation

Represents that two objects are not equal. If they can be shown to be definitively equal, this will reduce to False; if definitively unequal, this will reduce to True. Otherwise, the relation is maintained as an Unequality object.

Examples

```python
>>> from sympy import Ne
>>> from sympy import x, y
>>> Ne(y, x**2 + x)
Ne(y, x**2 + x)
```

Notes

This class is not the same as the != operator. The != operator tests for exact structural equality between two expressions; this class compares expressions mathematically.

This class is effectively the inverse of Equality. As such, it uses the same algorithms, including any available \texttt{evalEq} methods.

See also:

Equality (page 1071)

```python
class sympy.core.relational.StrictGreaterThan(lhs, rhs, **options)

Class representations of inequalities.
```
Explanation

The *Than classes represent inequal relationships, where the left-hand side is generally bigger or smaller than the right-hand side. For example, the GreaterThan class represents an inequal relationship where the left-hand side is at least as big as the right side, if not bigger. In mathematical notation:

\[ \text{lhs} \geq \text{rhs} \]

In total, there are four *Than classes, to represent the four inequalities:

<table>
<thead>
<tr>
<th>Class Name</th>
<th>Symbol</th>
</tr>
</thead>
<tbody>
<tr>
<td>GreaterThan</td>
<td>(\geq)</td>
</tr>
<tr>
<td>LessThan</td>
<td>(\leq)</td>
</tr>
<tr>
<td>StrictGreaterThan</td>
<td>(&gt;)</td>
</tr>
<tr>
<td>StrictLessThan</td>
<td>(&lt;)</td>
</tr>
</tbody>
</table>

All classes take two arguments, lhs and rhs.

<table>
<thead>
<tr>
<th>Signature Example</th>
<th>Math Equivalent</th>
</tr>
</thead>
<tbody>
<tr>
<td>GreaterThan(lhs, rhs)</td>
<td>lhs (\geq) rhs</td>
</tr>
<tr>
<td>LessThan(lhs, rhs)</td>
<td>lhs (\leq) rhs</td>
</tr>
<tr>
<td>StrictGreaterThan(lhs, rhs)</td>
<td>lhs (&gt;) rhs</td>
</tr>
<tr>
<td>StrictLessThan(lhs, rhs)</td>
<td>lhs (&lt;) rhs</td>
</tr>
</tbody>
</table>

In addition to the normal .lhs and .rhs of Relations, *Than inequality objects also have the .lts and .gts properties, which represent the “less than side” and “greater than side” of the operator. Use of .lts and .gts in an algorithm rather than .lhs and .rhs as an assumption of inequality direction will make more explicit the intent of a certain section of code, and will make it similarly more robust to client code changes:

```python
>>> from sympy import GreaterThan, StrictGreaterThan
>>> from sympy import LessThan, StrictLessThan
>>> from sympy import And, Ge, Gt, Le, Lt, Rel, S
>>> from sympy.abc import x, y, z
>>> from sympy.core.relational import Relational

>>> e = GreaterThan(x, 1)
>>> e
x >= 1
>>> '%s >= %s is the same as %s <= %s' % (e.gts, e.lts, e.lts, e.gts)
'x >= 1 is the same as 1 <= x'
```
Examples

One generally does not instantiate these classes directly, but uses various convenience methods:

```python
>>> for f in [Ge, Gt, Le, Lt]:  # convenience wrappers
...     print(f(x, 2))
x >= 2
x > 2
x <= 2
x < 2
```

Another option is to use the Python inequality operators (>=, >, <=, <) directly. Their main advantage over the Ge, Gt, Le, and Lt counterparts, is that one can write a more “mathematical looking” statement rather than littering the math with oddball function calls. However there are certain (minor) caveats of which to be aware (search for ‘gotcha’, below).

```python
>>> x >= 2
x >= 2
>>> _ == Ge(x, 2)
True
```

However, it is also perfectly valid to instantiate a *Than class less succinctly and less conveniently:

```python
>>> Rel(x, 1, ">")
x > 1
>>> Relational(x, 1, ">")
x > 1
```

```python
>>> StrictGreaterThan(x, 1)
x > 1
>>> GreaterThan(x, 1)
x >= 1
>>> LessThan(x, 1)
x <= 1
>>> StrictLessThan(x, 1)
x < 1
```

Notes

There are a couple of “gotchas” to be aware of when using Python’s operators. The first is that what your write is not always what you get:

```python
>>> 1 < x
x > 1
```

Due to the order that Python parses a statement, it may not immediately find two objects comparable. When 1 < x is evaluated, Python recognizes that the number 1 is a native number and that x is not. Because a native Python number does not know how to compare itself with a SymPy object Python will try
the reflective operation, \( x > 1 \) and that is the form that gets evaluated, hence returned.

If the order of the statement is important (for visual output to the console, perhaps), one can work around this annoyance in a couple ways:

(1) “sympify” the literal before comparison

\[
\text{```python}
>>> S(1) < x
1 < x
\text{```}
\]

(2) use one of the wrappers or less succinct methods described above

\[
\text{```python}
>>> Lt(1, x)
1 < x
>>> Relational(1, x, "<")
1 < x
\text{```}
\]

The second gotcha involves writing equality tests between relational when one or both sides of the test involve a literal relational:

\[
\text{```python}
>>> e = x < 1; e
x < 1
>>> e == e  # neither side is a literal
True
>>> e == x < 1  # expecting True, too
False
>>> e != x < 1  # expecting False
x < 1
>>> x < 1 != x < 1  # expecting False or the same thing as before
Traceback (most recent call last):
...
TypeError: cannot determine truth value of Relational
\text{```}
\]

The solution for this case is to wrap literal relationals in parentheses:

\[
\text{```python}
>>> e == (x < 1)
True
>>> e != (x < 1)
False
>>> (x < 1) != (x < 1)
False
\text{```}
\]

The third gotcha involves chained inequalities not involving == or !=. Occasionally, one may be tempted to write:

\[
\text{```python}
>>> e = x < y < z
Traceback (most recent call last):
...
TypeError: symbolic boolean expression has no truth value.
\text{```}
\]

Due to an implementation detail or decision of Python [R139], there is no way for SymPy to create a chained inequality with that syntax so one must use And:
```python
>>> e = And(x < y, y < z)
>>> type(e)
And
>>> e
(x < y) & (y < z)
```

Although this can also be done with the ‘&’ operator, it cannot be done with the ‘and’ operator:

```python
>>> (x < y) & (y < z)
(x < y) & (y < z)
>>> (x < y) and (y < z)
Traceback (most recent call last):
  ...TypeError: cannot determine truth value of Relational
```

```python
class sympy.core.relational.StrictLessThan(lhs, rhs, **options)
```

Class representations of inequalities.

**Explanation**

The *Than classes represent inequal relationships, where the left-hand side is generally bigger or smaller than the right-hand side. For example, the GreaterThan class represents an inequal relationship where the left-hand side is at least as big as the right side, if not bigger. In mathematical notation:

\[
\text{lhs} \geq \text{rhs}
\]

In total, there are four *Than classes, to represent the four inequalities:

<table>
<thead>
<tr>
<th>Class Name</th>
<th>Symbol</th>
</tr>
</thead>
<tbody>
<tr>
<td>GreaterThan</td>
<td>&gt;=</td>
</tr>
<tr>
<td>LessThan</td>
<td>&lt;=</td>
</tr>
<tr>
<td>StrictGreaterThan</td>
<td>&gt;</td>
</tr>
<tr>
<td>StrictLessThan</td>
<td>&lt;</td>
</tr>
</tbody>
</table>

All classes take two arguments, lhs and rhs.

<table>
<thead>
<tr>
<th>Signature Example</th>
<th>Math Equivalent</th>
</tr>
</thead>
<tbody>
<tr>
<td>GreaterThan(lhs, rhs)</td>
<td>lhs ≥ rhs</td>
</tr>
<tr>
<td>LessThan(lhs, rhs)</td>
<td>lhs ≤ rhs</td>
</tr>
<tr>
<td>StrictGreaterThan(lhs, rhs)</td>
<td>lhs &gt; rhs</td>
</tr>
<tr>
<td>StrictLessThan(lhs, rhs)</td>
<td>lhs &lt; rhs</td>
</tr>
</tbody>
</table>

In addition to the normal .lhs and .rhs of Relations, *Than inequality objects also have the .lts and .gts properties, which represent the “less than side” and “greater than side” of the operator. Use of .lts and .gts in an algorithm rather than .lhs and .rhs as an assumption of inequality direction will make more explicit the intent of a certain section of code, and will make it similarly more robust to client code changes:
Examples

One generally does not instantiate these classes directly, but uses various convenience methods:

```python
>>> for f in [Ge, Gt, Le, Lt]:    # convenience wrappers
...     print(f(x, 2))
 x >= 2
 x > 2
 x <= 2
 x < 2
```

Another option is to use the Python inequality operators (>=, >, <=, <) directly. Their main advantage over the Ge, Gt, Le, and Lt counterparts, is that one can write a more “mathematical looking” statement rather than littering the math with oddball function calls. However there are certain (minor) caveats of which to be aware (search for ‘gotcha’, below).

```python
>>> x >= 2
 x >= 2
 >>> _ == Ge(x, 2)
 True
```

However, it is also perfectly valid to instantiate a *Than class less succinctly and less conveniently:

```python
>>> Rel(x, 1, ">")
 x > 1
 >>> Relational(x, 1, ">")
 x > 1
```

```python
>>> StrictGreaterThan(x, 1)
 x > 1
 >>> GreaterThan(x, 1)
 x >= 1
 >>> LessThan(x, 1)
 x <= 1
 >>> StrictLessThan(x, 1)
 x < 1
```
Notes

There are a couple of “gotchas” to be aware of when using Python’s operators.
The first is that what your write is not always what you get:

```python
>>> 1 < x
x > 1
```

Due to the order that Python parses a statement, it may not immediately find
two objects comparable. When `1 < x` is evaluated, Python recognizes that the
number `1` is a native number and that `x` is not. Because a native Python num-
ber does not know how to compare itself with a SymPy object Python will try
the reflective operation, `x > 1` and that is the form that gets evaluated, hence
returned.

If the order of the statement is important (for visual output to the console, per-
haps), one can work around this annoyance in a couple ways:

1. “sympify” the literal before comparison

```python
>>> S(1) < x
1 < x
```

2. Use one of the wrappers or less succinct methods described above

```python
>>> Lt(1, x)
1 < x
>>> Relational(1, x, "<")
1 < x
```

The second gotcha involves writing equality tests between relationals when one or both
sides of the test involve a literal relational:

```python
>>> e = x < 1; e
x < 1
>>> e == e  # neither side is a literal
True
>>> e == x < 1  # expecting True, too
False
>>> e != x < 1  # expecting False
x < 1
>>> x < 1 != x < 1  # expecting False or the same thing as before
Traceback (most recent call last):
  ... TypeError: cannot determine truth value of Relational
```

The solution for this case is to wrap literal relationals in parentheses:

```python
>>> e == (x < 1)
True
>>> e != (x < 1)
False
>>> (x < 1) != (x < 1)
False
```
The third gotcha involves chained inequalities not involving == or !=. Occasionally, one may be tempted to write:

```python
>>> e = x < y < z
Traceback (most recent call last):
...TypeError: symbolic boolean expression has no truth value.
```

Due to an implementation detail or decision of Python [R140], there is no way for SymPy to create a chained inequality with that syntax so one must use And:

```python
>>> e = And(x < y, y < z)
>>> type(e)
And
>>> e
(x < y) & (y < z)
```

Although this can also be done with the ‘&’ operator, it cannot be done with the ‘and’ operator:

```python
>>> (x < y) & (y < z)
(x < y) & (y < z)
>>> (x < y) and (y < z)
Traceback (most recent call last):
...TypeError: cannot determine truth value of Relational
```

**multidimensional**

class sympy.core.multidimensional.vectorize(*mdargs)

Generalizes a function taking scalars to accept multidimensional arguments.

**Examples**

```python
>>> from sympy import vectorize, diff, sin, symbols, Function
>>> x, y, z = symbols('x y z')
>>> f, g, h = list(map(Function, 'fgh'))

>>> @vectorize(0)
... def vsin(x):
...     return sin(x)

>>> vsin([1, x, y])
[sin(1), sin(x), sin(y)]

>>> @vectorize(0, 1)
... def vdiff(f, y):
...     return diff(f, y)

>>> vdiff(f, y)
```

SymPy Documentation, Release 1.12.1

>>> vdiff([f(x, y, z), g(x, y, z), h(x, y, z)], [x, y, z])
[[Derivative(f(x, y, z), x), Derivative(f(x, y, z), y), Derivative(f(x, u → y, z), z)],
 [Derivative(g(x, y, z), x), Derivative(g(x, y, z), y), Derivative(g(x, y, z), z)],
 [Derivative(h(x, y, z), x), Derivative(h(x, y, z), y), Derivative(h(x, y, z), z)]]

**function**

class sympy.core.function.Lambda(signature, expr)

Lambda(x, expr) represents a lambda function similar to Python’s ‘lambda x: expr’. A function of several variables is written as Lambda((x, y, ...), expr).

**Examples**

A simple example:

```python
>>> from sympy import Lambda
>>> from sympy.abc import x
>>> f = Lambda(x, x**2)
>>> f(4)
16
```

For multivariate functions, use:

```python
>>> from sympy.abc import y, z, t
>>> f2 = Lambda((x, y, z, t), x + y*z + t*z)
>>> f2(1, 2, 3, 4)
73
```

It is also possible to unpack tuple arguments:

```python
>>> f = Lambda(((x, y), z), x + y + z)
>>> f((1, 2), 3)
6
```

A handy shortcut for lots of arguments:

```python
>>> p = x, y, z
>>> f = Lambda(p, x + y*z)
>>> f(*p)
x + y*z
```

**property bound_symbols**

The variables used in the internal representation of the function

**property expr**

The return value of the function

**property is_identity**

Return True if this Lambda is an identity function.
**property signature**

The expected form of the arguments to be unpacked into variables

**property variables**

The variables used in the internal representation of the function

```python
class sympy.core.function.WildFunction(*args)
A WildFunction function matches any function (with its arguments).
```

**Examples**

```python
>>> from sympy import WildFunction, Function, cos
>>> from sympy.abc import x, y
>>> F = WildFunction('F')
>>> f = Function('f')
>>> F.nargs
Naturals0
>>> x.match(F)
>>> F.match(F)
{F_: F_}
>>> f(x).match(F)
{F_: f(x)}
>>> cos(x).match(F)
{F_: cos(x)}
>>> f(x, y).match(F)
{F_: f(x, y)}
```

To match functions with a given number of arguments, set `nargs` to the desired value at instantiation:

```python
>>> F = WildFunction('F', nargs=2)
>>> F.nargs
{2}
>>> f(x).match(F)
>>> f(x, y).match(F)
{F_: f(x, y)}
```

To match functions with a range of arguments, set `nargs` to a tuple containing the desired number of arguments, e.g. if `nargs = (1, 2)` then functions with 1 or 2 arguments will be matched.

```python
>>> F = WildFunction('F', nargs=(1, 2))
>>> F.nargs
{1, 2}
>>> f(x).match(F)
{F_: f(x)}
>>> f(x, y).match(F)
{F_: f(x, y)}
>>> f(x, y, 1).match(F)
```

```python
class sympy.core.function.Derivative(expr, *variables, **kwargs)
```

Carries out differentiation of the given expression with respect to symbols.
Examples

```python
>>> from sympy import Derivative, Function, symbols, Subs
>>> from sympy.abc import x, y
>>> f, g = symbols('f g', cls=Function)

>>> Derivative(x**2, x, evaluate=True)
2*x
```

Denesting of derivatives retains the ordering of variables:

```python
>>> Derivative(Derivative(f(x, y), y), x)
Derivative(f(x, y), y, x)
```

Contiguously identical symbols are merged into a tuple giving the symbol and the count:

```python
>>> Derivative(f(x), x, x, y, x)
Derivative(f(x), (x, 2), y, x)
```

If the derivative cannot be performed, and evaluate is True, the order of the variables of differentiation will be made canonical:

```python
>>> Derivative(f(x, y), y, x, evaluate=True)
Derivative(f(x, y), x, y)
```

Derivatives with respect to undefined functions can be calculated:

```python
>>> Derivative(f(x)**2, f(x), evaluate=True)
2*f(x)
```

Such derivatives will show up when the chain rule is used to evaluate a derivative:

```python
>>> f(g(x)).diff(x)
Derivative(f(g(x)), g(x))*Derivative(g(x), x)
```

Substitution is used to represent derivatives of functions with arguments that are not symbols or functions:

```python
>>> f(2*x + 3).diff(x) == 2*Subs(f(y).diff(y), y, 2*x + 3)
True
```

Notes

Simplification of high-order derivatives:

Because there can be a significant amount of simplification that can be done when multiple differentiations are performed, results will be automatically simplified in a fairly conservative fashion unless the keyword simplify is set to False.

```python
>>> from sympy import sqrt, diff, Function, symbols
>>> from sympy.abc import x, y, z
>>> f, g = symbols('f,g', cls=Function)
```
```python
>>> e = sqrt((x + 1)**2 + x)
>>> diff(e, (x, 5), simplify=False).count_ops()
136
>>> diff(e, (x, 5)).count_ops()
30
```

Ordering of variables:

If evaluate is set to True and the expression cannot be evaluated, the list of differentiation symbols will be sorted, that is, the expression is assumed to have continuous derivatives up to the order asked.

Derivative wrt non-Symbols:

For the most part, one may not differentiate wrt non-symbols. For example, we do not allow differentiation wrt \( x \cdot y \) because there are multiple ways of structurally defining where \( x \cdot y \) appears in an expression: a very strict definition would make \((x*y+z).diff(x*y) == 0\). Derivatives wrt defined functions (like \( \cos(x) \)) are not allowed, either:

```python
>>> (x*y*z).diff(x*y)
Traceback (most recent call last):
...
ValueError: Can't calculate derivative wrt x*y.
```

To make it easier to work with variational calculus, however, derivatives wrt AppliedUnndef and Derivatives are allowed. For example, in the Euler-Lagrange method one may write \( F(t, u, v) \) where \( u = f(t) \) and \( v = f'(t) \). These variables can be written explicitly as functions of time:

```python
>>> from sympy import t
>>> F = Function('F')
>>> U = f(t)
>>> V = U.diff(t)
```

The derivative wrt \( f(t) \) can be obtained directly:

```python
>>> direct = F(t, U, V).diff(U)
```

When differentiation wrt a non-Symbol is attempted, the non-Symbol is temporarily converted to a Symbol while the differentiation is performed and the same answer is obtained:

```python
>>> indirect = F(t, U, V).subs(U, x).diff(x).subs(x, U)
```

The implication of this non-symbol replacement is that all functions are treated as independent of other functions and the symbols are independent of the functions that contain them:

```python
>>> x.diff(f(x))
0
>>> g(x).diff(f(x))
0
```

It also means that derivatives are assumed to depend only on the variables of differentiation, not on anything contained within the expression being differentiated:
The last example can be made explicit by showing the replacement of \( F_x \) in \( F_{xx} \) with \( y \):

\[
\text{>>> } F_{xx}.\text{subs}(F_x, y)
\]

\[
\text{Derivative}(y, x)
\]

Since that in itself will evaluate to zero, differentiating \( \text{wrt} \) \( F_x \) will also be zero:

\[
\text{>>> } _.\text{doit()}
\]

\[
0
\]

Replacing undefined functions with concrete expressions

One must be careful to replace undefined functions with expressions that contain variables consistent with the function definition and the variables of differentiation or else inconsistent result will be obtained. Consider the following example:

\[
\text{>>> eq} = f(x)\ast g(y)
\]

\[
\text{>>> eq}\text{.subs}(f(x), x\ast y).\text{diff(x, y)}.\text{doit()}
\]

\[
y\ast \text{Derivative}(g(y), y) + g(y)
\]

\[
\text{>>> eq}\text{.diff(x, y)}.\text{subs}(f(x), x\ast y).\text{doit()}
\]

\[
y\ast \text{Derivative}(g(y), y)
\]

The results differ because \( f(x) \) was replaced with an expression that involved both variables of differentiation. In the abstract case, differentiation of \( f(x) \) by \( y \) is 0; in the concrete case, the presence of \( y \) made that derivative nonvanishing and produced the extra \( g(y) \) term.

Defining differentiation for an object

An object must define \_eval_derivative(symbol) method that returns the differentiation result. This function only needs to consider the non-trivial case where expr contains symbol and it should call the \text{diff()} method internally (not \_eval_derivative); \text{Derivative} should be the only one to call \_eval_derivative.

Any class can allow derivatives to be taken with respect to itself (while indicating its scalar nature). See the docstring of Expr\_.diff_wrt.

\textbf{See also:}

\texttt{\_sort\_variable\_count} (page 1092)

\texttt{property \_diff\_wrt}

An expression may be differentiated \( \text{wrt} \) a Derivative if it is in elementary form.
Examples

```python
>>> from sympy import Function, Derivative, cos
>>> from sympy.abc import x
>>> f = Function('f')

>>> Derivative(f(x), x)._diff_wrt True
>>> Derivative(cos(x), x)._diff_wrt False
>>> Derivative(x + 1, x)._diff_wrt False
```

A Derivative might be an unevaluated form of what will not be a valid variable of differentiation if evaluated. For example,

```python
>>> Derivative(f(f(x)), x).doit()
Derivative(f(x), x)*Derivative(f(f(x)), f(x))
```

Such an expression will present the same ambiguities as arise when dealing with any other product, like 2*x, so _diff_wrt is False:

```python
>>> Derivative(f(f(x)), x)._diff_wrt False
```

classmethod _sort_variable_count(vc)

Sort (variable, count) pairs into canonical order while retaining order of variables that do not commute during differentiation:

- symbols and functions commute with each other
- derivatives commute with each other
- a derivative does not commute with anything it contains
- any other object is not allowed to commute if it has free symbols in common with another object

Examples

```python
>>> from sympy import Derivative, Function, symbols
>>> vsort = Derivative._sort_variable_count
>>> x, y, z = symbols('x y z')
>>> f, g, h = symbols('f g h', cls=Function)

Contiguous items are collapsed into one pair:

```python
>>> vsort([[x, 1], (x, 1)])
[(x, 2)]
>>> vsort([[y, 1], (f(x), 1), (y, 1), (f(x), 1)])
[(y, 2), (f(x), 2)]
```

Ordering is canonical.
```python
>>> def vsort0(*v):
    ... # docstring helper to
    ... # change vi -> (vi, 0), sort, and return vi vals
    ... return [i[0] for i in vsort([(i, 0) for i in v])]

>>> vsort0(y, x)
[x, y]
>>> vsort0(g(y), g(x), f(y))
[f(y), g(x), g(y)]
```

Symbols are sorted as far to the left as possible but never move to the left of a derivative having the same symbol in its variables; the same applies to AppliedUndef which are always sorted after Symbols:

```python
>>> dfx = f(x).diff(x)
>>> assert vsort0(dfx, y) == [y, dfx]
>>> assert vsort0(dfx, x) == [dfx, x]
```

**as_finite_difference**(*points=1, x0=None, wrt=None*)

Express a Derivative instance as a finite difference.

**Parameters**

- **points**: sequence or coefficient, optional
  
  If sequence: discrete values (length >= order+1) of the independent variable used for generating the finite difference weights. If it is a coefficient, it will be used as the step-size for generating an equidistant sequence of length order+1 centered around x0. Default: 1 (step-size 1)

- **x0**: number or Symbol, optional
  
  the value of the independent variable (wrt) at which the derivative is to be approximated. Default: same as wrt.

- **wrt**: Symbol, optional
  
  “with respect to” the variable for which the (partial) derivative is to be approximated for. If not provided it is required that the derivative is ordinary. Default: None.

**Examples**

```python
>>> from sympy import symbols, Function, exp, sqrt, Symbol
>>> x, h = symbols('x h')
>>> f = Function('f')
>>> f(x).diff(x).as_finite_difference()  
-f(x - 1/2) + f(x + 1/2)  
```

The default step size and number of points are 1 and order + 1 respectively. We can change the step size by passing a symbol as a parameter:

```python
>>> f(x).diff(x).as_finite_difference(h)  
-f(-h/2 + x)/h + f(h/2 + x)/h  
```
We can also specify the discretized values to be used in a sequence:

```python
>>> f(x).diff(x).as_finite_difference([x, x+h, x+2*h])
-3*f(x)/(2*h) + 2*f(h + x)/h - f(2*h + x)/(2*h)
```

The algorithm is not restricted to use equidistant spacing, nor do we need to make the approximation around x₀, but we can get an expression estimating the derivative at an offset:

```python
>>> e, sq2 = exp(1), sqrt(2)
>>> xl = [x-h, x+h, x+e*h]
>>> f(x).diff(x, 1).as_finite_difference(xl, x+h*sq2)
2*h*(((h + sqrt(2)*h)/(2*h) - (-sqrt(2)*h + h)/(2*h))*f(E*h + x)/...
```

To approximate Derivative around x₀ using a non-equidistant spacing step, the algorithm supports assignment of undefined functions to points:

```python
>>> dx = Function('dx')
>>> f(x).diff(x).as_finite_difference(points=dx(x), x0=x-h)
-f(-h + x - dx(-h + x)/2)/dx(-h + x) + f(-h + x + dx(-h + x)/2)/dx(-h + x)
```

Partial derivatives are also supported:

```python
>>> y = Symbol('y')
>>> d2fdxdy=f(x,y).diff(x,y)
>>> d2fdxdy.as_finite_difference(wrt=x)
-Derivative(f(x - 1/2, y), y) + Derivative(f(x + 1/2, y), y)
```

We can apply `as_finite_difference` to `Derivative` instances in compound expressions using replace:

```python
>>> (1 + 42**f(x).diff(x)).replace(lambda arg: arg.is_Derivative,
... lambda arg: arg.as_finite_difference())
42**(-f(x - 1/2) + f(x + 1/2)) + 1
```

See also:

- `sympy.calculus.finite_diff.apply_finite_diff` (page 294),
- `sympy.calculus.finite_diff.differentiate_finite` (page 296),
- `sympy.calculus.finite_diff.finite_diff_weights` (page 296)

**doit_numerically**(z₀)

Evaluate the derivative at z numerically.

When we can represent derivatives at a point, this should be folded into the normal evalf. For now, we need a special method.

```python
sympy.core.function.diff(f, *symbols, **kwargs)
```

Differentiate f with respect to symbols.
**Explanation**

This is just a wrapper to unify .diff() and the Derivative class; its interface is similar to that of integrate(). You can use the same shortcuts for multiple variables as with Derivative. For example, diff(f(x), x, x, x) and diff(f(x), x, 3) both return the third derivative of f(x).

You can pass evaluate=False to get an unevaluated Derivative class. Note that if there are 0 symbols (such as diff(f(x), x, 0), then the result will be the function (the zeroth derivative), even if evaluate=False.

**Examples**

```python
>>> from sympy import sin, cos, Function, diff
>>> from sympy.abc import x, y
>>> f = Function('f')

>>> diff(sin(x), x)
  cos(x)

>>> diff(f(x), x, x, x)
  Derivative(f(x), (x, 3))

>>> diff(f(x), x, 3)
  Derivative(f(x), (x, 3))

>>> diff(sin(x)*cos(y), x, 2, y, 2)
  sin(x)*cos(y)

>>> type(diff(sin(x), x))
  cos

>>> type(diff(sin(x), x, evaluate=False))
  <class 'sympy.core.function.Derivative'>

>>> type(diff(sin(x), x, 0))
  sin

>>> type(diff(sin(x), x, 0, evaluate=False))
  sin

>>> diff(sin(x))
  cos(x)

>>> diff(sin(x*y))
  Traceback (most recent call last):
    ...
  ValueError: specify differentiation variables to differentiate sin(x*y)
```

Note that diff(sin(x)) syntax is meant only for convenience in interactive sessions and should be avoided in library code.

**See also:**

*Derivative* (page 1088)

*idiff* (page 2276)

computes the derivative implicitly
class sympy.core.function.FunctionClass(*args, **kwargs)
Base class for function classes. FunctionClass is a subclass of type.
Use Function('<function name>'[, signature]) to create undefined function classes.

property nargs
Return a set of the allowed number of arguments for the function.

Examples

```python
>>> from sympy import Function
>>> f = Function('f')
```
If the function can take any number of arguments, the set of whole numbers is returned:

```python
>>> Function('f').nargs
Naturals0
```
If the function was initialized to accept one or more arguments, a corresponding set will be returned:

```python
>>> Function('f', nargs=1).nargs
{1}
>>> Function('f', nargs=(2, 1)).nargs
{1, 2}
```
The undefined function, after application, also has the nargs attribute; the actual number of arguments is always available by checking the args attribute:

```python
>>> f = Function('f')
>>> f(1).nargs
Naturals0
>>> len(f(1).args)
1
```

class sympy.core.function.Function(*args)
Base class for applied mathematical functions.
It also serves as a constructor for undefined function classes.

See the Writing Custom Functions (page 102) guide for details on how to subclass Function and what methods can be defined.
Examples

Undefined Functions

To create an undefined function, pass a string of the function name to Function.

```python
>>> from sympy import Function, Symbol
>>> x = Symbol('x')
>>> f = Function('f')
>>> g = Function('g')(x)
>>> f
f
>>> f(x)
f(x)
>>> g
g(x)
>>> g(x).diff(x)
Derivative(f(x), x)
>>> g.diff(x)
Derivative(g(x), x)
```

Assumptions can be passed to Function the same as with a `Symbol` (page 1028). Alternatively, you can use a Symbol with assumptions for the function name and the function will inherit the name and assumptions associated with the Symbol:

```python
>>> f_real = Function('f', real=True)
>>> f_real(x).is_real
True
>>> f_real_inherit = Function(Symbol('f', real=True))
>>> f_real_inherit(x).is_real
True
```

Note that assumptions on a function are unrelated to the assumptions on the variables it is called on. If you want to add a relationship, subclass `Function` and define custom assumptions handler methods. See the Assumptions (page 111) section of the Writing Custom Functions (page 102) guide for more details.

Custom Function Subclasses

The Writing Custom Functions (page 102) guide has several Complete Examples (page 122) of how to subclass `Function` to create a custom function.

```python
as_base_exp()
    Returns the method as the 2-tuple (base, exponent).

fdiff(argindex=1)
    Returns the first derivative of the function.

classmethod is_singular(a)
    Tests whether the argument is an essential singularity or a branch point, or the functions is non-holomorphic.
```

Note: Not all functions are the same

SymPy defines many functions (like *cos* and *factorial*). It also allows the user to create generic functions which act as argument holders. Such functions are created just like symbols:
```python
>>> from sympy import Function, cos
>>> from sympy.abc import x
>>> f = Function('f')
>>> f(2) + f(x)
f(2) + f(x)
```

If you want to see which functions appear in an expression you can use the atoms method:

```python
>>> e = (f(x) + cos(x) + 2)
>>> e.atoms(Function)
{f(x), cos(x)}
```

If you just want the function you defined, not SymPy functions, the thing to search for is AppliedUndef:

```python
>>> from sympy.core.function import AppliedUndef
>>> e.atoms(AppliedUndef)
{f(x)}
```

```python
class sympy.core.function.Subs(expr, variables, point, **assumptions)
Representes unevaluated substitutions of an expression.

Subs(expr, x, x0) represents the expression resulting from substituting x with x0 in expr.

Parameters

expr : Expr
    An expression.

x : tuple, variable
    A variable or list of distinct variables.

x0 : tuple or list of tuples
    A point or list of evaluation points corresponding to those variables.

Examples

>>> from sympy import Subs, Function, sin, cos
>>> from sympy.abc import x, y, z
>>> f = Function('f')

Subs are created when a particular substitution cannot be made. The x in the derivative cannot be replaced with 0 because 0 is not a valid variables of differentiation:

```python
>>> f(x).diff(x).subs(x, 0)
Subs(Derivative(f(x), x), x, 0)
```

Once f is known, the derivative and evaluation at 0 can be done:

```python
>>> _.subs(f, sin).doit() == sin(x).diff(x).subs(x, 0) == cos(0)
True
```
Subs can also be created directly with one or more variables:

```python
>>> Subs(f(x)*sin(y) + z, (x, y), (0, 1))
Subs(z + f(x)*sin(y), (x, y), (0, 1))
>>> _.doit()
z + f(0)*sin(1)
```

**Notes**

Subs objects are generally useful to represent unevaluated derivatives calculated at a point.

The variables may be expressions, but they are subjected to the limitations of subs(), so it is usually a good practice to use only symbols for variables, since in that case there can be no ambiguity.

There’s no automatic expansion - use the method .doit() to effect all possible substitutions of the object and also of objects inside the expression.

When evaluating derivatives at a point that is not a symbol, a Subs object is returned. One is also able to calculate derivatives of Subs objects - in this case the expression is always expanded (for the unevaluated form, use Derivative()).

In order to allow expressions to combine before doit is done, a representation of the Subs expression is used internally to make expressions that are superficially different compare the same:

```python
>>> a, b = Subs(x, x, 0), Subs(y, y, 0)
>>> a + b
2*Subs(x, x, 0)
```

This can lead to unexpected consequences when using methods like has that are cached:

```python
>>> s = Subs(x, x, 0)
>>> s.has(x), s.has(y)
(True, False)
>>> ss = s.subs(x, y)
>>> ss.has(x), ss.has(y)
(True, False)
>>> s, ss
(Subs(x, x, 0), Subs(y, y, 0))
```

**property bound_symbols**
- The variables to be evaluated

**property expr**
- The expression on which the substitution operates

**property point**
- The values for which the variables are to be substituted

**property variables**
- The variables to be evaluated
SymPy Documentation, Release 1.12.1

**sympy.core.function.expand**

\[ e, \text{deep}=True, \text{modulus}=None, \text{power_base}=True, \]
\[ \text{power_exp}=True, \text{mul}=True, \text{log}=True, \text{multinomial}=True, \]
\[ \text{basic}=True, **\text{hints} \]

Expand an expression using methods given as hints.

**Explanation**

Hints evaluated unless explicitly set to False are: basic, log, multinomial, mul, power_base, and power_exp. The following hints are supported but not applied unless set to True: complex, func, and trig. In addition, the following meta-hints are supported by some or all of the other hints: frac, numer, denom, modulus, and force. deep is supported by all hints. Additionally, subclasses of Expr may define their own hints or meta-hints.

The basic hint is used for any special rewriting of an object that should be done automatically (along with the other hints like mul) when expand is called. This is a catch-all hint to handle any sort of expansion that may not be described by the existing hint names. To use this hint an object should override the \_eval\_expand\_basic method. Objects may also define their own expand methods, which are not run by default. See the API section below.

If deep is set to True (the default), things like arguments of functions are recursively expanded. Use deep=False to only expand on the top level.

If the force hint is used, assumptions about variables will be ignored in making the expansion.

**Hints**

These hints are run by default

**Mul**

Distributes multiplication over addition:

```python
>>> from sympy import cos, exp, sin
>>> from sympy.abc import x, y, z
>>> (y*(x + z)).expand(mul=True)
x*y + y*z
```

**Multinomial**

Expand (x + y + ...)**n** where n is a positive integer.

```python
>>> ((x + y + z)**2).expand(multinomial=True)
x**2 + 2*x*y + 2*x*z + y**2 + 2*y*z + z**2
```
**Power_exp**

Expand addition in exponents into multiplied bases.

```python
>>> exp(x + y).expand(power_exp=True)
exp(x)*exp(y)
>>> (2**(x + y)).expand(power_exp=True)
2**x*2**y
```

**Power_base**

Split powers of multiplied bases.

This only happens by default if assumptions allow, or if the `force` meta-hint is used:

```python
>>> ((x*y)**z).expand(power_base=True)
(x*y)**z
>>> ((x*y)**z).expand(power_base=True, force=True)
x**z*y**z
>>> ((2*y)**z).expand(power_base=True)
2**z*y**z
```

Note that in some cases where this expansion always holds, SymPy performs it automatically:

```python
>>> (x*y)**2
x**2*y**2
```

**Log**

Pull out power of an argument as a coefficient and split logs products into sums of logs.

Note that these only work if the arguments of the log function have the proper assumptions–the arguments must be positive and the exponents must be real—or else the `force` hint must be True:

```python
>>> from sympy import log, symbols
>>> log(x**2*y).expand(log=True)
log(x**2*y)
>>> log(x**2*y).expand(log=True, force=True)
2*log(x) + log(y)
>>> x, y = symbols('x,y', positive=True)
>>> log(x**2*y).expand(log=True)
2*log(x) + log(y)
```
Basic

This hint is intended primarily as a way for custom subclasses to enable expansion by default.

These hints are not run by default:

Complex

Split an expression into real and imaginary parts.

```
>>> x, y = symbols('x, y')
>>> (x + y).expand(complex=True)
re(x) + re(y) + I*im(x) + I*im(y)
>>> cos(x).expand(complex=True)
-I*sin(re(x))*sinh(im(x)) + cos(re(x))*cosh(im(x))
```

Note that this is just a wrapper around as_real_imag(). Most objects that wish to redefine _eval_expand_complex() should consider redefining as_real_imag() instead.

Func

Expand other functions.

```
>>> from sympy import gamma
>>> gamma(x + 1).expand(func=True)
x*gamma(x)
```

Trig

Do trigonometric expansions.

```
>>> cos(x + y).expand(trig=True)
-sin(x)*sin(y) + cos(x)*cos(y)
>>> sin(2*x).expand(trig=True)
2*sin(x)*cos(x)
```

Note that the forms of \( \sin(n\times x) \) and \( \cos(n\times x) \) in terms of \( \sin(x) \) and \( \cos(x) \) are not unique, due to the identity \( \sin^2(x) + \cos^2(x) = 1 \). The current implementation uses the form obtained from Chebyshev polynomials, but this may change. See this MathWorld article for more information.
Notes

- You can shut off unwanted methods:

  ```python
  >>> (exp(x + y)*(x + y)).expand()
  x*exp(x)*exp(y) + y*exp(x)*exp(y)
  >>> (exp(x + y)*(x + y)).expand(power_exp=False)
  x*exp(x + y) + y*exp(x + y)
  >>> (exp(x + y)*(x + y)).expand(mul=False)
  (x + y)*exp(x)*exp(y)
  ```

- Use deep=False to only expand on the top level:

  ```python
  >>> exp(x + exp(x + y)).expand()
  exp(x)*exp(x)*exp(y)
  >>> exp(x + exp(x + y)).expand(deep=False)
  exp(x)*exp(x + y)
  ```

- Hints are applied in an arbitrary, but consistent order (in the current implementation, they are applied in alphabetical order, except multinomials come before `mul`, but this may change). Because of this, some hints may prevent expansion by other hints if they are applied first. For example, `mul` may distribute multiplications and prevent `log` and `power_base` from expanding them. Also, if `mul` is applied before `multinomial`, the expression might not be fully distributed. The solution is to use the various `expand_hint` helper functions or to use `hint=False` to this function to finely control which hints are applied. Here are some examples:

  ```python
  >>> from sympy import expand, expand_mul, expand_power_base
  >>> x, y, z = symbols('x,y,z', positive=True)
  >>> expand(log(x*(y + z)))
  log(x) + log(y + z)
  ```

  Here, we see that `log` was applied before `mul`. To get the `mul` expanded form, either of the following will work:

  ```python
  >>> expand_mul(log(x*(y + z)))
  log(x*y + x*z)
  >>> expand(log(x*(y + z)), log=False)
  log(x*y + x*z)
  ```

  A similar thing can happen with the `power_base` hint:

  ```python
  >>> expand((x*(y + z))**x)
  (x*y + x*z)**x
  ```

  To get the `power_base` expanded form, either of the following will work:

  ```python
  >>> expand((x*(y + z))**x, mul=False)
  x**x*(y + z)**x
  >>> expand_power_base((x*(y + z))**x)
  x**x*(y + z)**x
  ```

(continues on next page)
>>> expand((x + y)*y/x)
y + y**2/x

The parts of a rational expression can be targeted:

>>> expand((x + y)*y/x/(x + 1), frac=True)
(x*y + y**2)/(x**2 + x)

>>> expand((x + y)*y/x/(x + 1), numer=True)
(x*y + y**2)/(x*(x + 1))

>>> expand((x + y)*y/x/(x + 1), denom=True)
y*(x + y)/(x**2 + x)

• The modulus meta-hint can be used to reduce the coefficients of an expression post-expansion:

>>> expand((3*x + 1)**2)
9*x**2 + 6*x + 1

>>> expand((3*x + 1)**2, modulus=5)
4*x**2 + x + 1

• Either expand() the function or .expand() the method can be used. Both are equivalent:

>>> expand((x + 1)**2)
x**2 + 2*x + 1

>>> ((x + 1)**2).expand()
x**2 + 2*x + 1

**Api**

Objects can define their own expand hints by defining _eval_expand_hint(). The function should take the form:

```python
def _eval_expand_hint(self, **hints):
    # Only apply the method to the top-level expression
    ...
```

See also the example below. Objects should define _eval_expand_hint() methods only if hint applies to that specific object. The generic _eval_expand_hint() method defined in Expr will handle the no-op case.

Each hint should be responsible for expanding that hint only. Furthermore, the expansion should be applied to the top-level expression only. expand() takes care of the recursion that happens when deep=True.

You should only call _eval_expand_hint() methods directly if you are 100% sure that the object has the method, as otherwise you are liable to get unexpected AttributeError`s. Note, again, that you do not need to recursively apply the hint to args of your object: this is handled automatically by ```expand()```. _eval_expand_hint() should generally not be used at all outside of an _eval_expand_hint() method. If you want to apply a specific expansion from within another method, use the public expand() function, method, or expand_hint() functions.
In order for expand to work, objects must be rebuildable by their args, i.e., \( \text{obj. func(*obj.args)} \approx \text{obj} \) must hold.

Expand methods are passed **hints** so that expand hints may use ‘metahints’-hints that control how different expand methods are applied. For example, the force=True hint described above that causes expand(log=True) to ignore assumptions is such a metahint. The deep meta-hint is handled exclusively by expand() and is not passed to _eval_expand_hint() methods.

Note that expansion hints should generally be methods that perform some kind of ‘expansion’. For hints that simply rewrite an expression, use the .rewrite() API.

### Examples

```python
>>> from sympy import Expr, sympify
>>> class MyClass(Expr):
...     def __new__(cls, *args):
...         args = sympify(args)
...         return Expr.__new__(cls, *args)
...     
...     def _eval_expand_double(self, *, force=False, **hints):
...         """
...         Doubles the args of MyClass.
...         """
...         if not force and len(self.args) > 4:
...             return self
...         return self.func(*self.args + self.args)
... 
>>> a = MyClass(1, 2, MyClass(3, 4))
>>> a
MyClass(1, 2, MyClass(3, 4))
>>> a.expand(double=True)
MyClass(1, 2, MyClass(3, 4, 3, 4), 1, 2, MyClass(3, 4, 3, 4))
>>> a.expand(double=True, deep=False)
MyClass(1, 2, MyClass(3, 4), 1, 2, MyClass(3, 4))
>>> b = MyClass(1, 2, 3, 4, 5)
>>> b.expand(double=True)
MyClass(1, 2, 3, 4, 5)
>>> b.expand(double=True, force=True)
MyClass(1, 2, 3, 4, 5, 1, 2, 3, 4, 5)
```

- expand_log (page 1107), expand_mul (page 1107), expand_multinomial (page 1108), expand_complex (page 1108), expand_trig (page 1107), expand_power_base (page 1109), expand_power_exp (page 1108), expand_func (page 1107), sympy.simplify.hyperexpand.hyperexpand (page 743)

class sympy.core.function.PoleError
**SymPy Documentation, Release 1.12.1**

```python
sympy.core.function.count_ops(expr, visual=False)
```

Return a representation (integer or expression) of the operations in `expr`.

**Parameters**

- `expr`: Expr
  
  If `expr` is an iterable, the sum of the op counts of the items will be returned.

- `visual`: bool, optional
  
  If False (default) then the sum of the coefficients of the visual expression will be returned. If True then the number of each type of operation is shown with the core class types (or their virtual equivalent) multiplied by the number of times they occur.

**Examples**

```python
>>> from sympy.abc import a, b, x, y
>>> from sympy import sin, count_ops
```

Although there is not a SUB object, minus signs are interpreted as either negations or subtractions:

```python
>>> (x - y).count_ops(visual=True)
SUB
>>> (-x).count_ops(visual=True)
NEG
```

Here, there are two Adds and a Pow:

```python
>>> (1 + a + b**2).count_ops(visual=True)
2*ADD + POW
```

In the following, an Add, Mul, Pow and two functions:

```python
>>> (sin(x)*x + sin(x)**2).count_ops(visual=True)
ADD + MUL + POW + 2*SIN
```

for a total of 5:

```python
>>> (sin(x)*x + sin(x)**2).count_ops(visual=False)
5
```

Note that “what you type” is not always what you get. The expression `1/x/y` is translated by sympy into `1/(x*y)` so it gives a DIV and MUL rather than two DIVs:

```python
>>> (1/x/y).count_ops(visual=True)
DIV + MUL
```

The visual option can be used to demonstrate the difference in operations for expressions in different forms. Here, the Horner representation is compared with the expanded form of a polynomial:
>>> eq=x*(1 + x*(2 + x*(3 + x)))
>>> count_ops(eq.expand(), visual=True) - count_ops(eq, visual=True)
-MUL + 3*POW

The count_ops function also handles iterables:

>>> count_ops([x, sin(x), None, True, x + 2], visual=False)
2
>>> count_ops([x, sin(x), None, True, x + 2], visual=True)
ADD + SIN
>>> count_ops({x: sin(x), x + 2: y + 1}, visual=True)
2*ADD + SIN

**sympy.core.function.expand_mul**(expr, deep=True)

Wrapper around expand that only uses the mul hint. See the expand docstring for more information.

**Examples**

```python
>>> from sympy import symbols, expand_mul, exp, log
>>> x, y = symbols('x,y', positive=True)
>>> expand_mul(exp(x+y)*(x+y)*log(x*y**2))
x*exp(x + y)*log(x*y**2) + y*exp(x + y)*log(x*y**2)
```

**sympy.core.function.expand_log**(expr, deep=True, force=False, factor=False)

Wrapper around expand that only uses the log hint. See the expand docstring for more information.

**Examples**

```python
>>> from sympy import symbols, expand_log, exp, log
>>> x, y = symbols('x,y', positive=True)
>>> expand_log(exp(x+y)*(x+y)*log(x*y**2))
(x + y)*(log(x) + 2*log(y))*exp(x + y)
```

**sympy.core.function.expand_func**(expr, deep=True)

Wrapper around expand that only uses the func hint. See the expand docstring for more information.

**Examples**

```python
>>> from sympy import expand_func, gamma
>>> from sympy.abc import x
>>> expand_func(gamma(x + 2))
x*(x + 1)*gamma(x)
```

**sympy.core.function.expand_trig**(expr, deep=True)

Wrapper around expand that only uses the trig hint. See the expand docstring for more information.

**Examples**

```python
```
Examples

```python
>>> from sympy import expand_trig, sin
>>> from sympy.abc import x, y
>>> expand_trig(sin(x+y)*(x+y))
(x + y)*(sin(x)*cos(y) + sin(y)*cos(x))
```

`sympy.core.function.expand_complex(expr, deep=True)`

Wrapper around expand that only uses the complex hint. See the expand docstring for more information.

Examples

```python
>>> from sympy import expand_complex, exp, sqrt, I
>>> from sympy.abc import z
>>> expand_complex(exp(z))
I*exp(re(z))*sin(im(z)) + exp(re(z))*cos(im(z))
>>> expand_complex(sqrt(I))
sqrt(2)/2 + sqrt(2)*I/2
```

See also:

`sympy.core.expr.Expr.as_real_imag` (page 1008)

`sympy.core.function.expand_multinomial(expr, deep=True)`

Wrapper around expand that only uses the multinomial hint. See the expand docstring for more information.

Examples

```python
>>> from sympy import symbols, expand_multinomial, exp
>>> x, y = symbols('x y', positive=True)
>>> expand_multinomial((x + exp(x + 1))**2)
x**2 + 2*x*exp(x + 1) + exp(2*x + 2)
```

`sympy.core.function.expand_power_exp(expr, deep=True)`

Wrapper around expand that only uses the power_exp hint. See the expand docstring for more information.

Examples

```python
>>> from sympy import expand_power_exp, Symbol
>>> from sympy.abc import x, y
>>> expand_power_exp(3**(y + 2))
g3**(y + 2)
>>> expand_power_exp(x**(y + 2))
x**(y + 2)
```

If \( x = 0 \) the value of the expression depends on the value of \( y \); if the expression were expanded the result would be 0. So expansion is only done if \( x \neq 0 \):
```python
>>> expand_power_exp(Symbol('x', zero=False)**(y + 2))
x**2*x**y
```

SymPy's `expand_power_exp` function

```python
sympy.core.function.expand_power_base(expr, deep=True, force=False)
```

Wrapper around `expand` that only uses the `power_base` hint.

A wrapper to `expand(power_base=True)` which separates a power with a base that is a `Mul` into a product of powers, without performing any other expansions, provided that assumptions about the power's base and exponent allow.

- `deep=False` (default is True) will only apply to the top-level expression.
- `force=True` (default is False) will cause the expansion to ignore assumptions about the base and exponent. When False, the expansion will only happen if the base is non-negative or the exponent is an integer.

```python
>>> from sympy.abc import x, y, z

>>> from sympy import expand_power_base, sin, cos, exp, Symbol

>>> (x*y)**2
x**2*y**2

>>> (2*x)**y
(2*x)**y
>>> expand_power_base(_)
2**y*x**y

>>> expand_power_base((x*y)**z)
(x*y)**z
>>> expand_power_base((x*y)**z, force=True)
x**y*z**y

>>> expand_power_base(sin((x*y)**z), deep=False)
sin((x*y)**z)
>>> expand_power_base(sin((x*y)**z), force=True)
sin(x**y*z**y)

>>> expand_power_base((2*sin(x))**y + (2*cos(x))**y)
2**y*sin(x)**y + 2**y*cos(x)**y

>>> expand_power_base((2*exp(y))**x)
2**x*exp(y)**x

>>> expand_power_base((2*cos(x))**y)
2**y*cos(x)**y
```

Notice that sums are left untouched. If this is not the desired behavior, apply full `expand()` to the expression:

```python
>>> expand_power_base(((x+y)*z)**2)
z**2*(x + y)**2
>>> (((x+y)**z)**2).expand()
x**2*z**2 + 2*x*y*z**2 + y**2*z**2
```
>>> expand_power_base((2*y)**(1+z))
2**(z + 1)*y**(z + 1)
>>> ((2*y)**(1+z)).expand()
2*2**z*y**(z + 1)

The power that is unexpanded can be expanded safely when \( y \neq 0 \), otherwise different values might be obtained for the expression:

>>> prev = _

If we indicate that \( y \) is positive but then replace it with a value of 0 after expansion, the expression becomes 0:

>>> p = Symbol('p', positive=True)
>>> prev.subs(y, p).expand().subs(p, 0)
0

But if \( z = -1 \) the expression would not be zero:

>>> prev.subs(y, 0).subs(z, -1)
1

See also: 

`expand` (page 1099)

`sympy.core.function.nfloat(expr, n=15, exponent=False, dkeys=False)`

Make all Rationals in expr Floats except those in exponents (unless the exponents flag is set to True) and those in undefined functions. When processing dictionaries, do not modify the keys unless dkeys=True.

Examples

```python
>>> from sympy import nfloat, cos, pi, sqrt
>>> from sympy.abc import x, y
>>> nfloat(x**4 + x/2 + cos(pi/3) + 1 + sqrt(y))
x**4 + 0.5*x + sqrt(y) + 1.5
>>> nfloat(x**4 + sqrt(y), exponent=True)
x**4.0 + y**0.5
```

Container types are not modified:

```python
>>> type(nfloat((1, 2))) is tuple
True
```
evalf

class sympy.core.evalf.EvalfMixin
   Mixin class adding evalf capability.

   evalf(n=15, subs=None, maxn=100, chop=False, strict=False, quad=None, verbose=False)
   Evaluate the given formula to an accuracy of n digits.

   Parameters
   subs : dict, optional
      Substitute numerical values for symbols, e.g. subs={x:3, y:1+pi}. The substitutions must be given as a dictionary.
   maxn : int, optional
      Allow a maximum temporary working precision of maxn digits.
   chop : bool or number, optional
      Specifies how to replace tiny real or imaginary parts in subresults by exact zeros.
      When True the chop value defaults to standard precision.
      Otherwise the chop value is used to determine the magnitude of “small” for purposes of chopping.

>>> from sympy import N
>>> x = 1e-4
>>> N(x, chop=True)
0.00010000000000000
>>> N(x, chop=1e-5)
0.00010000000000000
>>> N(x, chop=1e-4)
0

   strict : bool, optional
      Raise PrecisionExhausted if any subresult fails to evaluate to full accuracy, given the available maxprec.

   quad : str, optional
      Choose algorithm for numerical quadrature. By default, tanh-sinh quadrature is used. For oscillatory integrals on an infinite interval, try quad='osc'.

   verbose : bool, optional
      Print debug information.
Notes

When Floats are naively substituted into an expression, precision errors may adversely affect the result. For example, adding 1e16 (a Float) to 1 will truncate to 1e16; if 1e16 is then subtracted, the result will be 0. That is exactly what happens in the following:

```python
>>> from sympy import x, y, z
>>> values = {x: 1e16, y: 1, z: 1e16}
>>> (x + y - z).subs(values)
0
```

Using the subs argument for evalf is the accurate way to evaluate such an expression:

```python
>>> (x + y - z).evalf(subs=values)
1.00000000000000
```

`n(n=15, subs=None, maxn=100, chop=False, strict=False, quad=None, verbose=False)`

Evaluate the given formula to an accuracy of n digits.

- **subs** : dict, optional
  Substitute numerical values for symbols, e.g. subs={x:3, y:1+pi}. The substitutions must be given as a dictionary.

- **maxn** : int, optional
  Allow a maximum temporary working precision of maxn digits.

- **chop** : bool or number, optional
  Specifies how to replace tiny real or imaginary parts in subresults by exact zeros.

  When True the chop value defaults to standard precision.

  Otherwise the chop value is used to determine the magnitude of “small” for purposes of chopping.

```python
>>> from sympy import N
>>> x = 1e-4
>>> N(x, chop=True)
0.00010000000000
>>> N(x, chop=1e-5)
0.00010000000000000
>>> N(x, chop=1e-4)
0
```

- **strict** : bool, optional
  Raise PrecisionExhausted if any subresult fails to evaluate to full accuracy, given the available maxprec.

- **quad** : str, optional
Choose algorithm for numerical quadrature. By default, tanh-sinh quadrature is used. For oscillatory integrals on an infinite interval, try quad='osc'.

verbose : bool, optional
Print debug information.

Notes

When Floats are naively substituted into an expression, precision errors may adversely affect the result. For example, adding 1e16 (a Float) to 1 will truncate to 1e16; if 1e16 is then subtracted, the result will be 0. That is exactly what happens in the following:

```python
from sympy import x, y, z
values = {x: 1e16, y: 1, z: 1e16}
(x + y - z).subs(values)
```

0

Using the subs argument for evaf is the accurate way to evaluate such an expression:

```python
(x + y - z).evalf(subs=values)
```

1.00000000000000

class sympy.core.evalf.PrecisionExhausted

sympy.core.evalf.N(x, n=15, **options)
Calls x.evalf(n, **options).

Explanations

Both .n() and N() are equivalent to .evalf(); use the one that you like better. See also the docstring of .evalf() for information on the options.

Examples

```python
from sympy import Sum, oo, N
from sympy.abc import k
Sum(1/k**k, (k, 1, oo))
Sum(k**(-k), (k, 1, oo))
N(_, 4)
```

1.291
containers

class sympy.core.containers.Tuple(*args, **kwargs)
    Wrapper around the builtin tuple object.

    Parameters
    =========
    sympify : bool
        If False, sympify is not called on args. This can be used for speedups
        for very large tuples where the elements are known to already be
        SymPy objects.

    Explanation

    The Tuple is a subclass of Basic, so that it works well in the SymPy framework. The
    wrapped tuple is available as self.args, but you can also access elements or slices with
    [:] syntax.

    Examples

    ```python
    >>> from sympy import Tuple, symbols
    >>> a, b, c, d = symbols('a b c d')
    >>> Tuple(a, b, c)[1:]  
    (b, c)
    >>> Tuple(a, b, c).subs(a, d)  
    (d, b, c)
    ```

    index(value, start=None, stop=None)
        Searches and returns the first index of the value.

    property kind
        The kind of a Tuple instance.
        The kind of a Tuple is always of TupleKind (page 1115) but parametrised by the
        number of elements and the kind of each element.

    Examples

    ```python
    >>> from sympy import Tuple, Matrix
    >>> Tuple(1, 2).kind
    TupleKind(NumberKind, NumberKind)
    >>> Tuple(Matrix([[1, 2]]), 1).kind
    TupleKind(MatrixKind(NumberKind), NumberKind)
    >>> Tuple(1, 2).kind.element_kind
    (NumberKind, NumberKind)
    ```

    See also:

    sympy.matrices.common.MatrixKind (page 1405), sympy.core.kind.NumberKind
    (page 1118)
**tuple_count**(value) → int

Return number of occurrences of value.

**class** sympy.core.containers.TupleKind(*args)

TupleKind is a subclass of Kind, which is used to define Kind of Tuple.

Parameters of TupleKind will be kinds of all the arguments in Tuples, for example

**Parameters**

args : tuple(element_kind)

element_kind is kind of element. args is tuple of kinds of element

**Examples**

```python
>>> from sympy import Tuple
>>> Tuple(1, 2).kind
TupleKind(NumberKind, NumberKind)
>>> Tuple(1, 2).kind.element_kind
(NumberKind, NumberKind)
```

**See also:**

sympy.core.kind.NumberKind (page 1118), MatrixKind (page 1405), sympy.sets.sets.SetKind (page 1259)

**class** sympy.core.containers.Dict(*args)

Wrapper around the built-in dict object.

**Explanation**

The Dict is a subclass of Basic, so that it works well in the SymPy framework. Because it is immutable, it may be included in sets, but its values must all be given at instantiation and cannot be changed afterwards. Otherwise it behaves identically to the Python dict.

**Examples**

```python
>>> from sympy import Dict, Symbol
>>>
>>> D = Dict({1: 'one', 2: 'two'})
>>> for key in D:
...     if key == 1:
...         print('%s %s' % (key, D[key]))
1 one
```

The args are sympified so the 1 and 2 are Integers and the values are Symbols. Queries automatically sympify args so the following work:

```python
>>> 1 in D
True
>>> D.has(Symbol('one')) # searches keys and values
True
```

(continues on next page)
get(key, default=None)

Returns the value for key if the key is in the dictionary.

items()

Returns a set-like object providing a view on dict’s items.

keys()

Returns the list of the dict’s keys.

values()

Returns the list of the dict’s values.

exprtools

sympy.core.expertools.gcd_terms(terms, isprimitive=False, clear=True, fraction=True)

Compute the GCD of terms and put them together.

Parameters

terms : Expr

Can be an expression or a non-Basic sequence of expressions which will be handled as though they are terms from a sum.

isprimitive : bool, optional

If isprimitive is True the _gcd_terms will not run the primitive method on the terms.

clear : bool, optional

It controls the removal of integers from the denominator of an Add expression. When True (default), all numerical denominator will be cleared; when False the denominators will be cleared only if all terms had numerical denominators other than 1.

fraction : bool, optional

When True (default), will put the expression over a common denominator.

Examples

>>> from sympy import gcd_terms
>>> from sympy.abc import x, y

>>> gcd_terms((x + 1)**2*y + (x + 1)*y**2)
y*(x + 1)*(x + y + 1)
>>> gcd_terms(x/2 + 1)
The `clear` flag was ignored in this case because the returned expression was a rational expression, not a simple sum.

**See also:**

`factor_terms` (page 1117), `sympy.polys.polytools.terms_gcd` (page 2441)

Remove common factors from terms in all arguments without changing the underlying structure of the expr. No expansion or simplification (and no processing of non-commutatives) is performed.

**Parameters**

- **radical**: bool, optional
  
  If `radical=True` then a radical common to all terms will be factored out of any Add sub-expressions of the expr.

- **clear**: bool, optional
  
  If `clear=False` (default) then coefficients will not be separated from a single Add if they can be distributed to leave one or more terms with integer coefficients.

- **fraction**: bool, optional
  
  If `fraction=True` (default is False) then a common denominator will be constructed for the expression.

- **sign**: bool, optional
  
  If `sign=True` (default) then even if the only factor in common is a -1, it will be factored out of the expression.
Examples

```python
>>> from sympy import factor_terms, Symbol
>>> from sympy.abc import x, y
>>> factor_terms(x + x*(2 + 4*y)**3)
x*(8*(2*y + 1)**3 + 1)
>>> A = Symbol('A', commutative=False)
>>> factor_terms(x*A + x*A + x*y*A)
x*(y*A + 2*A)
```

When `clear` is False, a rational will only be factored out of an Add expression if all terms of the Add have coefficients that are fractions:

```python
>>> factor_terms(x/2 + 1, clear=False)
x/2 + 1
>>> factor_terms(x/2 + 1, clear=True)
(x + 2)/2
```

If a -1 is all that can be factored out, to not factor it out, the flag `sign` must be False:

```python
>>> factor_terms(-x - y)
-(x + y)
>>> factor_terms(-x - y, sign=False)
-x - y
>>> factor_terms(-2*x - 2*y, sign=False)
-2*(x + y)
```

See also:

- `gcd_terms` (page 1116), `sympy.polys.polytools.terms_gcd` (page 2441)

kind

class sympy.core.kind.Kind(*args)

Base class for kinds.

Kind of the object represents the mathematical classification that the entity falls into. It is expected that functions and classes recognize and filter the argument by its kind.

Kind of every object must be carefully selected so that it shows the intention of design. Expressions may have different kind according to the kind of its arguments. For example, arguments of `Add` must have common kind since addition is group operator, and the resulting `Add()` has the same kind.

For the performance, each kind is as broad as possible and is not based on set theory. For example, `NumberKind` includes not only complex number but expression containing `S.Infinity` or `S.NaN` which are not strictly number.

Kind may have arguments as parameter. For example, `MatrixKind()` may be constructed with one element which represents the kind of its elements.

Kind behaves in singleton-like fashion. Same signature will return the same object.

`sympy.core.kind.NumberKind`

alias of `NumberKind`
SymPy.core.kind.UndefinedKind
    alias of UndefinedKind
SymPy.core.kind.BooleanKind
    alias of BooleanKind

Sorting

SymPy.core.sorting.default_sort_key(item, order=None)
    Return a key that can be used for sorting.
    The key has the structure:
    (class_key, (len(args), args), exponent.sort_key(), coefficient)
    This key is supplied by the sort_key routine of Basic objects when item is a Basic object or
    an object (other than a string) that sympifies to a Basic object. Otherwise, this function
    produces the key.
    The order argument is passed along to the sort_key routine and is used to determine
    how the terms within an expression are ordered. (See examples below) order options are: 'lex', 'grlex', 'grevlex', and reversed values of the same (e.g. 'rev-lex'). The default
    order value is None (which translates to 'lex').

Examples

```python
>>> from sympy import S, I, default_sort_key, sin, cos, sqrt
>>> from sympy.core.function import UndefinedFunction
>>> from sympy.abc import x
```

The following are equivalent ways of getting the key for an object:

```python
>>> x.sort_key() == default_sort_key(x)
True
```

Here are some examples of the key that is produced:

```python
>>> default_sort_key(UndefindedFunction('f'))
((0, 0, 'UndefindedFunction'), (1, ('f',)), ((1, 0, 'Number'),
    (0, ()), (1), 1))
>>> default_sort_key('1')
((0, 0, 'str'), (1, ('1',)), ((1, 0, 'Number'), (0, ()), ()), 1)
```

While sort_key is a method only defined for SymPy objects, default_sort_key will accept
anything as an argument so it is more robust as a sorting key. For the following, using
key=lambda i: i.sort_key() would fail because 2 does not have a sort_key method; that's
why default_sort_key is used. Note, that it also handles sympification of non-string items
likes ints:
>>> a = [2, I, -I]
>>> sorted(a, key=default_sort_key)
[2, -I, I]

The returned key can be used anywhere that a key can be specified for a function, e.g. sort, min, max, etc.:

>>> a.sort(key=default_sort_key); a[0]
2
>>> min(a, key=default_sort_key)
2

**Notes**

The key returned is useful for getting items into a canonical order that will be the same across platforms. It is not directly useful for sorting lists of expressions:

>>> a, b = x, 1/x

Since a has only 1 term, its value of sort_key is unaffected by order:

>>> a.sort_key() == a.sort_key('rev-lex')
True

If a and b are combined then the key will differ because there are terms that can be ordered:

>>> eq = a + b
>>> eq.sort_key() == eq.sort_key('rev-lex')
False
>>> eq.as_ordered_terms()
[x, 1/x]
>>> eq.as_ordered_terms('rev-lex')
[1/x, x]

But since the keys for each of these terms are independent of order’s value, they do not sort differently when they appear separately in a list:

>>> sorted(eq.args, key=default_sort_key)
[1/x, x]
>>> sorted(eq.args, key=lambda i: default_sort_key(i, order='rev-lex'))
[1/x, x]

The order of terms obtained when using these keys is the order that would be obtained if those terms were factors in a product.

Although it is useful for quickly putting expressions in canonical order, it does not sort expressions based on their complexity defined by the number of operations, power of variables and others:

>>> sorted([sin(x)*cos(x), sin(x)], key=default_sort_key)
[sin(x)*cos(x), sin(x)]

(continues on next page)
See also:

ordered (page 1121), sympy.core.expr.Expr.as_ordered_factors (page 1007),
sympy.core.expr.Expr.as_ordered_terms (page 1007)

sympy.core.sorting.ordered(seq, keys=None, default=True, warn=False)

Return an iterator of the seq where keys are used to break ties in a conservative fashion:
if, after applying a key, there are no ties then no other keys will be computed.

Two default keys will be applied if 1) keys are not provided or 2) the given keys do not
resolve all ties (but only if default is True). The two keys are _nodes (which places
smaller expressions before large) and default_sort_key which (if the sort_key for an
object is defined properly) should resolve any ties.

If warn is True then an error will be raised if there were no keys remaining to break ties.
This can be used if it was expected that there should be no ties between items that are
not identical.

Examples

```python
>>> from sympy import ordered, count_ops
>>> from sympy.abc import x, y
```

The count_ops is not sufficient to break ties in this list and the first two items appear in
their original order (i.e. the sorting is stable):

```python
>>> list(ordered([y + 2, x + 2, x**2 + y + 3],
... count_ops, default=False, warn=False))
[...]
[y + 2, x + 2, x**2 + y + 3]
```

The default_sort_key allows the tie to be broken:

```python
>>> list(ordered([y + 2, x + 2, x**2 + y + 3]))
[x + 2, y + 2, x**2 + y + 3]
```

Here, sequences are sorted by length, then sum:

```python
>>> seq, keys = [[1, 2, 1], [0, 3, 1], [1, 1, 3], [2], [1]], [
... lambda x: len(x),
... lambda x: sum(x)]
```

```python
>>> list(ordered(seq, keys, default=False, warn=False))
[[1], [2], [1, 2, 1], [0, 3, 1], [1, 1, 3]]
```

If warn is True, an error will be raised if there were not enough keys to break ties:

```python
>>> list(ordered(seq, keys, default=False, warn=True))
Traceback (most recent call last):
```
... 

```
ValueError: not enough keys to break ties
```

**Notes**

The decorated sort is one of the fastest ways to sort a sequence for which special item comparison is desired: the sequence is decorated, sorted on the basis of the decoration (e.g. making all letters lower case) and then undecorated. If one wants to break ties for items that have the same decorated value, a second key can be used. But if the second key is expensive to compute then it is inefficient to decorate all items with both keys: only those items having identical first key values need to be decorated. This function applies keys successively only when needed to break ties. By yielding an iterator, use of the tie-breaker is delayed as long as possible.

This function is best used in cases when use of the first key is expected to be a good hashing function; if there are no unique hashes from application of a key, then that key should not have been used. The exception, however, is that even if there are many collisions, if the first group is small and one does not need to process all items in the list then time will not be wasted sorting what one was not interested in. For example, if one were looking for the minimum in a list and there were several criteria used to define the sort order, then this function would be good at returning that quickly if the first group of candidates is small relative to the number of items being processed.

**Random**

When you need to use random numbers in SymPy library code, import from here so there is only one generator working for SymPy. Imports from here should behave the same as if they were being imported from Python’s random module. But only the routines currently used in SymPy are included here. To use others import rng and access the method directly. For example, to capture the current state of the generator use rng.getstate().

There is intentionally no Random to import from here. If you want to control the state of the generator, import seed and call it with or without an argument to set the state.

**Examples**

```python
>>> from sympy.core.random import random, seed
>>> assert random() < 1
>>> seed(1); a = random()
>>> b = random()
>>> seed(1); c = random()
>>> assert a == c
>>> assert a != b  # remote possibility this will fail
```

```
sympy.core.random.random_complex_number(a=2, b=-1, c=3, d=1, rational=False, tolerance=None)
```

Return a random complex number.

To reduce chance of hitting branch cuts or anything, we guarantee $b \leq \text{Im} \ z \leq d$, $a \leq \text{Re} \ z \leq c$.
When rational is True, a rational approximation to a random number is obtained within specified tolerance, if any.

`sympy.core.random.verify_numerically(f, g, z=None, tol=1e-06, a=2, b=-1, c=3, d=1)`

Test numerically that $f$ and $g$ agree when evaluated in the argument $z$.

If $z$ is None, all symbols will be tested. This routine does not test whether there are Floats present with precision higher than 15 digits so if there are, your results may not be what you expect due to round-off errors.

**Examples**

```python
>>> from sympy import sin, cos
>>> from sympy.abc import x
>>> from sympy.core.random import verify_numerically as tn
>>> tn(sin(x)**2 + cos(x)**2, 1, x)
True
```

`sympy.core.random.test_derivative_numerically(f, z, tol=1e-06, a=2, b=-1, c=3, d=1)`

Test numerically that the symbolically computed derivative of $f$ with respect to $z$ is correct.

This routine does not test whether there are Floats present with precision higher than 15 digits so if there are, your results may not be what you expect due to round-off errors.

**Examples**

```python
>>> from sympy import sin
>>> from sympy.abc import x
>>> from sympy.core.random import test_derivative_numerically as td
>>> td(sin(x), x)
True
```

`sympy.core.random._randrange(seed=None)`

Return a randrange generator.

`seed` can be

- None - return randomly seeded generator
- int - return a generator seeded with the int
- list - the values to be returned will be taken from the list in the order given; the provided list is not modified.
Examples

```python
>>> from sympy.core.random import _randrange
>>> rr = _randrange()
999
>>> rr = _randrange(3)
>>> rr(1000)
238
>>> rr = _randrange([0, 5, 1, 3, 4])
>>> rr(3), rr(3)
(0, 1)
```

**sympy.core.random._randint**(seed=None)

Return a randint generator.

seed can be

- None - return randomly seeded generator
- int - return a generator seeded with the int
- list - the values to be returned will be taken from the list in the order given; the provided list is not modified.

Examples

```python
>>> from sympy.core.random import _randint
>>> ri = _randint()
>>> ri(1, 1000)
999
>>> ri = _randint(3)
>>> ri(1, 1000)
238
>>> ri = _randint([0, 5, 1, 2, 4])
>>> ri(1, 3), ri(1, 3)
(1, 2)
```

Traversal

**sympy.core.traversal.bottom_up**(rv, F, atoms=False, nonbasic=False)

Apply F to all expressions in an expression tree from the bottom up. If atoms is True, apply F even if there are no args; if nonbasic is True, try to apply F to non-Basic objects.

**sympy.core.traversal.postorder_traversal**(node, keys=None)

Do a postorder traversal of a tree.

This generator recursively yields nodes that it has visited in a postorder fashion. That is, it descends through the tree depth-first to yield all of a node’s children’s postorder traversal before yielding the node itself.

**Parameters**

- **node**: SymPy expression
The expression to traverse.

**keys** : (default None) sort key(s)

The key(s) used to sort args of Basic objects. When None, args of Basic objects are processed in arbitrary order. If key is defined, it will be passed along to ordered() as the only key(s) to use to sort the arguments; if key is simply True then the default keys of ordered will be used (node count and default_sort_key).

**Yields**

**subtree** : SymPy expression

All of the subtrees in the tree.

### Examples

```python
>>> from sympy import postorder_traversal
>>> from sympy.abc import w, x, y, z
```

The nodes are returned in the order that they are encountered unless key is given; simply passing key=True will guarantee that the traversal is unique.

```python
>>> list(postorder_traversal(w + (x + y)*z))
[z, y, x, x + y, z*(x + y), w, w + z*(x + y)]
```

```python
>>> list(postorder_traversal(w + (x + y)*z, keys=True))
[w, z, x, y, x + y, z*(x + y), w + z*(x + y)]
```

**sympy.core.traversal.preorder_traversal** *(node, keys=None)*

Do a pre-order traversal of a tree.

This iterator recursively yields nodes that it has visited in a pre-order fashion. That is, it yields the current node then descends through the tree breadth-first to yield all of a node’s children’s pre-order traversal.

For an expression, the order of the traversal depends on the order of .args, which in many cases can be arbitrary.

### Parameters

**node** : SymPy expression

The expression to traverse.

**keys** : (default None) sort key(s)

The key(s) used to sort args of Basic objects. When None, args of Basic objects are processed in arbitrary order. If key is defined, it will be passed along to ordered() as the only key(s) to use to sort the arguments; if key is simply True then the default keys of ordered will be used.

**Yields**

**subtree** : SymPy expression

All of the subtrees in the tree.
Examples

```python
>>> from sympy import preorder_traversal, symbols
>>> x, y, z = symbols('x y z')
```

The nodes are returned in the order that they are encountered unless key is given; simply passing key=True will guarantee that the traversal is unique.

```python
>>> list(preorder_traversal((x + y) * z, keys=None))
[z*(x + y), z, x + y, y, x]
>>> list(preorder_traversal((x + y) * z, keys=True))
[z*(x + y), z, x + y, x, y]
```

```python
sympy.core.traversal.use(expr, func, level=0, args=(), kwargs={})
```

Use func to transform expr at the given level.

Examples

```python
>>> from sympy import use, expand
>>> from sympy import x, y
```

```python
>>> f = (x + y)**2*x + 1
```

```python
>>> use(f, expand, level=2)
```

```python
x*(x**2 + 2*x*y + y**2) + 1
```

```python
>>> expand(f)
```

```python
x**3 + 2*x**2*y + x*y**2 + 1
```

```python
sympy.core.traversal.walk(e, *target)
```

Iterate through the args that are the given types (target) and return a list of the args that were traversed; arguments that are not of the specified types are not traversed.

Examples

```python
>>> from sympy.core.traversal import walk
>>> from sympy import Min, Max
```

```python
>>> list(walk(Min(x, Max(y, Min(1, z))), Min))
[Min(x, Max(y, Min(1, z)))]
```

```python
>>> list(walk(Min(x, Max(y, Min(1, z))), Min, Max))
[Min(x, Max(y, Min(1, z))), Max(y, Min(1, z)), Min(1, z)]
```

`bottom_up` (page 1124)
**Discrete**

The discrete module in SymPy implements methods to compute discrete transforms and convolutions of finite sequences. This module contains functions which operate on discrete sequences.

**Transforms** - `fft`, `ifft`, `ntt`, `intt`, `fwht`, `ifwht`, `mobius_transform`, `inverse_mobius_transform`

**Convolutions** - `convolution`, `convolution_fft`, `convolution_ntt`, `convolution_fwht`, `convolution_subset`, `covering_product`, `intersecting_product`

Since the discrete transforms can be used to reduce the computational complexity of the discrete convolutions, the convolutions module makes use of the transforms module for efficient computation (notable for long input sequences).

**Transforms**

This section lists the methods which implement the basic transforms for discrete sequences.

**Fast Fourier Transform**

```python
def fft(seq, dps=None):
    # Perform the Discrete Fourier Transform (DFT) in the complex domain.
    # The sequence is automatically padded to the right with zeros, as the radix-2 FFT requires
    # the number of sample points to be a power of 2.
    # This method should be used with default arguments only for short sequences as the
    # complexity of expressions increases with the size of the sequence.
    #
    # Parameters
    # seq : iterable
    #     The sequence on which DFT is to be applied.
    #
    # dps : Integer
    #     Specifies the number of decimal digits for precision.
```

**Examples**

```python
>>> from sympy import fft, ifft

>>> fft([1, 2, 3, 4])
[10, -2 - 2*I, -2, -2 + 2*I]
>>> ifft(_)
[1, 2, 3, 4]

>>> ifft([1, 2, 3, 4])
[5/2, -1/2 + I/2, -1/2, -1/2 - I/2]
>>> fft(_)
[1, 2, 3, 4]
```
>>> ifft([1, 7, 3, 4], dps=15)
[3.75, -0.5 - 0.75*I, -1.75, -0.5 + 0.75*I]
>>> fft(_)
[1.0, 7.0, 3.0, 4.0]

References

[R169], [R170]
sympy.discrete.transforms.ifft(seq, dps=None)
Performsthe Discrete Fourier Transform (DFT) in the complex domain.
The sequence is automatically padded to the right with zeros, as the radix-2 FFT requires
the number of sample points to be a power of 2.
This method should be used with default arguments only for short sequences as the
complexity of expressions increases with the size of the sequence.

Parameters

seq : iterable
The sequence on which DFT is to be applied.
dps : Integer
Specifiesthenumberofdecimaldigitsforprecision.

Examples

>>> from sympy import fft, ifft

>>> fft([1, 2, 3, 4])
[10, -2 - 2*I, -2, -2 + 2*I]
>>> ifft(_)
[1, 2, 3, 4]

>>> ifft([1, 2, 3, 4])
[5/2, -1/2 + I/2, -1/2, -1/2 - I/2]
>>> fft(_)
[1, 2, 3, 4]

>>> ifft([1, 7, 3, 4], dps=15)

Number Theoretic Transform

sympy.discrete.transforms.ntt(seq, prime)

Performs the Number Theoretic Transform (NTT), which specializes the Discrete Fourier Transform (DFT) over quotient ring \( \mathbb{Z}/p\mathbb{Z} \) for prime \( p \) instead of complex numbers \( C \).

The sequence is automatically padded to the right with zeros, as the \( \text{radix-2 NTT} \) requires the number of sample points to be a power of 2.

Parameters

seq : iterable

The sequence on which DFT is to be applied.

prime : Integer

Prime modulus of the form \((m^{2^k} + 1)\) to be used for performing NTT on the sequence.

Examples

```python
>>> from sympy import ntt, intt
>>> ntt([1, 2, 3, 4], prime=3*2**8 + 1)
[10, 643, 767, 122]
>>> intt(_, 3*2**8 + 1)
[1, 2, 3, 4]
>>> intt([1, 2, 3, 4], prime=3*2**8 + 1)
[387, 415, 384, 353]
>>> ntt(_, prime=3*2**8 + 1)
[1, 2, 3, 4]
```

References

[R173], [R174], [R175]

sympy.discrete.transforms.intt(seq, prime)

Performs the Number Theoretic Transform (NTT), which specializes the Discrete Fourier Transform (DFT) over quotient ring \( \mathbb{Z}/p\mathbb{Z} \) for prime \( p \) instead of complex numbers \( C \).

The sequence is automatically padded to the right with zeros, as the \( \text{radix-2 NTT} \) requires the number of sample points to be a power of 2.

Parameters

seq : iterable

The sequence on which DFT is to be applied.

prime : Integer

Prime modulus of the form \((m^{2^k} + 1)\) to be used for performing NTT on the sequence.
Examples

```python
>>> from sympy import ntt, intt
>>> ntt([1, 2, 3, 4], prime=3*2**8 + 1)
[10, 643, 767, 122]
>>> intt(_, 3*2**8 + 1)
[1, 2, 3, 4]
>>> intt([1, 2, 3, 4], prime=3*2**8 + 1)
[387, 415, 384, 353]
>>> ntt(_, prime=3*2**8 + 1)
[1, 2, 3, 4]
```

Fast Walsh Hadamard Transform

`sympy.discrete.transforms.fwht(seq)`

Performs the Walsh Hadamard Transform (WHT), and uses Hadamard ordering for the sequence.

The sequence is automatically padded to the right with zeros, as the radix-2 FWHT requires the number of sample points to be a power of 2.

Parameters

- `seq`: iterable

  The sequence on which WHT is to be applied.

Examples

```python
>>> from sympy import fwh, ifwht
>>> fwh([4, 2, 2, 0, 0, 2, -2, 0])
[8, 0, 8, 0, 8, 0, 0, 0]
>>> ifwht(_)
[4, 2, 2, 0, 0, 2, -2, 0]

>>> ifwht([19, -1, 11, -9, -7, 13, -15, 5])
[2, 0, 4, 0, 3, 10, 0, 0]
>>> fwh(_)
[19, -1, 11, -9, -7, 13, -15, 5]
```
SymPy Documentation, Release 1.12.1

References

[R179], [R180]

sympy.discrete.transforms.ifwht(seq)
PerformstheWalshHadamardTransform(WHT), and uses Hadamard ordering for the sequence.
The sequence is automatically padded to the right with zeros, as the radix-2 FWHT requires the number of sample points to be a power of 2.

Parameters

seq : iterable
The sequence on which WHT is to be applied.

Examples

```python
>>> from sympy import fwhit, ifwht
>>> fwhit([4, 2, 2, 0, 2, -2, 0])
[8, 0, 8, 0, 8, 8, 0, 0]
>>> ifwht(_)
[4, 2, 2, 0, 0, 2, -2, 0]
```

```python
>>> ifwht([19, -1, 11, -9, -7, 13, -15, 5])
[2, 0, 4, 0, 3, 10, 0, 0]
>>> fwhit(_)
[19, -1, 11, -9, -7, 13, -15, 5]
```

Möbius Transform

sympy.discrete.transforms.mobius_transform(seq, subset=True)
PerformstheMobiusTransformforsubsetlatticewithindicesofsequenceasbitmasks.
The indices of each argument, considered as bit strings, correspond to subsets of a finite set.
The sequence is automatically padded to the right with zeros, as the definition of subset/superset based on bitmasks (indices) requires the size of sequence to be a power of 2.

Parameters

seq : iterable
The sequence on which Mobius Transform is to be applied.

subset : bool
Specifies if Mobius Transform is applied by enumerating subsets or supersets of the given set.
Examples

```python
>>> from sympy import symbols
>>> from sympy import mobius_transform, inverse_mobius_transform
>>> x, y, z = symbols('x y z')

>>> mobius_transform([x, y, z])
[x, x + y, x + z, x + y + z]

>>> inverse_mobius_transform(_)
[x, y, z, 0]

>>> mobius_transform([x, y, z], subset=False)
[x + y + z, y, z, 0]

>>> inverse_mobius_transform(_, subset=False)
[x, y, z, 0]

>>> mobius_transform([1, 2, 3, 4])
[1, 3, 4, 10]

>>> inverse_mobius_transform(_)
[1, 2, 3, 4]

>>> mobius_transform([1, 2, 3, 4], subset=False)
[10, 6, 7, 4]

>>> inverse_mobius_transform(_, subset=False)
[1, 2, 3, 4]
```

References

[R183], [R184], [R185]

`sympy.discrete.transforms.inverse_mobius_transform(seq, subset=True)`

Performs the Mobius Transform for subset lattice with indices of sequence as bitmasks. The indices of each argument, considered as bit strings, correspond to subsets of a finite set. The sequence is automatically padded to the right with zeros, as the definition of subset/superset based on bitmasks (indices) requires the size of sequence to be a power of 2.

**Parameters**

- **seq**: iterable
  The sequence on which Mobius Transform is to be applied.

- **subset**: bool
  Specifies if Mobius Transform is applied by enumerating subsets or superset of the given set.
Examples

```python
>>> from sympy import symbols
>>> from sympy import mobius_transform, inverse_mobius_transform
>>> x, y, z = symbols('x y z')

>>> mobius_transform([x, y, z])
[x, x + y, x + z, x + y + z]
>>> inverse_mobius_transform(_)
[x, y, z, 0]

>>> mobius_transform([x, y, z], subset=False)
[x + y + z, y, z, 0]
>>> inverse_mobius_transform(_, subset=False)
[x, y, z, 0]

>>> mobius_transform([1, 2, 3, 4])
[1, 3, 4, 10]
>>> inverse_mobius_transform(_)
[1, 2, 3, 4]
>>> mobius_transform([1, 2, 3, 4], subset=False)
[10, 6, 7, 4]
>>> inverse_mobius_transform(_, subset=False)
[1, 2, 3, 4]
```

Convolutions

This section lists the methods which implement the basic convolutions for discrete sequences.

Convolution

This is a general method for calculating the convolution of discrete sequences, which internally calls one of the methods convolution_fft, convolution_ntt, convolution_fwht, or convolution_subset.

```python
sympy.discrete.convolutions.convolutions.convolution(a, b, cycle=0, dps=None, prime=None, dyadic=None, subset=None)
```

Performs convolution by determining the type of desired convolution using hints.

Exactly one of dps, prime, dyadic, subset arguments should be specified explicitly for identifying the type of convolution, and the argument cycle can be specified optionally.

For the default arguments, linear convolution is performed using FFT.

Parameters
- `a, b`: iterables
The sequences for which convolution is performed.

**cycle** : Integer
Specifies the length for doing cyclic convolution.

**dps** : Integer
Specifies the number of decimal digits for precision for performing FFT on the sequence.

**prime** : Integer
Prime modulus of the form \((m^{2^k} + 1)\) to be used for performing NTT on the sequence.

**dyadic** : bool
Identifies the convolution type as dyadic (bitwise-XOR) convolution, which is performed using FWHIT.

**subset** : bool
Identifies the convolution type as subset convolution.

**Examples**

```python
>>> from sympy import convolution, symbols, S, I
>>> u, v, w, x, y, z = symbols('u v w x y z')

>>> convolution([1 + 2*I, 4 + 3*I], [S(5)/4, 6], dps=3)
[1.25 + 2.5*I, 11.0 + 15.8*I, 24.0 + 18.0*I]

>>> convolution([1, 2, 3], [4, 5, 6], cycle=3)
[31, 31, 28]

>>> convolution([111, 777], [888, 444], prime=19*2**10 + 1)
[1283, 19351, 14219]

>>> convolution([111, 777], [888, 444], prime=19*2**10 + 1, cycle=2)
[15502, 19351]

>>> convolution([u, v], [x, y, z], dyadic=True)
[u*x + v*y, u*y + v*x, u*z, v*z]

>>> convolution([u, v], [x, y, z], dyadic=True, cycle=2)
[u*x + u*z + v*y, u*y + v*x + v*z]

>>> convolution([u, v, w], [x, y, z], subset=True)
[u*x, u*y + v*x, u*z + w*x, v*z + w*y]

>>> convolution([u, v, w], [x, y, z], subset=True, cycle=3)
[u*x + v*z + w*y, u*y + v*x, u*z + w*x]
```
Convolution using Fast Fourier Transform

\texttt{sympy.discrete.convolutions.convolution\_fft(a, b, dps=None)}

Performs linear convolution using Fast Fourier Transform.

\textbf{Parameters}
\begin{itemize}
  \item \texttt{a, b} : iterables
    The sequences for which convolution is performed.
  \item \texttt{dps} : Integer
    Specifies the number of decimal digits for precision.
\end{itemize}

\textbf{Examples}

\begin{verbatim}
>>> from sympy import S, I
>>> from sympy.discrete.convolutions import convolution_fft

>>> convolution_fft([2, 3], [4, 5])
[8, 22, 15]
>>> convolution_fft([2, 5], [6, 7, 3])
[12, 44, 41, 15]
>>> convolution_fft([1 + 2*I, 4 + 3*I], [S(5)/4, 6])
[5/4 + 5*I/2, 11 + 63*I/4, 24 + 18*I]
\end{verbatim}

Convolution using Number Theoretic Transform

\texttt{sympy.discrete.convolutions.convolution\_ntt(a, b, prime)}

Performs linear convolution using Number Theoretic Transform.

\textbf{Parameters}
\begin{itemize}
  \item \texttt{a, b} : iterables
    The sequences for which convolution is performed.
  \item \texttt{prime} : Integer
    Prime modulus of the form \((m^{2^k} + 1)\) to be used for performing NTT
    on the sequence.
\end{itemize}
Examples

```python
>>> from sympy.discrete.convolutions import convolution_ntt
>>> convolution_ntt([2, 3], [4, 5], prime=19*2**10 + 1)
[8, 22, 15]
>>> convolution_ntt([2, 5], [6, 7, 3], prime=19*2**10 + 1)
[12, 44, 41, 15]
>>> convolution_ntt([333, 555], [222, 666], prime=19*2**10 + 1)
[15555, 14219, 19404]
```

Convolution using Fast Walsh Hadamard Transform

```python
sympy.discrete.convolutions.convolution_fwht(a, b)
```

Performs dyadic (bitwise-XOR) convolution using Fast Walsh Hadamard Transform.

The convolution is automatically padded to the right with zeros, as the radix-2 FWHT requires the number of sample points to be a power of 2.

**Parameters**

- `a, b` : iterables

  The sequences for which convolution is performed.

Examples

```python
>>> from sympy import symbols, S, I
>>> from sympy.discrete.convolutions import convolution_fwht
```

```python
>>> u, v, x, y = symbols('u v x y')
>>> convolution_fwht([u, v], [x, y])
[u*x + v*y, u*y + v*x]
```

```python
>>> convolution_fwht([2, 3], [4, 5])
[23, 22]
>>> convolution_fwht([2, 5 + 4*I, 7], [6*I, 7, 3 + 4*I])
[56 + 68*I, -10 + 30*I, 6 + 50*I, 48 + 32*I]
```

```python
>>> convolution_fwht([S(33)/7, S(55)/6, S(7)/4], [S(2)/3, 5])
[2057/42, 1870/63, 7/6, 35/4]
```
Subset Convolution

```
sympy.discrete.convolutions.convolution_subset(a, b)
```

Performs Subset Convolution of given sequences.

The indices of each argument, considered as bit strings, correspond to subsets of a finite set.

The sequence is automatically padded to the right with zeros, as the definition of subset based on bitmasks (indices) requires the size of sequence to be a power of 2.

**Parameters**

- `a, b`: iterables
  
  The sequences for which convolution is performed.

**Examples**

```
>>> from sympy import symbols, S
>>> from sympy.discrete.convolutions import convolution_subset
>>> u, v, x, y, z = symbols('u v x y z')

>>> convolution_subset([u, v], [x, y])
[u*x, u*y + v*x]

>>> convolution_subset([u, v, x], [y, z])
[u*y, u*z + v*y, x*y, x*z]

>>> convolution_subset([1, S(2)/3], [3, 4])
[3, 6]

>>> convolution_subset([1, 3, S(5)/7], [7])
[7, 21, 5, 0]
```

**References**

[R193], [R194]

Covering Product

```
sympy.discrete.convolutions.covering_product(a, b)
```

Returns the covering product of given sequences.

The indices of each argument, considered as bit strings, correspond to subsets of a finite set.

The covering product of given sequences is a sequence which contains the sum of products of the elements of the given sequences grouped by the bitwise-OR of the corresponding indices.
The sequence is automatically padded to the right with zeros, as the definition of subset based on bitmasks (indices) requires the size of sequence to be a power of 2.

**Parameters**

\[a, b\] : iterables

The sequences for which covering product is to be obtained.

**Examples**

```python
>>> from sympy import symbols, S, I, covering_product
>>> u, v, x, y, z = symbols('u v x y z')

>>> covering_product([u, v], [x, y])
[u*x, u*y + v*x + v*y]

>>> covering_product([u, v, x], [y, z])
[u*y, u*z + v*y + v*z, x*y, x*z]

>>> covering_product([1, S(2)/3], [3, 4 + 5*I])
[3, 26/3 + 25*I/3]

>>> covering_product([1, 3, S(5)/7], [7, 8])
[7, 53, 5, 40/7]
```

**References**

[R196]

### Intersecting Product

sympy.discrete.convolutions\.__intersecting_product\(a, b\)

Returns the intersecting product of given sequences.

The indices of each argument, considered as bit strings, correspond to subsets of a finite set.

The intersecting product of given sequences is the sequence which contains the sum of products of the elements of the given sequences grouped by the bitwise-AND of the corresponding indices.

The sequence is automatically padded to the right with zeros, as the definition of subset based on bitmasks (indices) requires the size of sequence to be a power of 2.

**Parameters**

\[a, b\] : iterables

The sequences for which intersecting product is to be obtained.
Examples

```python
>>> from sympy import symbols, S, I, intersecting_product
>>> u, v, x, y, z = symbols('u v x y z')

>>> intersecting_product([u, v], [x, y])
[u*x + u*y + v*x, v*y]

>>> intersecting_product([u, v, x], [y, z])
[u*y + u*z + v*y + x*y + x*z, v*z, 0, 0]

>>> intersecting_product([1, S(2)/3], [3, 4 + 5*I])
[9 + 5*I, 8/3 + 10*I/3]

>>> intersecting_product([1, 3, S(5)/7], [7, 8])
[327/7, 24, 0, 0]
```

[R197]

Numerical Evaluation

Basics

Exact SymPy expressions can be converted to floating-point approximations (decimal numbers) using either the .evalf() method or the N() function. N(expr, <args>) is equivalent to sympify(expr).evalf(<args>).

```python
>>> from sympy import *

>>> N(sqrt(2)*pi)
4.44288293815837

>>> (sqrt(2)*pi).evalf()
4.44288293815837
```

By default, numerical evaluation is performed to an accuracy of 15 decimal digits. You can optionally pass a desired accuracy (which should be a positive integer) as an argument to evalf or N:

```python
>>> N(sqrt(2)*pi, 5)
4.4429

>>> N(sqrt(2)*pi, 50)
4.4428829385185576441794882829564277581138933281738
```

Complex numbers are supported:

```python
>>> N(1/(pi + I), 20)
0.289025482222362421 - 0.09199668350375232456*I
```

If the expression contains symbols or for some other reason cannot be evaluated numerically, calling .evalf() or N() returns the original expression, or in some cases a partially evaluated expression. For example, when the expression is a polynomial in expanded form, the coefficients are evaluated:
You can also use the standard Python functions \texttt{float()}, \texttt{complex()} to convert SymPy expressions to regular Python numbers:

\begin{verbatim}
>>> float(pi)
3.1415926535...

>>> complex(pi+E*I)
(3.1415926535...+2.7182818284...j)
\end{verbatim}

If these functions are used, failure to evaluate the expression to an explicit number (for example if the expression contains symbols) will raise an exception.

There is essentially no upper precision limit. The following command, for example, computes the first 100,000 digits of $\pi/e$:

\begin{verbatim}
>>> N(pi/E, 10**6)
...
\end{verbatim}

This shows digits 999,951 through 1,000,000 of $\pi$:

\begin{verbatim}
>>> str(N(pi, 10**6))[-50:]
'95678796130331164628399634646042209010610577945815'
\end{verbatim}

High-precision calculations can be slow. It is recommended (but entirely optional) to install gmpy (https://github.com/aleaxit/gmpy), which will significantly speed up computations such as the one above.

**Floating-point numbers**

Floating-point numbers in SymPy are instances of the class \texttt{Float}. A \texttt{Float} can be created with a custom precision as second argument:

\begin{verbatim}
>>> Float(0.1)
0.100000000000000

>>> Float(0.1, 10)
0.1000000000

>>> Float(0.125, 30)
0.12500000000000000000000000000000000000

>>> Float(0.1, 30)
0.100000000000000005551115123126
\end{verbatim}

As the last example shows, some Python floats are only accurate to about 15 digits as inputs, while others (those that have a denominator that is a power of 2, like $0.125 = 1/8$) are exact. To create a \texttt{Float} from a high-precision decimal number, it is better to pass a string, \texttt{Rational}, or \texttt{evalf} a \texttt{Rational}:

\begin{verbatim}
>>> Float('0.1', 30)
0.10000000000000000000000000000000000000

>>> Float(Rational(1, 10), 30)
0.10000000000000000000000000000000000000
\end{verbatim}
Rational(1, 10).evalf(30)
0.100000000000000000000000000000

The precision of a number determines 1) the precision to use when performing arithmetic with the number, and 2) the number of digits to display when printing the number. When two numbers with different precision are used together in an arithmetic operation, the higher of the precisions is used for the result. The product of 0.1 +/- 0.001 and 3.1415 +/- 0.0001 has an uncertainty of about 0.003 and yet 5 digits of precision are shown.

Float(0.1, 3)*Float(3.1415, 5)
0.31417

So the displayed precision should not be used as a model of error propagation or significance arithmetic; rather, this scheme is employed to ensure stability of numerical algorithms.

N and evalf can be used to change the precision of existing floating-point numbers:

Accuracy and error handling

When the input to N or evalf is a complicated expression, numerical error propagation becomes a concern. As an example, consider the 100'th Fibonacci number and the excellent (but not exact) approximation \( \phi^{100}/\sqrt{5} \) where \( \phi \) is the golden ratio. With ordinary floating-point arithmetic, subtracting these numbers from each other erroneously results in a complete cancellation:

a, b = GoldenRatio**100/sqrt(5), fibonacci(1000)
float(a)
4.3465576869e+208
float(b)
4.3465576869e+208
float(a) - float(b)
0.0

N and evalf keep track of errors and automatically increase the precision used internally in order to obtain a correct result:

N(fibonacci(100) - GoldenRatio**100/sqrt(5))
-5.64613129282185e-22

Unfortunately, numerical evaluation cannot tell an expression that is exactly zero apart from one that is merely very small. The working precision is therefore capped, by default to around 100 digits. If we try with the 1000'th Fibonacci number, the following happens:

N(fibonacci(1000) - (GoldenRatio)**1000/sqrt(5))
0.e+85
The lack of digits in the returned number indicates that \( N \) failed to achieve full accuracy. The result indicates that the magnitude of the expression is something less than \( 10^{84} \), but that is not a particularly good answer. To force a higher working precision, the \( \text{maxn} \) keyword argument can be used:

```
>>> N(fibonacci(1000) - (GoldenRatio)**1000/sqrt(5), maxn=500)
-4.60123853010113e-210
```

Normally, \( \text{maxn} \) can be set very high (thousands of digits), but be aware that this may cause significant slowdown in extreme cases. Alternatively, the \( \text{strict=True} \) option can be set to force an exception instead of silently returning a value with less than the requested accuracy:

```
>>> N(fibonacci(1000) - (GoldenRatio)**1000/sqrt(5), strict=True)
Traceback (most recent call last):
  ...
PrecisionExhausted: Failed to distinguish the expression:
-\sqrt{5}*GoldenRatio**1000/5 + ...
  -434665576869374564356885276758025646605173717804024817290895365541794905189040387...

from zero. Try simplifying the input, using \( \text{chop=True} \), or providing a higher \( \text{maxn} \) for \( \text{evalf} \)
```

If we add a term so that the Fibonacci approximation becomes exact (the full form of Binet’s formula), we get an expression that is exactly zero, but \( N \) does not know this:

```
>>> f = fibonacci(100) - (GoldenRatio**100 - (GoldenRatio - 1)**100)/sqrt(5)
>>> N(f)
0.e-104
>>> N(f, maxn=1000)
0.e-1336
```

In situations where such cancellations are known to occur, the \( \text{chop} \) options is useful. This basically replaces very small numbers in the real or imaginary portions of a number with exact zeros:

```
>>> N(f, chop=True)
0
```

```
>>> N(3 + I*f, chop=True)
3.00000000000000
```

In situations where you wish to remove meaningless digits, re-evaluation or the use of the \( \text{round} \) method are useful:

```
>>> Float('1.', '')*Float('1.2345', '')
0.012297
>>> ans = _
>>> N(ans, 1)
0.01
>>> ans.round(2)
0.01
```

If you are dealing with a numeric expression that contains no floats, it can be evaluated to arbitrary precision. To round the result relative to a given decimal, the \( \text{round} \) method is useful:
Sums and integrals

Sums (in particular, infinite series) and integrals can be used like regular closed-form expressions, and support arbitrary-precision evaluation:

```python
>>> var('n x')
(n, x)
>>> Sum(1/n**n, (n, 1, oo)).evalf()
1.29128599706266
>>> Integral(x**(-x), (x, 0, 1)).evalf()
1.29128599706266
>>> Sum(1/n**n, (n, 1, oo)).evalf(50)
1.291285997062663540407839297800340614319785661292
>>> Integral(x**(-x), (x, 0, 1)).evalf(50)
1.291285997062663540407839297800340614319785661292
>>> (Integral(exp(-x**2), (x, -oo, oo)) ** 2).evalf(30)
3.14159265358979323846264338328
```

By default, the tanh-sinh quadrature algorithm is used to evaluate integrals. This algorithm is very efficient and robust for smooth integrands (and even integrals with endpoint singularities), but may struggle with integrals that are highly oscillatory or have mid-interval discontinuities. In many cases, `evalf/N` will correctly estimate the error. With the following integral, the result is accurate but only good to four digits:

```python
>>> f = abs(sin(x))
>>> Integral(abs(sin(x)), (x, 0, 4)).evalf()
2.346
```

It is better to split this integral into two pieces:

```python
>>> (Integral(f, (x, 0, pi)) + Integral(f, (x, pi, 4))).evalf()
2.34635637913639
```

A similar example is the following oscillatory integral:

```python
>>> Integral(sin(x)/x**2, (x, 1, oo)).evalf(maxn=20)
0.5
```

It can be dealt with much more efficiently by telling `evalf` or `N` to use an oscillatory quadrature algorithm:

```python
>>> Integral(sin(x)/x**2, (x, 1, oo)).evalf(quad='osc')
0.504067061906928
>>> Integral(sin(x)/x**2, (x, 1, oo)).evalf(20, quad='osc')
0.50406706190692837199
```

5.8. Topics
Oscillatory quadrature requires an integrand containing a factor $\cos(ax+b)$ or $\sin(ax+b)$. Note that many other oscillatory integrals can be transformed to this form with a change of variables:

```python
>>> init_printing(use_unicode=False, wrap_line=False)
>>> intgrl = Integral(sin(1/x), (x, 0, 1)).transform(x, 1/x)
>>> intgrl
oo
/ | sin(x)  ------- dx
| 2
/  x
1
>>> N(intgrl, quad='osc')
0.504067061906928
```

Infinite series use direct summation if the series converges quickly enough. Otherwise, extrapolation methods (generally the Euler-Maclaurin formula but also Richardson extrapolation) are used to speed up convergence. This allows high-precision evaluation of slowly convergent series:

```python
>>> var('k')
k
>>> Sum(1/k**2, (k, 1, oo)).evalf()  
1.64493406684823
>>> zeta(2).evalf()  
1.64493406684823
>>> Sum(1/k-log(1+1/k), (k, 1, oo)).evalf()  
0.577215664901533
>>> Sum(1/k-log(1+1/k), (k, 1, oo)).evalf(50)
0.5772156649015328606651209008240243104215933593992
>>> EulerGamma.evalf(50)
0.5772156649015328606651209008240243104215933593992
```

The Euler-Maclaurin formula is also used for finite series, allowing them to be approximated quickly without evaluating all terms:

```python
>>> Sum(1/k, (k, 1000000, 2000000)).evalf()  
0.693147255559946
```

Note that `evalf` makes some assumptions that are not always optimal. For fine-tuned control over numerical summation, it might be worthwhile to manually use the method `Sum.euler_maclaurin`.

Special optimizations are used for rational hypergeometric series (where the term is a product of polynomials, powers, factorials, binomial coefficients and the like). `N/evalf` sum series of this type very rapidly to high precision. For example, this Ramanujan formula for pi can be summed to 10,000 digits in a fraction of a second with a simple command:

```python
>>> f = factorial
>>> n = Symbol('n', integer=True)
```
Numerical simplification

The function `nsimplify` attempts to find a formula that is numerically equal to the given input. This feature can be used to guess an exact formula for an approximate floating-point input, or to guess a simpler formula for a complicated symbolic input. The algorithm used by `nsimplify` is capable of identifying simple fractions, simple algebraic expressions, linear combinations of given constants, and certain elementary functional transformations of any of the preceding.

Optionally, `nsimplify` can be passed a list of constants to include (e.g. `pi`) and a minimum numerical tolerance. Here are some elementary examples:

>>> nsimplify(0.1)
1/10

>>> nsimplify(6.28, [pi], tolerance=0.01)
2*pi

>>> nsimplify(pi, tolerance=0.01)
22/7

>>> nsimplify(pi, tolerance=0.001)
355

---

113

>>> nsimplify(0.33333, tolerance=1e-4)
1/3

>>> nsimplify(2.0**(1/3.), tolerance=0.001)
635

---

504

>>> nsimplify(2.0**(1/3.), tolerance=0.001, full=True)
3

\sqrt{2}

Here are several more advanced examples:

>>> nsimplify(Float('0.130198866629986772369127970337', 30), [pi, E])
1

-------
5*pi

---- + 2*e
7

>>> nsimplify(cos(atan('1/3')))

(continues on next page)
3*\ / 10
---
10

```python
>>> nsimplify(4/(1+sqrt(5)), [GoldenRatio])
-2 + 2*GoldenRatio
```

```python
>>> nsimplify(2 + exp(2*atan('1/4')*I))
49 8*I
-- + ---
17 17
```

```python
>>> nsimplify((1/(exp(3*pi*I/5)+1))
```

```
1  / \ 5 1
--- I* / ------ + -
2  \ / 10 4
```

```python
>>> nsimplify(I**I, [pi])
-pi
----
2
e
```

```python
>>> n = Symbol('n')
```

```python
>>> nsimplify(Sum(1/n**2, (n, 1, oo)), [pi])
2
pi
---
6
```

```python
>>> nsimplify(gamma('1/4')*gamma('3/4'), [pi])
\sqrt{2}*pi
```

### Numeric Computation

Symbolic computer algebra systems like SymPy facilitate the construction and manipulation of mathematical expressions. Unfortunately when it comes time to evaluate these expressions on numerical data, symbolic systems often have poor performance.

Fortunately SymPy offers a number of easy-to-use hooks into other numeric systems, allowing you to create mathematical expressions in SymPy and then ship them off to the numeric system of your choice. This page documents many of the options available including the math library, the popular array computing package numpy, code generation in Fortran or C, and the use of the array compiler Aesara.
Subs/evalf

Subs is the slowest but simplest option. It runs at SymPy speeds. The \( \text{.subs(...).evalf()} \) method can substitute a numeric value for a symbolic one and then evaluate the result within SymPy.

```python
>>> from sympy import *
>>> from sympy.abc import x
>>> expr = sin(x)/x
>>> expr.evalf(subs={x: 3.14})
0.000507214304613640
```

This method is slow. You should use this method production only if performance is not an issue. You can expect \( \text{.subs} \) to take tens of microseconds. It can be useful while prototyping or if you just want to see a value once.

Lambdify

The \( \text{lambdify} \) function translates SymPy expressions into Python functions, leveraging a variety of numerical libraries. It is used as follows:

```python
>>> from sympy import *
>>> from sympy.abc import x
>>> expr = sin(x)/x
>>> f = lambdify(x, expr)
>>> f(3.14)
0.000507214304614
```

Here lambdify makes a function that computes \( f(x) = \sin(x)/x \). By default lambdify relies on implementations in the \text{math} standard library. This numerical evaluation takes on the order of hundreds of nanoseconds, roughly two orders of magnitude faster than the \( \text{.subs} \) method. This is the speed difference between SymPy and raw Python.

Lambdify can leverage a variety of numerical backends. By default it uses the \text{math} library. However it also supports mpmath and most notably, \text{numpy}. Using the \text{numpy} library gives the generated function access to powerful vectorized ufuncs that are backed by compiled C code.

```python
>>> from sympy import *
>>> from sympy.abc import x
>>> expr = sin(x)/x
>>> f = lambdify(x, expr, "numpy")

>>> import numpy
>>> data = numpy.linspace(1, 10, 10000)
>>> f(data)
[ 0.84147098  0.84119981  0.84092844 ... -0.05426074 -0.05433146 -0.05440211]
```

If you have array-based data this can confer a considerable speedup, on the order of 10 nanoseconds per element. Unfortunately \text{numpy} incurs some start-up time and introduces an overhead of a few microseconds.

CuPy is a NumPy-compatible array library that mainly runs on CUDA, but has increasing support for other GPU manufacturers. It can in many cases be used as a drop-in replacement.
for numpy.

```python
>>> f = lambdify(x, expr, "cupy")
>>> import cupy as cp
>>> data = cp.linspace(1, 10, 10000)
>>> y = f(data) # perform the computation
>>> cp.asnumpy(y) # explicitly copy from GPU to CPU / numpy array
[ 0.84147098 0.84119981 0.84092844 ... -0.05426074 -0.05433146
 -0.05440211]
```

JAX is a similar alternative to CuPy that provides GPU and TPU acceleration via just-in-time compilation to XLA. It too, can in some cases, be used as a drop-in replacement for numpy.

```python
>>> f = lambdify(x, expr, "jax")
>>> import jax.numpy as jnp
>>> data = jnp.linspace(1, 10, 10000)
>>> y = f(data) # perform the computation
>>> numpy.asarray(y) # explicitly copy to CPU / numpy array
array([ 0.84147096, 0.8411998 , 0.84092844, ..., -0.05426079,
       -0.05433151, -0.05440211], dtype=float32)
```

### uFuncify

The autowrap module contains methods that help in efficient computation.

- **autowrap** (page 1159) method for compiling code generated by the `codegen` (page 1153) module, and wrap the binary for use in python.
- **binary_function** (page 1160) method automates the steps needed to autowrap the SymPy expression and attaching it to a Function object with `implemented_function()`.
- **ufuncify** (page 1160) generates a binary function that supports broadcasting on numpy arrays using different backends that are faster as compared to `subs/evalf` and `lambdify`.

The API reference of all the above is listed here: `sympy.utilities.autowrap()` (page 2110).

### Aesara

SymPy has a strong connection with Aesara, a mathematical array compiler. SymPy expressions can be easily translated to Aesara graphs and then compiled using the Aesara compiler chain.

```python
>>> from sympy import *
>>> from sympy.abc import x
>>> expr = sin(x)/x

>>> from sympy.printing.aesaracode import aesara_function
>>> f = aesara_function([x], [expr])
```

If array broadcasting or types are desired then Aesara requires this extra information
Aesara has a more sophisticated code generation system than SymPy’s C/Fortran code printers. Among other things it handles common sub-expressions and compilation onto the GPU. Aesara also supports SymPy Matrix and Matrix Expression objects.

**So Which Should I Use?**

The options here were listed in order from slowest and least dependencies to fastest and most dependencies. For example, if you have Aesara installed then that will often be the best choice. If you don’t have Aesara but do have f2py then you should use ufuncify. If you have been comfortable using lambdify with the numpymodule, but have a GPU, CuPy and JAX can provide substantial speedups with little effort.

**Term Rewriting**

Term rewriting is a very general class of functionalities which are used to convert expressions of one type in terms of expressions of different kind. For example expanding, combining and converting expressions apply to term rewriting, and also simplification routines can be included here. Currently SymPy has several functions and basic built-in methods for performing various types of rewriting.

**Expanding**

The simplest rewrite rule is expanding expressions into a _sparse_ form. Expanding has several flavors and include expanding complex valued expressions, arithmetic expand of products and powers but also expanding functions in terms of more general functions is possible. Below are listed all currently available expand rules.

**Expanding of arithmetic expressions involving products and powers:**

```
>>> from sympy import *
>>> x, y, z = symbols('x,y,z')
>>> ((x + y)*(x - y)).expand(basic=True)

x**2 - y**2

>>> ((x + y + z)**2).expand(basic=True)

x**2 + 2*x*y + 2*x*z + y**2 + 2*y*z + z**2
```
Arithmetic expand is done by default in expand() so the keyword basic can be omitted. However you can set basic=False to avoid this type of expand if you use rules described below. This give complete control on what is done with the expression.

Another type of expand rule is expanding complex valued expressions and putting them into a normal form. For this complex keyword is used. Note that it will always perform arithmetic expand to obtain the desired normal form:

```python
>>> (x + I*y).expand(complex=True)
re(x) + I*re(y) + I*im(x) - im(y)
```

```python
>>> sin(x + I*y).expand(complex=True)
sin(re(x) - im(y))*cosh(re(y) + im(x)) + I*cos(re(x) - im(y))*sinh(re(y) + im(x))
```

Note also that the same behavior can be obtained by using as_real_imag() method. However it will return a tuple containing the real part in the first place and the imaginary part in the other. This can be also done in a two step process by using collect function:

```python
>>> (x + I*y).as_real_imag()
(re(x) - im(y), re(y) + im(x))
```

```python
>>> collect((x + I*y).expand(complex=True), I, evaluate=False)
{1: re(x) - im(y), I: re(y) + im(x)}
```

There is also possibility for expanding expressions in terms of expressions of different kind. This is very general type of expanding and usually you would use rewrite() to do specific type of rewrite:

```python
>>> GoldenRatio.expand(func=True)
1/2 + sqrt(5)/2
```

**Common Subexpression Detection and Collection**

Before evaluating a large expression, it is often useful to identify common subexpressions, collect them and evaluate them at once. This is implemented in the cse function. Examples:

```python
>>> from sympy import cse, sqrt, sin, pprint
>>> from sympy.abc import x

>>> pprint(cse(sqrt(sin(x))), use_unicode=True)
( [ ], [ \sqrt{\sin(x)} ] )

>>> pprint(cse(sqrt(sin(x)+5)*sqrt(sin(x)+4)), use_unicode=True)
( [ [ x_0, \sin(x) ] ], [ \sqrt{x_0 + 4} \cdot \sqrt{x_0 + 5} ] )

>>> pprint(cse(sqrt(sin(x+1) + 5 + cos(y))*sqrt(sin(x+1) + 4 + cos(y))), use_unicode=True)
( [ [ x_0, \sin(x + 1) + \cos(y) ] ], [ \sqrt{x_0 + 4} \cdot \sqrt{x_0 + 5} ] )
```

(continues on next page)
>>> pprint(cse((x-y)*(z-y) + sqrt((x-y)*(z-y))), use_unicode=True)

\[
\left\{
\begin{array}{l}
\left(x_0, (x - y) \cdot (-y + z)\right), \\
\left(\sqrt{x_0^2 + x_0}\right)
\end{array}
\right.
\]

Optimizations to be performed before and after common subexpressions elimination can be passed in the optimizations optional argument. A set of predefined basic optimizations can be applied by passing optimizations='basic':

>>> pprint(cse((x-y)*(z-y) + sqrt((x-y)*(z-y)), optimizations='basic'),
          use_unicode=True)

\[
\left\{
\begin{array}{l}
\left(x_0, -(x - y) \cdot (y - z)\right), \\
\left(\sqrt{x_0^2 + x_0}\right)
\end{array}
\right.
\]

However, these optimizations can be very slow for large expressions. Moreover, if speed is a concern, one can pass the option order='none'. Order of terms will then be dependent on hashing algorithm implementation, but speed will be greatly improved.

More information:

sympy.simplify.cse_main.cse(exprs, symbols=None, optimizations=None,
                           postprocess=None, order='canonical', ignore=(),
                           list=True)

Perform common subexpression elimination on an expression.

Parameters

texprs : list of SymPy expressions, or a single SymPy expression

The expressions to reduce.

symbols : infinite iterator yielding unique Symbols

The symbols used to label the common subexpressions which are pulled out. The numbered_symbols generator is useful. The default is a stream of symbols of the form “x0”, “x1”, etc. This must be an infinite iterator.

optimizations : list of (callable, callable) pairs

The (preprocessor, postprocessor) pairs of external optimization functions. Optionally ‘basic’ can be passed for a set of predefined basic optimizations. Such ‘basic’ optimizations were used by default in old implementation, however they can be really slow on larger expressions. Now, no pre or post optimizations are made by default.

postprocess : a function which accepts the two return values of cse and returns the desired form of output from cse, e.g. if you want the replacements reversed the function might be the following lambda: lambda r, e: return reversed(r), e

order : string, ‘none’ or ‘canonical’

The order by which Mul and Add arguments are processed. If set to ‘canonical’, arguments will be canonically ordered. If set to ‘none’, ordering will be faster but dependent on expressions hashes, thus machine dependent and variable. For large expressions where speed is a concern, use the setting order=‘none’.

5.8. Topics
ignore : iterable of Symbols

Substitutions containing any Symbol from ignore will be ignored.

list : bool, (default True)

Returns expression in list or else with same type as input (when False).

Returns

replacements : list of (Symbol, expression) pairs

All of the common subexpressions that were replaced. Subexpressions earlier in this list might show up in subexpressions later in this list.

reduced_exprs : list of SymPy expressions

The reduced expressions with all of the replacements above.

Examples

```python
>>> from sympy import cse, SparseMatrix
>>> from sympy.abc import x, y, z, w
>>> cse(((w + x + y + z)*(w + y + z))/(w + x)**3)
([(x0, y + z), (x1, w + x)], [(w + x0)*(x0 + x1)/x1**3])
```

List of expressions with recursive substitutions:

```python
>>> m = SparseMatrix([[x + y, x + y + z]])
>>> cse([(x+y)**2, x + y + z, y + z, x + z + y, m])
([(x0, x + y), (x1, x0 + z)], [x0**2, x1, y + z, x1, Matrix([x0], [x1])])
```

Note: the type and mutability of input matrices is retained.

```python
>>> isinstance(_[1][-1], SparseMatrix)
True
```

The user may disallow substitutions containing certain symbols:

```python
>>> cse([y**2*(x + 1), 3*y**2*(x + 1)], ignore=(y,))
([(x0, x + 1)], [x0*y**2, 3*x0*y**2])
```

The default return value for the reduced expression(s) is a list, even if there is only one expression. The list flag preserves the type of the input in the output:

```python
>>> cse(x)
([], [x])
>>> cse(x, list=False)
([], x)
```
5.8.2 Code Generation

Contents

Code Generation

Several submodules in SymPy allow one to generate directly compilable and executable code in a variety of different programming languages from SymPy expressions. In addition, there are functions that generate Python importable objects that can evaluate SymPy expressions very efficiently.

We will start with a brief introduction to the components that make up the code generation capabilities of SymPy.

Introduction

There are four main levels of abstractions:

```
expression
  | code printers
  | code generators
  | autowrap
```

`sympy.utilities.autowrap` (page 2110) uses codegen, and codegen uses the code printers. `sympy.utilities.autowrap` (page 2110) does everything: it lets you go from SymPy expression to numerical function in the same Python process in one step. Codegen is actual code generation, i.e., to compile and use later, or to include in some larger project.

The code printers translate the SymPy objects into actual code, like `abs(x) -> fabs(x)` (for C).

The code printers don’t print optimal code in many cases. An example of this is powers in C. `x**2` prints as `pow(x, 2)` instead of `x*x`. Other optimizations (like mathematical simplifications) should happen before the code printers.

Currently, `sympy.simplify.cse_main.cse()` (page 741) is not applied automatically anywhere in this chain. It ideally happens at the codegen level, or somewhere above it.

We will iterate through the levels below.

The following three lines will be used to setup each example:

```
>>> from sympy import *
>>> init_printing(use_unicode=True)
>>> from sympy.abc import a, e, k, n, r, t, x, y, z, T, Z
>>> from sympy.abc import beta, omega, tau
>>> f, g = symbols('f, g', cls=Function)
```
Code printers (sympy.printing)

This is where the meat of code generation is; the translation of SymPy actually more like a lightweight version of codegen for Python, and Python (sympy.printing.pcode.pcode() (page 2251)), and sympy.printing.lambdarepr.lambdarepr() (page 2245), which supports many libraries (like NumPy), and Aesara (sympy.printing.aesaracode.aesara_function() (page 2242)). The code printers are special cases of the other prints in SymPy (str printer, pretty printer, etc.).

An important distinction is that the code printer has to deal with assignments (using the sympy.codegen.ast.Assignment (page 1170) object). This serves as building blocks for the code printers and hence the codegen module. An example that shows the use of Assignment in C code:

```python
>>> from sympy.codegen.ast import Assignment
>>> print(ccode(Assignment(x, y + 1)))
x = y + 1;
```

Here is another simple example of printing a C version of a SymPy expression:

```python
>>> expr = (Rational(-1, 2) * Z * k * (e**2) / r)
>>> ccode(expr)
-1.0/2.0*Z*pow(e, 2)*k/r
>>> from sympy.codegen.ast import real, float80
>>> ccode(expr, assign_to="E", type_aliases={real: float80})
E = -1.0L/2.0L*Z*powl(e, 2)*k/r;
```

To generate code with some math functions provided by e.g. the C99 standard we need to import functions from sympy.codegen.cfunctions (page 1187):

```python
>>> from sympy.codegen.cfunctions import expm1
>>> ccode(expm1(x), standard='C99')
expm1(x)
```

Piecewise expressions are converted into conditionals. If an assign_to variable is provided an if statement is created, otherwise the ternary operator is used. Note that if the Piecewise lacks a default term, represented by (expr, True) then an error will be thrown. This is to prevent generating an expression that may not evaluate to anything. A use case for Piecewise:

```python
>>> expr = Piecewise((x + 1, x > 0), (x, True))
>>> print(fcode(expr, tau))
if (x > 0) then
tau = x + 1
else
  tau = x
end if
```

The various printers also tend to support Indexed objects well. With contract=True these expressions will be turned into loops, whereas contract=False will just print the assignment expression that should be looped over:
Custom printing can be defined for certain types by passing a dictionary of "type": "function" to the user_functions kwarg. Alternatively, the dictionary value can be a list of tuples i.e., [(argument_test, cfunction_string)]. This can be used to call a custom Octave function:

```python
custom_functions = {
    "f": "existing_octave_fcn",
    "g": [(lambda x: x.is_Matrix, "my_mat_fcn"),
          (lambda x: not x.is_Matrix, "my_fcn")]
}
mat = Matrix([[1, x]])
octave_code(f(x) + g(x) + g(mat), user_functions=custom_functions)
```

An example of Mathematica code printer:

```python
x_ = Function('x')
expr = x_((n*T) * sin((t - n*T) / T))
expr = expr / ((-T*n + t) / T)
expr
```

We can go through a common expression in different languages we support and see how it

5.8. Topics 1155
## Codegen (sympy.utilities.codegen)

This module deals with creating compilable code from SymPy expressions. This is lower level than autowrap, as it doesn’t actually attempt to compile the code, but higher level than the printers, as it generates compilable files (including header files), rather than just code snippets.

The user friendly functions, here, are codegen and make_routine. codegen takes a list of (variable, expression) pairs and a language (C, F95, and Octave/Matlab are supported). It returns, as strings, a code file and a header file (for relevant languages). The variables are created as functions that return the value of the expression as output.

**Note:** The codegen callable is not in the sympy namespace automatically, to use it you must first import codegen from sympy.utilities.codegen

For instance:

```python
>>> from sympy.utilities.codegen import codegen
>>> length, breadth, height = symbols('length, breadth, height')
>>> [(c_name, c_code), (h_name, c_header)] = \
... codegen(('volume', length*breadth*height), "C99", "test", \
... header=False, empty=False)
>>> print(c_name)

test.c
```
Various flags to codegen let you modify things. The project name for preprocessor instructions can be varied using project. Variables listed as global variables in arg global_vars will not show up as function arguments.

language is a case-insensitive string that indicates the source code language. Currently, C, F95 and Octave are supported. Octave generates code compatible with both Octave and Matlab.

to_files when True, the code will be written to one or more files with the given prefix.

Here is an example:

```python
>>> [(f_name, f_code), header] = codegen(("volume", length*breadth*height), ...
    ... "F95", header=False, empty=False, argument_sequence=(breadth, length), ...
    ... global_vars=(height,))
>>> print(f_code)
REAL*8 function volume(breadth, length)
implicit none
REAL*8, intent(in) :: breadth
REAL*8, intent(in) :: length
volume = breadth*height*length
end function
```

The method make_routine creates a Routine object, which represents an evaluation routine for a set of expressions. This is only good for internal use by the CodeGen objects, as an intermediate representation from SymPy expression to generated code. It is not recommended to make a Routine object yourself. You should instead use make_routine method. make_routine in turn calls the routine method of the CodeGen object depending upon the language of choice. This creates the internal objects representing assignments and so on, and creates the Routine class with them.

The various codegen objects such as Routine and Variable aren’t SymPy objects (they don’t subclass from Basic).
For example:

```python
>>> from sympy.utilities.codegen import make_routine
>>> from sympy.physics.hydrogen import R_nl
>>> expr = R_nl(3, y, x, 6)
>>> routine = make_routine('my_routine', expr)
[result]
>>> [arg.result_var for arg in routine.results]
[514 234168139771 9428]
>>> [arg.expr for arg in routine.results]
[[y \sqrt{(2 - y)!} -2\cdot x \cdot \text{e}^{\text{assoc_laguerre}(2 - y, 2\cdot y + 1, 4\cdot x)} \sqrt{(y + 3)!}]]
>>> [arg.name for arg in routine.arguments]
[x, y]
```

Another more complicated example with a mixture of specified and automatically-assigned names. Also has Matrix output:

```python
>>> routine = make_routine('fcn', [x*y, Eq(a, 1), Eq(r, x + r), Matrix([[x, 2]])])
>>> [arg.result_var for arg in routine.results]
[result]
>>> [arg.expr for arg in routine.results]
[x\cdot y]
>>> [arg.name for arg in routine.arguments]
[x, y, a, r, out_8598435338784878]
```

We can examine the various arguments more closely:

```python
>>> [a.name for a in routine.arguments if isinstance(a, InputArgument)]
[x, y]
```
Autowrap

Autowrap automatically generates code, writes it to disk, compiles it, and imports it into the current session. Main functions of this module are autowrap, binary_function, and ufuncify.

It also automatically converts expressions containing Indexed objects into summations. The classes IndexedBase, Indexed and Idx represent a matrix element M[i, j]. See Tensor (page 1432) for more on this.

autowrap creates a wrapper using f2py or Cython and creates a numerical function.

**Note:** The autowrap callable is not in the sympy namespace automatically, to use it you must first import autowrap from sympy.utilities.autowrap

The callable returned from autowrap() is a binary Python function, not a SymPy object. For example:

```python
>>> from sympy.utilities.autowrap import autowrap
>>> expr = ((x - y + z)**(13)).expand()
>>> binary_func = autowrap(expr)
>>> binary_func(1, 4, 2)
-1.0
```

The various flags available with autowrap() help to modify the services provided by the method. The argument tempdir tells autowrap to compile the code in a specific directory, and leave the files intact when finished. For instance:

```python
>>> from sympy.utilities.autowrap import autowrap
>>> from sympy.physics.qho_1d import psi_n
>>> x_ = IndexedBase('x')
>>> y_ = IndexedBase('y')
>>> m = symbols('m', integer=True)
>>> i = Idx('i', m)
>>> qho = autowrap(Eq(y_[i], psi_n(0, x_[i], m, omega)), tempdir='/tmp')
```

Checking the Fortran source code in the directory specified reveals this:

```
subroutine autofunc(m, omega, x, y)
implicit none
INTEGER*4, intent(in) :: m
REAL*8, intent(in) :: omega
REAL*8, intent(in), dimension(1:m) :: x
REAL*8, intent(out), dimension(1:m) :: y
INTEGER*4 :: i

REAL*8, parameter :: hbar = 1.05457162d-34
REAL*8, parameter :: pi = 3.14159265358979d0

do i = 1, m
   y(i) = (m*omega)**((1.0d0/4.0d0)*exp(-4.74126166983329d+33*m*omega*x(i & )**2))/(hbar**(1.0d0/4.0d0)*pi**(1.0d0/4.0d0))
end do
```

5.8. Topics

1159
Using the argument args along with it changes argument sequence:

```python
>>> eq = Eq(y[i], psi_n(0, x[i], m, omega))
>>> qho = autowrap(eq, tempdir='~/tmp', args=[y, x, m, omega])
```

yields:

```fortran
subroutine autofunc(y, x, m, omega)
implicit none
INTEGER*4, intent(in) :: m
REAL*8, intent(in) :: omega
REAL*8, intent(out), dimension(1:m) :: y
REAL*8, intent(in), dimension(1:m) :: x
INTEGER*4 :: i

REAL*8, parameter :: hbar = 1.05457162d-34
REAL*8, parameter :: pi = 3.14159265358979d0

do i = 1, m
y(i) = (m*omega)**(1.0d0/4.0d0)*exp(-4.74126166983329d+33*m*omega*x(i & )**2)/(hbar**(1.0d0/4.0d0)*pi**(1.0d0/4.0d0))
end do

end subroutine
```

The argument verbose is boolean, optional and if True, autowrap will not mute the command line backends. This can be helpful for debugging.

The argument language and backend are used to change defaults: Fortran and f2py to C and Cython. The argument helpers is used to define auxiliary expressions needed for the main expression. If the main expression needs to call a specialized function it should be put in the helpers iterable. Autowrap will then make sure that the compiled main expression can link to the helper routine. Items should be tuples with (<function_name>, <sympy_expression>, <arguments>). It is mandatory to supply an argument sequence to helper routines.

Another method available at the autowrap level is binary_function. It returns a sympy function. The advantage is that we can have very fast functions as compared to SymPy speeds. This is because we will be using compiled functions with SymPy attributes and methods. An illustration:

```python
>>> from sympy.utilities.autowrap import binary_function
>>> from sympy.physics.hydrogen import R_nl
>>> psi_nl = R_nl(1, 0, a, r)
>>> f = binary_function('f', psi_nl)
>>> f(a, r).evalf(3, subs={a: 1, r: 2})
0.766
```

While NumPy operations are very efficient for vectorized data but they sometimes incur unnecessary costs when chained together. Consider the following operation

```python
>>> x = get_numpy_array(...) 
>>> y = sin(x) / x
```

The operators sin and / call routines that execute tight for loops in C. The resulting computation looks something like this.
```c
for(int i = 0; i < n; i++)
{
    temp[i] = sin(x[i]);
}
for(int i = i; i < n; i++)
{
    y[i] = temp[i] / x[i];
}
```

This is slightly sub-optimal because

1. We allocate an extra temp array
2. We walk over x memory twice when once would have been sufficient

A better solution would fuse both element-wise operations into a single for loop

```c
for(int i = i; i < n; i++)
{
    y[i] = sin(x[i]) / x[i];
}
```

Statically compiled projects like NumPy are unable to take advantage of such optimizations. Fortunately, SymPy is able to generate efficient low-level C or Fortran code. It can then depend on projects like Cython or f2py to compile and reconnect that code back up to Python. Fortunately this process is well automated and a SymPy user wishing to make use of this code generation should call the ufuncify function.

ufuncify is the third method available with Autowrap module. It basically implies ‘Universal functions’ and follows an ideology set by NumPy. The main point of ufuncify as compared to autowrap is that it allows arrays as arguments and can operate in an element-by-element fashion. The core operation done element-wise is in accordance to Numpy’s array broadcasting rules. See this for more.

```python
>>> from sympy import *
>>> from sympy.abc import x
>>> expr = sin(x)/x
```  

```python
>>> from sympy.utilities.autowrap import ufuncify
>>> f = ufuncify([x], expr)
```  

This function f consumes and returns a NumPy array. Generally ufuncify performs at least as well as lambdify. If the expression is complicated then ufuncify often significantly outperforms the NumPy backed solution. Jensen has a good blog post on this topic.

Let us see an example for some quantitative analysis:

```python
>>> from sympy.physics.hydrogen import R_nl
>>> expr = R_nl(3, 1, x, 6)
>>> expr
-2*x
8*x*(4 - 4*x)*e
3
```
The lambdify function translates SymPy expressions into Python functions, leveraging a variety of numerical libraries. By default, lambdify relies on implementations in the math standard library. Naturally, Raw Python is faster than SymPy. However, it also supports mpmath and most notably, numpy. Using the NumPy library gives the generated function access to powerful vectorized ufuncs that are backed by compiled C code.

Let us compare the speeds:

```python
>>> from sympy.utilities.autowrap import ufuncify
>>> from sympy.utilities.lambdify import lambdify
>>> fn_numpy = lambdify(x, expr, 'numpy')
>>> fn_fortran = ufuncify([x], expr, backend='f2py')
>>> from numpy import linspace
>>> xx = linspace(0, 1, 5)
>>> fn_numpy(xx)
array([ 0.        ,  1.21306132,  0.98101184,  0.44626032,  0.        ])
>>> fn_fortran(xx)
array([ 0.        ,  1.21306132,  0.98101184,  0.44626032,  0.        ])
>>> import timeit
>>> timeit.timeit('fn_numpy(xx)', 'from __main__ import fn_numpy, xx', number=10000)
0.18891601900395472
>>> timeit.timeit('fn_fortran(xx)', 'from __main__ import fn_fortran, xx', number=10000)
0.004707066000264604
```

The options available with ufuncify are more or less the same as those available with autowrap.

There are other facilities available with SymPy to do efficient numeric computation. See this (page 1146) page for a comparison among them.

### Classes and functions for rewriting expressions (sympy.codegen.rewriting)

Classes and functions useful for rewriting expressions for optimized code generation. Some languages (or standards thereof), e.g., C99, offer specialized math functions for better performance and/or precision.

Using the optimize function in this module, together with a collection of rules (represented as instances of Optimization), one can rewrite the expressions for this purpose:

```python
>>> from sympy import Symbol, exp, log
>>> from sympy.codegen.rewriting import optimize, optims_c99
>>> x = Symbol('x')
>>> optimize(3*exp(2*x) - 3, optims_c99)
3*expm1(2*x)
>>> optimize(exp(2*x) - 1 - exp(-33), optims_c99)
expm1(2*x) - expm1(33)
>>> optimize(log(3*x + 3), optims_c99)
log1p(x) + log(3)
>>> optimize(log(2*x + 3), optims_c99)
log(2*x + 3)
```

The optims_c99 imported above is tuple containing the following instances (which may be imported from sympy.codegen.rewriting):
```python
>>> from sympy import symbols, exp
>>> from sympy.codegen.rewriting import FuncMinusOneOptim
>>> from sympy.codegen.cfunctions import expm1
>>> x, y = symbols('x y')
>>> expm1_opt = FuncMinusOneOptim(exp, expm1)
>>> expm1_opt(exp(x) + 2*exp(5*y) - 3)
expm1(x) + 2*expm1(5*y)
```

replace_in_Add(e)  
passed as second argument to Basic.replace(...)  

```python
class sympy.codegen.rewriting.Optimization(cost_function=None, priority=1)
Abstract base class for rewriting optimization.
Subclasses should implement __call__ taking an expression as argument.
```
class sympy.codegen.rewriting.ReplaceOptim(query, value, **kwargs)

Rewriting optimization calling replace on expressions.

Parameters
query :
First argument passed to replace.

value :
Second argument passed to replace.

Explanation

The instance can be used as a function on expressions for which it will apply the replace
method (see sympy.core.basic.Basic.replace() (page 989)).

Examples

```python
>>> from sympy import Symbol
>>> from sympy.codegen.rewriting import ReplaceOptim
>>> from sympy.codegen.cfunctions import exp2
>>> x = Symbol('x')
>>> exp2_opt = ReplaceOptim(lambda p: p.is_Pow and p.base == 2,
...     lambda p: exp2(p.exp))
>>> exp2_opt(2**x)
exp2(x)
```

sympy.codegen.rewriting.create_expand_pow_optimization(limit, *,
    base_req=<function
    <lambda>>)

Creates an instance of ReplaceOptim (page 1164) for expanding Pow.

Parameters

limit : int
The highest power which is expanded into multiplication.

base_req : function returning bool
Requirement on base for expansion to happen, default is to return the
is_symbol attribute of the base.

Explanation

The requirements for expansions are that the base needs to be a symbol and the exponent
needs to be an Integer (and be less than or equal to limit).
Examples

```python
>>> from sympy import Symbol, sin
cpy>>> from sympy.codegen.rewriting import create_expand_pow_optimization
>>> x = Symbol('x')
cpy>>> expand_opt = create_expand_pow_optimization(3)
>>> expand_opt(x**5 + x**3)
x**5 + x*x*x
>>> expand_opt(x**5 + x**3 + sin(x)**3)
x**5 + sin(x)**3 + x*x*x
>>> opt2 = create_expand_pow_optimization(3, base_req=lambda b: not b.is_Function)
>>> opt2((x+1)**2 + sin(x)**2)
sin(x)**2 + (x + 1)*(x + 1)
```

sympy.codegen.rewriting.optimize(expr, optimizations)

Apply optimizations to an expression.

**Parameters**

- **expr**: expression
- **optimizations**: iterable of Optimization instances

The optimizations will be sorted with respect to priority (highest first).

Examples

```python
>>> from sympy import log, Symbol
cpy>>> from sympy.codegen.rewriting import optims_c99, optimize
>>> x = Symbol('x')
>>> optimize(log(x + 3)/log(2) + log(x**2 + 1), optims_c99)
log1p(x**2) + log2(x + 3)
```

Additional AST nodes for operations on matrices. The nodes in this module are meant to represent optimization of matrix expressions within codegen's target languages that cannot be represented by SymPy expressions.

As an example, we can use sympy.codegen.rewriting.optimize() (page 1165) and the matin_opt optimization provided in sympy.codegen.rewriting (page 1162) to transform matrix multiplication under certain assumptions:

```python
>>> from sympy import symbols, MatrixSymbol
>>> n = symbols('n', integer=True)
>>> A = MatrixSymbol('A', n, n)
>>> x = MatrixSymbol('x', n, 1)
>>> expr = A**(-1) * x
>>> from sympy import assuming, Q
>>> from sympy.codegen.rewriting import matinv_opt, optimize
>>> with assuming(Q.fullrank(A)):
...    optimize(expr, [matinv_opt])
MatrixSolve(A, vector=x)
```
class sympy.codegen.matrix_nodes.MatrixSolve(*args, **kwargs)

Represents an operation to solve a linear matrix equation.

Parameters

matrix : MatrixSymbol
    Matrix representing the coefficients of variables in the linear equation. This matrix must be square and full-rank (i.e. all columns must be linearly independent) for the solving operation to be valid.

vector : MatrixSymbol
    One-column matrix representing the solutions to the equations represented in matrix.

Examples

>>> from sympy import symbols, MatrixSymbol
>>> from sympy.codegen.matrix_nodes import MatrixSolve
>>> n = symbols('n', integer=True)
>>> A = MatrixSymbol('A', n, n)
>>> x = MatrixSymbol('x', n, 1)
>>> from sympy.printing.numpy import NumPyPrinter
>>> NumPyPrinter().doprint(MatrixSolve(A, x))
'numpy.linalg.solve(A, x)'
>>> from sympy import octave_code
>>> octave_code(MatrixSolve(A, x))
'A \ x'

Tools for simplifying expressions using approximations (sympy.codegen.approximations)

class sympy.codegen.approximations.SeriesApprox(bounds, reltol, max_order=4, n_point_checks=4, **kwargs)

Approximates functions by expanding them as a series.

Parameters

bounds : dict
    Mapping expressions to length 2 tuple of bounds (low, high).

reltol : number
    Threshold for when to ignore a term. Taken relative to the largest lower bound among bounds.

max_order : int
    Largest order to include in series expansion

n_point_checks : int (even)
    The validity of an expansion (with respect to reltol) is checked at discrete points (linearly spaced over the bounds of the variable). The number of points used in this numerical check is given by this number.
Examples

```python
>>> from sympy import sin, pi
>>> from sympy.abc import x, y
>>> from sympy.codegen.rewriting import optimize
>>> from sympy.codegen.approximations import SeriesApprox
>>> bounds = {x: (-.1, .1), y: (pi-1, pi+1)}
>>> series_approx2 = SeriesApprox(bounds, reltol=1e-2)
>>> series_approx3 = SeriesApprox(bounds, reltol=1e-3)
>>> series_approx8 = SeriesApprox(bounds, reltol=1e-8)
>>> expr = sin(x) * sin(y)
>>> optimize(expr, [series_approx2])
x*(-y + (y - pi)**3/6 + pi)
>>> optimize(expr, [series_approx3])
(-x**3/6 + x)*sin(y)
>>> optimize(expr, [series_approx8])
sin(x)*sin(y)
```

```python
class sympy.codegen.approximations.SumApprox(bounds, reltol, **kwargs)
    Approximates sum by neglecting small terms.

    Parameters
    ----------
    bounds : dict
        Mapping expressions to length 2 tuple of bounds (low, high).
    reltol : number
        Threshold for when to ignore a term. Taken relative to the largest lower bound among bounds.

Explanation

If terms are expressions which can be determined to be monotonic, then bounds for those expressions are added.

Examples

```python
>>> from sympy import exp
>>> from sympy.abc import x, y, z
>>> from sympy.codegen.rewriting import optimize
>>> from sympy.codegen.approximations import SumApprox
>>> bounds = {x: (-1, 1), y: (1000, 2000), z: (-10, 3)}
>>> sum_approx3 = SumApprox(bounds, reltol=1e-3)
>>> sum_approx2 = SumApprox(bounds, reltol=1e-2)
>>> sum_approx1 = SumApprox(bounds, reltol=1e-1)
>>> expr = 3*(x + y + exp(z))
>>> optimize(expr, [sum_approx3])
3*(x + y + exp(z))
>>> optimize(expr, [sum_approx2])
3*y + 3*exp(z)
>>> optimize(expr, [sum_approx1])
3*y
```
Classes for abstract syntax trees (sympy.codegen.ast)

Types used to represent a full function/module as an Abstract Syntax Tree.
Most types are small, and are merely used as tokens in the AST. A tree diagram has been included below to illustrate the relationships between the AST types.

AST Type Tree

```
*Basic*  
   |  
CodegenAST  
   |  
   -->AssignmentBase  
      |  
      |  -->Assignment  
      |  -->AugmentedAssignment
      |  -->AddAugmentedAssignment
      |  -->SubAugmentedAssignment
      |  -->MulAugmentedAssignment
      |  -->DivAugmentedAssignment
      |  -->ModAugmentedAssignment
      -->CodeBlock
      -->Token
         |  
         |  -->Attribute
         |  -->For
         |  -->String
         |      |  -->QuotedString
         |      |  -->Comment
         |  -->Type
         |      |  -->IntBaseType
         |      |      |  -->_SizedIntType
         |      |      |  -->SignedIntType
         |      |      |  -->UnsignedIntType
         |      |  -->FloatBaseType
         |      |      |  -->FloatType
         |      |      |  -->ComplexBaseType

         -->Element
         -->Declaration
         -->While
         -->Scope
         -->Stream
         -->Print
```

(continues on next page)
Predefined types

A number of Type instances are provided in the sympy.codegen.ast module for convenience. Perhaps the two most common ones for code-generation (of numeric codes) are float32 and float64 (known as single and double precision respectively). There are also precision generic versions of Types (for which the codeprinters selects the underlying data type at time of printing): real, integer, complex, bool.

The other Type instances defined are:
- intc: Integer type used by C’s “int”.
- intp: Integer type used by C’s “unsigned”.
- int8, int16, int32, int64: n-bit integers.
- uint8, uint16, uint32, uint64: n-bit unsigned integers.
- float80: known as “extended precision” on modern x86/amd64 hardware.
- complex64: Complex number represented by two float32 numbers
- complex128: Complex number represented by two float64 numbers

Using the nodes

It is possible to construct simple algorithms using the AST nodes. Let’s construct a loop applying Newton’s method:

```python
>>> from sympy import symbols, cos
>>> from sympy.codegen.ast import While, Assignment, aug_assign, Print
>>> t, dx, x = symbols('tol delta val')
>>> expr = cos(x) - x**3
>>> whl = While(abs(dx) > t, [
...     Assignment(dx, -expr/expr.diff(x)),
...     aug_assign(x, '+', dx),
...     Print([x])
... ])
>>> from sympy import pycode
>>> py_str = pycode(whl)
>>> print(py_str)
while (abs(delta) > tol):
    delta = (val**3 - math.cos(val))/(-3*val**2 - math.sin(val))
    val += delta
    print(val)
>>> import math
>>> tol, val, delta = 1e-5, 0.5, float('inf')
```

(continues on next page)
If we want to generate Fortran code for the same while loop we simple call fcode:

```python
>>> from sympy import fcode
>>> print(fcode(whl, standard=2003, source_format='free'))
do while (abs(delta) > tol)
    delta = (val**3 - cos(val))/(-3*val**2 - sin(val))
    val = val + delta
    print *, val
end do
```

There is a function constructing a loop (or a complete function) like this in `sympy.codegen.algorithms` (page 1201).

```python
class sympy.codegen.ast.Assignment(lhs, rhs)

    Represents variable assignment for code generation.

    Parameters
    
    lhs : Expr
        SymPy object representing the lhs of the expression. These should
        be singular objects, such as one would use in writing code. Notable
        types include Symbol, MatrixSymbol, MatrixElement, and Indexed.
        Types that subclass these types are also supported.

    rhs : Expr
        SymPy object representing the rhs of the expression. This can be any
        type, provided its shape corresponds to that of the lhs. For example,
        a Matrix type can be assigned to MatrixSymbol, but not to Symbol,
        as the dimensions will not align.
```
Assignment(A[0, 1], x)
Assignment(A[0, 1], x)

```python
>>> from sympy.codegen.ast import Assignment
>>> Assignment(A[0, 1], x)
```

**class** sympy.codegen.ast.AssignmentBase(lhs, rhs)

Abstract base class for Assignment and AugmentedAssignment.

**Attributes:**

**op**

[str] Symbol for assignment operator, e.g. “=”, “+=”, etc.

```python
>>> Assignment(A[0, 1], x)
```

**class** sympy.codegen.ast.Attribute(possibly parametrized)

For use with `sympy.codegen.ast.Node` (page 1178) (which takes instances of Attribute as attrs).

**Parameters**

- **name**: str
- **parameters**: Tuple

**Examples**

```python
>>> from sympy.codegen.ast import Attribute
>>> volatile = Attribute('volatile')
>>> volatile
Attribute(String('volatile'))
>>> a = Attribute('foo', [1, 2, 3])
>>> a
foo(1, 2, 3)
>>> a.parameters == (1, 2, 3)
True
```

**class** sympy.codegen.ast.AugmentedAssignment(lhs, rhs)

Base class for augmented assignments.

**Attributes:**

**binop**

[str] Symbol for binary operation being applied in the assignment, such as “+”, “*”, etc.

**class** sympy.codegen.ast.BreakToken(*args, **kwargs)

Represents ‘break’ in C/Python (‘exit’ in Fortran).

Use the premade instance break_ or instantiate manually.

---

5.8. Topics
Examples

```python
>>> from sympy import ccode, fcode
>>> from sympy.codegen.ast import break_
>>> ccode(break_)
'broke'
>>> fcode(break_, source_format='free')
'exit'
```

class symy.codegen.ast.CodeBlock(*args)

Represents a block of code.

Explanation

For now only assignments are supported. This restriction will be lifted in the future.

Useful attributes on this object are:

- `left_hand_sides`:
  Tuple of left-hand sides of assignments, in order.

- `left_hand_sides`:
  Tuple of right-hand sides of assignments, in order.

- `free_symbols`:
  Free symbols of the expressions in the right-hand sides
  which do not appear in the left-hand side of an assignment.

Useful methods on this object are:

- `topological_sort`:
  Class method. Return a CodeBlock with assignments sorted so that variables are
  assigned before they are used.

- `cse`:
  Return a new CodeBlock with common subexpressions eliminated and pulled out as
  assignments.

Examples

```python
>>> from sympy import symbols, ccode
>>> from sympy.codegen.ast import CodeBlock, Assignment
>>> x, y = symbols('x y')
>>> c = CodeBlock(Assignment(x, 1), Assignment(y, x + 1))
>>> print(ccode(c))
x = 1;
y = x + 1;
```

cse(symbols=None, optimizations=None, postprocess=None, order='canonical')

Return a new code block with common subexpressions eliminated.
Explanation

See the docstring of `sympy.simplify.cse_main.cse()` (page 741) for more information.

Examples

```python
>>> from sympy import symbols, sin
>>> from sympy.codegen.ast import CodeBlock, Assignment
>>> x, y, z = symbols('x y z')
>>> c = CodeBlock(  
...    Assignment(x, 1),  
...    Assignment(y, sin(x) + 1),  
...    Assignment(z, sin(x) - 1),  
... )
>>> c.cse()
CodeBlock(  
    Assignment(x, 1),  
    Assignment(x0, sin(x)),  
    Assignment(y, x0 + 1),  
    Assignment(z, x0 - 1)
)
```

classmethod topological_sort(assignments)

Return a CodeBlock with topologically sorted assignments so that variables are assigned before they are used.

Examples

The existing order of assignments is preserved as much as possible.

This function assumes that variables are assigned to only once.

This is a class constructor so that the default constructor for CodeBlock can error when variables are used before they are assigned.

```python
>>> from sympy import symbols
>>> from sympy.codegen.ast import CodeBlock, Assignment
>>> x, y, z = symbols('x y z')
>>> assignments = [  
...    Assignment(x, y + z),  
...    Assignment(y, z + 1),  
...    Assignment(z, 2),  
... ]
>>> CodeBlock.topological_sort(assignments)
CodeBlock(  
    Assignment(z, 2),  
    Assignment(y, z + 1),
```

(continues on next page)
class sympy.codegen.ast.Comment(*args, **kwargs)
    Represents a comment.

class sympy.codegen.ast.ComplexType(*args, **kwargs)
    Represents a complex floating point number.

class sympy.codegen.ast.ContinueToken(*args, **kwargs)
    Represents ‘continue’ in C/Python (‘cycle’ in Fortran)
    Use the premade instance continue_ or instantiate manually.

Examples

```python
>>> from sympy import ccode, fcode
>>> from sympy.codegen.ast import continue_
>>> ccode(continue_)
'continue'
>>> fcode(continue_, source_format='free')
'cycle'
```

class sympy.codegen.ast.Declaration(*args, **kwargs)
    Represents a variable declaration

    Parameters
    ----------
    variable : Variable

Examples

```python
>>> from sympy.codegen.ast import Declaration, NoneToken, untyped
>>> z = Declaration('z')
>>> z.variable.type == untyped
True
>>> # value is special NoneToken() which must be tested with == operator
>>> z.variable.value is None  # won't work
False
>>> z.variable.value == None  # not PEP-8 compliant
True
>>> z.variable.value == NoneToken()  # OK
True
```

class sympy.codegen.ast.Element(*args, **kwargs)
    Element in (a possibly N-dimensional) array.
Examples

```python
>>> from sympy.codegen.ast import Element
>>> elem = Element('x', 'ijk')
>>> elem.symbol.name == 'x'
True
>>> elem.indices
(i, j, k)
>>> from sympy import ccode
>>> ccode(elem)
'x[i][j][k]'
>>> ccode(Element('x', 'ijk', strides='lmn', offset='o'))
'x[i*l + j*m + k*n + o]'
```

class sympy.codegen.ast.FloatBaseType(*args, **kwargs)
Represents a floating point number type.

cast_nocheck
    alias of Float (page 1033)

class sympy.codegen.ast.FloatType(*args, **kwargs)
Represents a floating point type with fixed bit width.
Base 2 & one sign bit is assumed.

Parameters

- **name** : str
  Name of the type.

- **nbits** : integer
  Number of bits used (storage).

- **nmant** : integer
  Number of bits used to represent the mantissa.

- **nexp** : integer
  Number of bits used to represent the mantissa.

Examples

```python
>>> from sympy import S
>>> from sympy.codegen.ast import FloatType
>>> half_precision = FloatType('f16', nbits=16, nmant=10, nexp=5)
>>> half_precision.max
65504
>>> half_precision.tiny == S(2)**-14
True
>>> half_precision.eps == S(2)**-10
True
>>> half_precision.dig == 3
True
>>> half_precision.decimal_dig == 5
```
(continues on next page)
True
>>> half_precision.cast_check(1.0)
1.0
>>> half_precision.cast_check(1e5)
Traceback (most recent call last):
...
  ValueError: Maximum value for data type smaller than new value.

cast_nocheck(value)
  Casts without checking if out of bounds or subnormal.

property decimal_dig
  Number of digits needed to store & load without loss.

  **Explanation**

  Number of decimal digits needed to guarantee that two consecutive conversions
  (float -> text -> float) to be idempotent. This is useful when one do not want to loose
  precision due to rounding errors when storing a floating point value as text.

property dig
  Number of decimal digits that are guaranteed to be preserved in text.
  
  When converting text -> float -> text, you are guaranteed that at least dig number
  of digits are preserved with respect to rounding or overflow.

property eps
  Difference between 1.0 and the next representable value.

property max
  Maximum value representable.

property max_exponent
  The largest positive number n, such that 2**(n - 1) is a representable finite value.

property min_exponent
  The lowest negative number n, such that 2**(n - 1) is a valid normalized number.

property tiny
  The minimum positive normalized value.

class sympy.codegen.ast.For(*args, **kwargs)
  Represents a ‘for-loop’ in the code.

  **Expressions are of the form:**

  "for target in iter:
    body..."

  **Parameters**

  target : symbol
    iter : iterable body : CodeBlock or iterable
    
    ! When passed an iterable it is used to instantiate a CodeBlock.
Examples

```python
>>> from sympy import symbols, Range
>>> from sympy.codegen.ast import aug_assign, For
>>> x, i, j, k = symbols('x i j k')
>>> for i = For(i, Range(10), [aug_assign(x, '+', i*j*k)]
>>> for i
For(i, iterable=Range(0, 10, 1), body=CodeBlock(AddAugmentedAssignment(x, i*j*k))
)
>>> for ji = For(j, Range(7), [for_i])
>>> for ji
For(j, iterable=Range(0, 7, 1), body=CodeBlock(For(i, iterable=Range(0, 10, 1), body=CodeBlock(AddAugmentedAssignment(x, i*j*k))
))
>>> for kji =For(k, Range(5), [for_ji])
>>> for kji
For(k, iterable=Range(0, 5, 1), body=CodeBlock(For(j, iterable=Range(0, 7, 1), body=CodeBlock(For(i, iterable=Range(0, 10, 1), body=CodeBlock(AddAugmentedAssignment(x, i*j*k))
))
))
)
```
**attrs** : iterable of Attribute instances

**Examples**

```python
>>> from sympy import ccode, symbols
>>> from sympy.codegen.ast import real, FunctionPrototype
>>> x, y = symbols('x y', real=True)
>>> fp = FunctionPrototype(real, 'foo', [x, y])
>>> ccode(fp)
'double foo(double x, double y)'
>>> from sympy.codegen.ast import FunctionDefinition, Return
>>> body = [Return(x*y)]
>>> fd = FunctionDefinition.from_FunctionPrototype(fp, body)
>>> print(ccode(fd))
double foo(double x, double y){
    return x*y;
}
```

class sympy.codegen.ast.FunctionPrototype(*args, **kwargs)

Represents a function prototype

Allows the user to generate forward declaration in e.g. C/C++.

**Parameters**

- **return_type** : Type
- **name** : str
- **parameters** : iterable of Variable instances
- **attrs** : iterable of Attribute instances

**Examples**

```python
>>> from sympy import ccode, symbols
>>> from sympy.codegen.ast import real, FunctionPrototype
>>> x, y = symbols('x y', real=True)
>>> fp = FunctionPrototype(real, 'foo', [x, y])
>>> ccode(fp)
'double foo(double x, double y)'
```

class sympy.codegen.ast.IntBaseType(*args, **kwargs)

Integer base type, contains no size information.

class sympy.codegen.ast.Node(*args, **kwargs)

Subclass of Token, carrying the attribute ‘attrs’ (Tuple)
Examples

```python
>>> from sympy.codegen.ast import Node, value_const, pointer_const
>>> n1 = Node([value_const])
>>> n1.attr_params('value_const')  # get the parameters of attribute (by
˓→name)
()  
>>> from sympy.codegen.fnodes import dimension
>>> n2 = Node([value_const, dimension(5, 3)])
>>> n2.attr_params(value_const)  # get the parameters of attribute (by
˓→Attribute instance)
()  
>>> n2.attr_params('dimension')  # get the parameters of attribute (by
˓→name)
(5, 3)
>>> n2.attr_params(pointer_const) is None
True
```

``attr_params(looking_for)``

Returns the parameters of the Attribute with name `looking_for` in `self.attrs`

class sympy.codegen.ast.NoneToken(*args, **kwargs)

The AST equivalence of Python’s `NoneType`

The corresponding instance of Python’s `None` is `None`.

Examples

```python
>>> from sympy.codegen.ast import none, Variable
>>> from sympy import pycode
>>> print(pycode(Variable('x').as_Declaration(value=none)))
```

``x = None``

class sympy.codegen.ast.Pointer(*args, **kwargs)

Represents a pointer. See `Variable`.

Examples

Can create instances of Element:

```python
>>> from sympy import Symbol
>>> from sympy.codegen.ast import Pointer
>>> i = Symbol('i', integer=True)
>>> p = Pointer('x')
>>> p[i+1]
Element(x, indices=(i + 1,))
```

class sympy.codegen.ast.Print(*args, **kwargs)

Represents print command in the code.

Parameters

- **formatstring**: str
*args : Basic instances (or convertible to such through sympify)

Examples

```python
>>> from sympy.codegen.ast import Print
>>> from sympy import pycode
>>> print(pycode(Print('x y'.split(), "coordinate: %12.5g %12.5g")))
print("coordinate: %12.5g %12.5g" % (x, y))
```

class sympy.codegen.ast.QuotedString(*args, **kwargs)
Represents a string which should be printed with quotes.

class sympy.codegen.ast.Return(*args, **kwargs)
Represents a return command in the code.

Parameters

- return : Basic

Examples

```python
>>> from sympy.codegen.ast import Return
>>> from sympy.printing.pycode import pycode
>>> from sympy import Symbol
>>> x = Symbol('x')
>>> print(pycode(Return(x)))
return x
```

class sympy.codegen.ast.Scope(*args, **kwargs)
Represents a scope in the code.

Parameters

- body : CodeBlock or iterable

When passed an iterable it is used to instantiate a CodeBlock.

class sympy.codegen.ast.SignedIntType(*args, **kwargs)
Represents a signed integer type.

class sympy.codegen.ast.Stream(*args, **kwargs)
Represents a stream.

There are two predefined Stream instances stdout & stderr.

Parameters

- name : str
Examples

```py
>>> from sympy import pcode, Symbol
>>> from sympy.codegen import Print, stderr, QuotedString
>>> print(pcode(Print(['x'], file=stderr)))
print(x, file=sys.stderr)
>>> x = Symbol('x')
>>> print(pcode(Print([QuotedString('x')], file=stderr)))  # print_literally "x"
print("x", file=sys.stderr)
```

class sympy.codegen.ast.String(*args, **kwargs)

SymPy object representing a string.

Atomic object which is not an expression (as opposed to Symbol).

Parameters

- text : str

Examples

```py
>>> from sympy.codegen.ast import String
>>> f = String('foo')
>>> f
foo
>>> str(f)
'foo'
>>> f.text
'foo'
>>> print(repr(f))
String('foo')
```

class sympy.codegen.ast.Token(*args, **kwargs)

Base class for the AST types.

Explanation

Defining fields are set in _fields. Attributes (defined in _fields) are only allowed to contain instances of Basic (unless atomic, see String). The arguments to __new__() correspond to the attributes in the order defined in _fields`. The ``defaults class attribute is a dictionary mapping attribute names to their default values.

Subclasses should not need to override the __new__() method. They may define a class or static method named _construct_<attr> for each attribute to process the value passed to __new__(). Attributes listed in the class attribute not_in_args are not passed to Basic (page 979).

kwargsexclude=(), apply=None)

Get instance’s attributes as dict of keyword arguments.

Parameters

- exclude : collection of str

5.8. Topics
Collection of keywords to exclude.

**apply**: callable, optional
Function to apply to all values.

class sympy.codegen.ast.Type(*args, **kwargs)
Represents a type.

**Parameters**

- **name**: str
  Name of the type, e.g. object, int16, float16 (where the latter two would use the Type sub-classes IntType and FloatType respectively). If a Type instance is given, the said instance is returned.

**Explanation**

The naming is a super-set of NumPy naming. Type has a classmethod `from_expr` which offer type deduction. It also has a method `cast_check` which casts the argument to its type, possibly raising an exception if rounding error is not within tolerances, or if the value is not representable by the underlying data type (e.g. unsigned integers).

**Examples**

```python
>>> from sympy.codegen.ast import Type
>>> t = Type.from_expr(42)
>>> t
integer
>>> print(repr(t))
IntBaseType(String('integer'))
>>> from sympy.codegen.ast import uint8
>>> uint8.cast_check(-1)
Traceback (most recent call last):
  ... ValueError: Minimum value for data type bigger than new value.
>>> from sympy.codegen.ast import float32
>>> v6 = 0.123456
>>> float32.cast_check(v6)
0.123456
>>> v10 = 12345.67894
>>> float32.cast_check(v10)
Traceback (most recent call last):
  ... ValueError: Casting gives a significantly different value.
>>> boost_mp50 = Type('boost::multiprecision::cpp_dec_float_50')
>>> from sympy import cxxcode
>>> from sympy.codegen.ast import Declaration, Variable
>>> cxxcode(Declaration(Variable('x', type=boost_mp50)))
'boost::multiprecision::cpp_dec_float_50 x'
```
References

[R39]

cast_check(value, rtol=None, atol=0, precision_targets=None)

Casts a value to the data type of the instance.

Parameters

value : number

rtol : floating point number
    Relative tolerance. (will be deduced if not given).

atol : floating point number
    Absolute tolerance (in addition to rtol).

type_aliases : dict
    Maps substitutions for Type, e.g. {integer: int64, real: float32}

Examples

```python
>>> from sympy.codegen.ast import integer, float32, int8
>>> integer.cast_check(3.0) == 3
True
>>> float32.cast_check(1e-40)
Traceback (most recent call last):
...
ValueError: Minimum value for data type bigger than new value.
>>> int8.cast_check(256)
Traceback (most recent call last):
...
ValueError: Maximum value for data type smaller than new value.
>>> v10 = 12345.67894
>>> float32.cast_check(v10)
Traceback (most recent call last):
...
ValueError: Casting gives a significantly different value.
>>> from sympy.codegen.ast import float64
>>> float64.cast_check(v10)
12345.67894
>>> from sympy import Float
>>> v18 = Float('0.123456789012345646')
>>> float64.cast_check(v18)
Traceback (most recent call last):
...
ValueError: Casting gives a significantly different value.
>>> from sympy.codegen.ast import float80
>>> float80.cast_check(v18)
0.123456789012345649
```

classmethod from_expr(expr)

Deduces type from an expression or a Symbol.
Parameters

- expr: number or SymPy object
  The type will be deduced from type or properties.

Raises

- ValueError when type deduction fails.

Examples

```python
>>> from sympy.codegen.ast import Type, integer, complex_
>>> Type.from_expr(2) == integer
True
>>> from sympy import Symbol
>>> Type.from_expr(Symbol('z', complex=True)) == complex_
True
>>> Type.from_expr(sum)
Traceback (most recent call last):
...
ValueError: Could not deduce type from expr.
```

class sympy.codegen.ast.UnsignedIntType(*args, **kwargs)

Represents an unsigned integer type.

class sympy.codegen.ast.Variable(*args, **kwargs)

Represents a variable.

Parameters

- symbol: Symbol
- type: Type (optional)
  Type of the variable.
- attrs: iterable of Attribute instances
  Will be stored as a Tuple.

Examples

```python
>>> from sympy import Symbol
>>> from sympy.codegen.ast import Variable, float32, integer
>>> x = Symbol('x')
>>> v = Variable(x, type=float32)
>>> v.attrs
()  # False
>>> v == Variable('x')
False
>>> v == Variable('x', type=float32)
True
>>> v
Variable(x, type=float32)
```

One may also construct a Variable instance with the type deduced from assumptions about the symbol using the deduced classmethod:
>>> i = Symbol('i', integer=True)
>>> v = Variable.deduced(i)
>>> v.type == integer
True
>>> v == Variable('i')
False
>>> from sympy.codegen.ast import value_const
>>> value_const in v.attrs
False
>>> w = Variable('w', attrs=[value_const])
>>> w
Variable(w, attrs=(value_const,))
>>> value_const in w.attrs
True
>>> w.as_Declaration(value=42)
Declaration(Variable(w, value=42, attrs=(value_const,)))

asm_classmethod deduced(symbol, value=None, attrs=(), cast_check=True)
Alt. constructor with type deduction from Type.from_expr.
Deduces type primarily from symbol, secondarily from value.

Parameters

symbol : Symbol

value : expr
    (optional) value of the variable.

Explanation

If the variable of the Declaration need to wrap a modified variable keyword arguments may be passed (overriding e.g. the value of the Variable instance).

Examples

>>> from sympy.codegen.ast import Variable, NoneToken
>>> x = Variable('x')
>>> decl1 = x.as_Declaration()
>>> # value is special NoneToken() which must be tested with ==
>>> decl1.variable.value is None  # won't work
False
>>> decl1(variable.value == None  # not PEP-8 compliant
True
>>> decl1.variable.value == NoneToken()  # OK
True
>>> decl2 = x.as_Declaration(value=42.0)
>>> decl2.variable.value == 42.0
True
**attrs**: iterable of Attribute instances

*cast_check*: bool

Whether to apply `Type.cast_check` on value.

### Examples

```python
>>> from sympy import Symbol
>>> from sympy.codegen.ast import Variable, complex_
>>> n = Symbol('n', integer=True)
>>> str(Variable.deduced(n).type)
'integer'
>>> x = Symbol('x', real=True)
>>> v = Variable.deduced(x)
>>> v.type
real
>>> z = Symbol('z', complex=True)
>>> Variable.deduced(z).type == complex_
True
```

```python
class sympy.codegen.ast.While(*args, **kwargs)
```

Represents a `for-loop` in the code.

**Expressions are of the form:**

```
“while condition:
  body...”
```

**Parameters**

*condition*: expression convertible to Boolean

*body*: CodeBlock or iterable

When passed an iterable it is used to instantiate a CodeBlock.

### Examples

```python
>>> from sympy import symbols, Gt, Abs
>>> from sympy.codegen import aug_assign, Assignment, While
>>> x, dx = symbols('x dx')
>>> expr = 1 - x**2
>>> whl = While(Gt(Abs(dx), 1e-9), [
  ... Assignment(dx, -expr/expr.diff(x)),
  ... aug_assign(x, '+', dx)
  ... ])
```

```python
sympy.codegen.ast.aug_assign(lhs, op, rhs)
```

Create `lhs op= rhs`.

**Parameters**

*lhs*: Expr
SymPy object representing the lhs of the expression. These should be singular objects, such as one would use in writing code. Notable types include Symbol, MatrixSymbol, MatrixElement, and Indexed. Types that subclass these types are also supported.

**op**: str
Operator (+, -, /, *, %).

**rhs**: Expr
SymPy object representing the rhs of the expression. This can be any type, provided its shape corresponds to that of the lhs. For example, a Matrix type can be assigned to MatrixSymbol, but not to Symbol, as the dimensions will not align.

### Explanation

Represents augmented variable assignment for code generation. This is a convenience function. You can also use the AugmentedAssignment classes directly, like AddAugmentedAssignment(x, y).

### Examples

```python
>>> from sympy import symbols
>>> from sympy.codegen.ast import aug_assign
>>> x, y = symbols('x, y')
>>> aug_assign(x, '+', y)
AddAugmentedAssignment(x, y)
```

### Special C math functions (sympy.codegen.cfunctions)

This module contains SymPy functions mathcin corresponding to special math functions in the C standard library (since C99, also available in C++11).

The functions defined in this module allows the user to express functions such as expm1 as a SymPy function for symbolic manipulation.

**class** sympy.codegen.cfunctions.Cbrt(*args)

 Represents the cube root function.

### Explanation

The reason why one would use Cbrt(x) over cbrrt(x) is that the latter is internally represented as Pow(x, Rational(1, 3)) which may not be what one wants when doing code-generation.
Examples

```python
>>> from sympy.abc import x
>>> from sympy.codegen.cfunctions import Cbrt
>>> Cbrt(x)
Cbrt(x)
>>> Cbrt(x).diff(x)
1/(3*x**(2/3))
```

See also:

- `Sqrt` (page 1188)
- `fdiff(argindex=1)`
  Returns the first derivative of this function.

**Explanation**

The reason why one would use `Sqrt(x)` over `sqrt(x)` is that the latter is internally represented as `Pow(x, S.Half)` which may not be what one wants when doing code-generation.

Examples

```python
>>> from sympy.abc import x
>>> from sympy.codegen.cfunctions import Sqrt
>>> Sqrt(x)
Sqrt(x)
>>> Sqrt(x).diff(x)
1/(2*sqrt(x))
```

See also:

- `Cbzt` (page 1187)
- `fdiff(argindex=1)`
  Returns the first derivative of this function.

**Explanation**

The reason why one would use `Sqrt(x)` over `sqrt(x)` is that the latter is internally represented as `Pow(x, S.Half)` which may not be what one wants when doing code-generation.
**Explanation**

The benefit of using \( \exp2(x) \) over \( 2^x \) is that the latter is not as efficient under finite precision arithmetic.

**Examples**

```python
>>> from sympy.abc import x
>>> from sympy.codegen.cfunctions import exp2
>>> exp2(2).evalf() == 4.0
True
>>> exp2(x).diff(x)
log(2)*exp2(x)
```

See also:
- \( \log2 \) (page 1191)
- \( \text{fdiff}(\text{argindex}=1) \)
  Returns the first derivative of this function.

**class** sympy.codegen.cfunctions.expml(arg)

Represents the exponential function minus one.

**Explanation**

The benefit of using \( \expml(x) \) over \( \exp(x) - 1 \) is that the latter is prone to cancellation under finite precision arithmetic when \( x \) is close to zero.

**Examples**

```python
>>> from sympy.abc import x
>>> from sympy.codegen.cfunctions import expml
>>> '%.0e' % expml(1e-99).evalf()
'1e-99'
>>> from math import exp
>>> exp(1e-99) - 1
0.0
>>> expml(x).diff(x)
exp(x)
```

See also:
- \( \log1p \) (page 1191)
- \( \text{fdiff}(\text{argindex}=1) \)
  Returns the first derivative of this function.

**class** sympy.codegen.cfunctions.fma(*args)

Represents “fused multiply add”.
Explanation

The benefit of using \( \text{fma}(x, y, z) \) over \( x \cdot y + z \) is that, under finite precision arithmetic, the former is supported by special instructions on some CPUs.

Examples

```python
>>> from sympy.abc import x, y, z
>>> from sympy.codegen.cfunctions import fma
>>> fma(x, y, z).diff(x)
```

\( fdiff(\text{argindex}=1) \)

Returns the first derivative of this function.

```python
class sympy.codegen.cfunctions.hypot(*args)
```

Represents the hypotenuse function.

Explanation

The hypotenuse function is provided by e.g. the math library in the C99 standard, hence one may want to represent the function symbolically when doing code-generation.

Examples

```python
>>> from sympy.abc import x, y
>>> from sympy.codegen.cfunctions import hypot
>>> hypot(3, 4).evalf() == 5.0
True
>>> hypot(x, y)
hypot(x, y)
>>> hypot(x, y).diff(x)
x/hypot(x, y)
```

\( fdiff(\text{argindex}=1) \)

Returns the first derivative of this function.

```python
class sympy.codegen.cfunctions.log10(arg)
```

Represents the logarithm function with base ten.
Examples

```python
>>> from sympy.abc import x
>>> from sympy.codegen.cfunctions import log10
>>> log10(100).evalf() == 2.0
True
>>> log10(x).diff(x)
1/(x*log(10))
```

See also:

- `log2` (page 1191)
- `fdiff(argindex=1)`
  Returns the first derivative of this function.

```python
class sympy.codegen.cfunctions.log1p(arg)

    Represents the natural logarithm of a number plus one.
```

Explanation

The benefit of using `log1p(x)` over `log(x + 1)` is that the latter is prone to cancellation under finite precision arithmetic when `x` is close to zero.

Examples

```python
>>> from sympy.abc import x
>>> from sympy.codegen.cfunctions import log1p
>>> from sympy import expand_log
>>> '%.0e' % expand_log(log1p(1e-99)).evalf()
'1e-99'
>>> from math import log
>>> log(1 + 1e-99)
0.0
>>> log1p(x).diff(x)
1/(x + 1)
```

See also:

- `expm1` (page 1189)
- `fdiff(argindex=1)`
  Returns the first derivative of this function.

```python
class sympy.codegen.cfunctions.log2(arg)

    Represents the logarithm function with base two.
```
**Explanation**

The benefit of using \( \log_2(x) \) over \( \log(x)/\log(2) \) is that the latter is not as efficient under finite precision arithmetic.

**Examples**

```python
>>> from sympy.abc import x
>>> from sympy.codegen.cfunctions import log2
>>> log2(4).evalf() == 2.0
True
>>> log2(x).diff(x)
1/(x*log(2))
```

See also:

- \( \exp_2 \) (page 1188), \( \log_{10} \) (page 1190)
- \( \texttt{fdiff} \) (argindex=1)
  
  Returns the first derivative of this function.

**C specific AST nodes (sympy.codegen.cnodes)**

AST nodes specific to the C family of languages

- **class sympy.codegen.cnodes.CommaOperator(*args)**
  
  Represents the comma operator in C

- **class sympy.codegen.cnodes.Label(*args, **kwargs)**
  
  Label for use with e.g. goto statement.

**Examples**

```python
>>> from sympy import ccode, Symbol
>>> from sympy.codegen.cnodes import Label, PreIncrement
>>> print(ccode(Label('foo')))
foo:
>>> print(ccode(Label('bar', [PreIncrement(Symbol('a'))])))
bar:
  ++(a);
```

- **class sympy.codegen.cnodes.PostDecrement(*args)**
  
  Represents the post-decrement operator

- **class sympy.codegen.cnodes.PostIncrement(*args)**
  
  Represents the post-increment operator

- **class sympy.codegen.cnodes.PreDecrement(*args)**
  
  Represents the pre-decrement operator
Examples

```python
from sympy.abc import x
from sympy.codegen.cnodes import PreDecrement
from sympy import ccode
ccode(PreDecrement(x))
'--(x)'
```

class sympy.codegen.cnodes.PreIncrement(*args)
 Represents the pre-increment operator

sympy.codegen.cnodes.alignof(arg)
 Generate of FunctionCall instance for calling ‘alignof’

class sympy.codegen.cnodes.goto(*args, **kwargs)
 Represents goto in C

sympy.codegen.cnodes.sizeof(arg)
 Generate of FunctionCall instance for calling ‘sizeof’

Examples

```python
from sympy.codegen.ast import real
from sympy.codegen.cnodes import sizeof
from sympy import ccode
ccode(sizeof(real))
'sizeof(double)'
```

class sympy.codegen.cnodes.struct(*args, **kwargs)
 Represents a struct in C

class sympy.codegen.cnodes.union(*args, **kwargs)
 Represents a union in C

C++ specific AST nodes (sympy.codegen.cxxnodes)

AST nodes specific to C++.

class sympy.codegen.cxxnodes.using(*args, **kwargs)
 Represents a ‘using’ statement in C++

Fortran specific AST nodes (sympy.codegen.fnodes)

AST nodes specific to Fortran.
The functions defined in this module allows the user to express functions such as dsign as a
SymPy function for symbolic manipulation.

class sympy.codegen.fnodes.ArrayConstructor(*args, **kwargs)
 Represents an array constructor.
Examples

```python
>>> from sympy import fcode
>>> from sympy.codegen.fnodes import ArrayConstructor
>>> ac = ArrayConstructor([1, 2, 3])
>>> fcode(ac, standard=95, source_format='free')
'(/1, 2, 3/)

>>> fcode(ac, standard=2003, source_format='free')
'[1, 2, 3]
```

class sympy.codegen.fnodes.Do(*args, **kwargs)
Represents a Do loop in in Fortran.

Examples

```python
>>> from sympy import fcode, symbols
>>> from sympy.codegen.ast import aug_assign, Print
>>> from sympy.codegen.fnodes import Do
>>> i, n = symbols('i n', integer=True)
>>> r = symbols('r', real=True)
>>> body = [aug_assign(r, '+', 1/i), Print([i, r])]
>>> do1 = Do(body, i, 1, n)
>>> print(fcode(do1, source_format='free'))
do i = 1, n
  r = r + 1d0/i
  print *, i, r
end do

>>> do2 = Do(body, i, 1, n, 2)
>>> print(fcode(do2, source_format='free'))
do i = 1, n, 2
  r = r + 1d0/i
  print *, i, r
end do
```

class sympy.codegen.fnodes.Extent(*args)
Represents a dimension extent.

Examples

```python
>>> from sympy.codegen.fnodes import Extent
>>> e = Extent(-3, 3)  # -3, -2, -1, 0, 1, 2, 3
>>> from sympy import fcode
>>> fcode(e, source_format='free')
'--3:3'
>>> from sympy.codegen.ast import Variable, real
>>> from sympy.codegen.fnodes import dimension, intent_out
>>> dim = dimension(e, e)
>>> arr = Variable('x', real, attrs=[dim, intent_out])
>>> fcode(arr.as_Declaration(), source_format='free', standard=2003)
'real*8, dimension(-3:3, -3:3), intent(out) :: x'
```
class sympy.codegen.fnodes.FortranReturn(*args, **kwargs)
AST node explicitly mapped to a fortran “return”.

Explanation

Because a return statement in fortran is different from C, and in order to aid reuse of our codegen ASTs the ordinary .codegen.ast.Return is interpreted as assignment to the result variable of the function. If one for some reason needs to generate a fortran RETURN statement, this node should be used.

Examples

```python
>>> from sympy.codegen.fnodes import FortranReturn
>>> from sympy import fcode
>>> fcode(FortranReturn('x'))
' return x'
```

class sympy.codegen.fnodes.GoTo(*args, **kwargs)
Represents a goto statement in Fortran

Examples

```python
>>> from sympy.codegen.fnodes import GoTo
>>> go = GoTo([10, 20, 30], 'i')
>>> from sympy import fcode
>>> fcode(go, source_format='free')
'go to (10, 20, 30), i'
```

class sympy.codegen.fnodes.ImpliedDoLoop(*args, **kwargs)
Represents an implied do loop in Fortran.

Examples

```python
>>> from sympy import Symbol, fcode
>>> from sympy.codegen.fnodes import ImpliedDoLoop, ArrayConstructor
>>> i = Symbol('i', integer=True)
>>> idl = ImpliedDoLoop(i**3, i, -3, 3, 2)  # -27, -1, 1, 27
>>> ac = ArrayConstructor([-28, idl, 28])  # -28, -27, -1, 1, 27, 28
>>> fcode(ac, standard=2003, source_format='free')
'[-28, (i**3, i = -3, 3, 2), 28]
```

class sympy.codegen.fnodes.Module(*args, **kwargs)
Represents a module in Fortran.
Examples

```python
>>> from sympy.codegen.fnodes import Module
>>> from sympy import fcode
>>> print(fcode(Module('signallib', ['implicit none'], []), source_format='free'))
module signallib
implicit none
contains
end module
```

class sympy.codegen.fnodes.Program(*args, **kwargs)
Represents a ‘program’ block in Fortran.

Examples

```python
>>> from sympy.codegen.ast import Print
>>> from sympy.codegen.fnodes import Program
>>> prog = Program('myprogram', [Print([42])])
>>> from sympy import fcode
>>> print(fcode(prog, source_format='free'))
program myprogram
 print *, 42
end program
```

class sympy.codegen.fnodes.Subroutine(*args, **kwargs)
Represents a subroutine in Fortran.

Examples

```python
>>> from sympy import fcode, symbols
>>> from sympy.codegen.ast import Print
>>> from sympy.codegen.fnodes import Subroutine
>>> x, y = symbols('x y', real=True)
>>> sub = Subroutine('mysub', [x, y], [Print([x**2 + y**2, x*y])])
>>> print(fcode(sub, source_format='free', standard=2003))
subroutine mysub(x, y)
 real*8 :: x
 real*8 :: y
 print *, x**2 + y**2, x*y
end subroutine
```

class sympy.codegen.fnodes.SubroutineCall(*args, **kwargs)
Represents a call to a subroutine in Fortran.
Examples

```python
>>> from sympy.codegen.fnodes import SubroutineCall
>>> from sympy import fcode
>>> fcode(SubroutineCall('mysub', 'x y'.split()))
'call mysub(x, y)'
```

`sympy.codegen.fnodes.allocated(array)`

Creates an AST node for a function call to Fortran’s “allocated(...)

Examples

```python
>>> from sympy import fcode
>>> from sympy.codegen.fnodes import allocated
>>> alloc = allocated('x')
>>> fcode(alloc, source_format='free')
'allocated(x)'
```

`sympy.codegen.fnodes.array(symbol, dim, intent=None, *, attrs=(), value=None, type=None)`

Convenience function for creating a Variable instance for a Fortran array.

**Parameters**

- **symbol**: symbol
- **dim**: Attribute or iterable
  - If `dim` is an Attribute it need to have the name ‘dimension’. If it is not an Attribute, then it is passed to `dimension()` (page 1198) as *dim
- **intent**: str
  - One of: ‘in’, ‘out’, ‘inout’ or None
- ****kwargs**:
  - Keyword arguments for `Variable` (‘type’ & ‘value’)

Examples

```python
>>> from sympy import fcode
>>> from sympy.codegen.ast import integer, real
>>> from sympy.codegen.fnodes import array
>>> arr = array('a', '*', 'in', type=integer)
>>> print(fcode(arr.as_Declaration(), source_format='free',
... standard=2003))
integer*4, dimension(*), intent(in) :: a
>>> x = array('x', [3, ':', ':'], intent='out', type=real)
>>> print(fcode(x.as_Declaration(value=1), source_format='free',
... standard=2003))
real*8, dimension(3, :, :), intent(out) :: x = 1
```
sympy.codegen.fnodes.bind_C(name=None)

Creates an Attribute bind_C with a name.

**Parameters**

name : str

**Examples**

```python
>>> from sympy import fcode, Symbol
>>> from sympy.codegen.ast import FunctionDefinition, real, Return
>>> from sympy.codegen.fnodes import array, sum_, bind_C
>>> a = Symbol('a', real=True)
>>> s = Symbol('s', integer=True)
>>> arr = array(a, dim=[s], intent='in')
>>> body = [Return((sum_(a**2)/s)**.5)]
>>> fd = FunctionDefinition(real, 'rms', [arr, s], body, attrs=[bind_C(→'rms')])
>>> print(fcode(fd, source_format='free', standard=2003))
real*8 function rms(a, s) bind(C, name="rms")
real*8, dimension(s), intent(in) :: a
integer*4 :: s
rms = sqrt(sum(a**2)/s)
end function
```

class sympy.codegen.fnodes.cmplx(*args)

Fortran complex conversion function.

class sympy.codegen.fnodes.dimension(*args)

Creates a ‘dimension’ Attribute with (up to 7) extents.

**Examples**

```python
>>> from sympy import fcode
>>> from sympy.codegen.fnodes import dimension, intent_in
>>> dim = dimension('2', ':')  # 2 rows, runtime determined number of columns
>>> from sympy.codegen.ast import Variable, integer
>>> arr = Variable('a', integer, attrs=[dim, intent_in])
>>> fcode(arr.as_Declaration(), source_format='free', standard=2003)
'integer*4, dimension(2, :), intent(in) :: a'
```

class sympy.codegen.fnodes.dsign(*args)

Fortran sign intrinsic for double precision arguments.

class sympy.codegen.fnodes.isign(*args)

Fortran sign intrinsic for integer arguments.

class sympy.codegen.fnodes.kind(*args)

Fortran kind function.

sympy.codegen.fnodes.lbound(array, dim=None, kind=None)

Creates an AST node for a function call to Fortran’s “lbound(...)”
**Parameters**

- **array**: Symbol or String
- **dim**: expr
- **kind**: expr

**Examples**

```python
class sympy.codegen.fnodes.literal_dp(num, dps=None, precision=None)
    Fortran double precision real literal
class sympy.codegen.fnodes.literal_sp(num, dps=None, precision=None)
    Fortran single precision real literal
class sympy.codegen.fnodes.merge(*args)
    Fortran merge function
sympy.codegen.fnodes.reshape(source, shape, pad=None, order=None)
    Creates an AST node for a function call to Fortran’s “reshape(...)”
    **Parameters**
    - **source**: Symbol or String
    - **shape**: ArrayExpr
sympy.codegen.fnodes.shape(source, kind=None)
    Creates an AST node for a function call to Fortran’s “shape(...)”
    **Parameters**
    - **source**: Symbol or String
    - **kind**: expr
```

```python
class sympy.codegen.fnodes.size(array, dim=None, kind=None)
    Creates an AST node for a function call to Fortran’s “size(...)”
```
Examples

```python
>>> from sympy import fcode, Symbol
>>> from sympy.codegen.ast import FunctionDefinition, real, Return
>>> from sympy.codegen.fnodes import array, sum_, size
>>> a = Symbol('a', real=True)
>>> body = [Return((sum_(a ** 2) / size(a)) ** 0.5)]
>>> arr = array(a, dim=[':'], intent='in')
>>> fd = FunctionDefinition(real, ['rms'], [arr], body)
>>> print(fcode(fd, source_format='free', standard=2003))
real*8 function rms(a)
  real*8, dimension(:), intent(in) :: a
  rms = sqrt(sum(a**2)*1d0/size(a))
end function
```

class sympy.codegen.fnodes.use(*args, **kwargs)

Represents a use statement in Fortran.

Examples

```python
>>> from sympy.codegen.fnodes import use
>>> from sympy import fcode

use signallib

fcode(use('signallib'), source_format='free')

use signallib, metric => snr

fcode(use('signallib', only=['snr', 'convolution2d']), source_format='free')

use signallib, only: snr, convolution2d
```

class sympy.codegen.fnodes.use_rename(*args, **kwargs)

Represents a renaming in a use statement in Fortran.

Examples

```python
>>> from sympy.codegen.fnodes import use_rename, use
>>> from sympy import fcode

ren = use_rename("thingy", "convolution2d")

print(fcode(ren, source_format='free'))
thingy => convolution2d

full = use('signallib', only=['snr', ren])

print(fcode(full, source_format='free'))
use signallib, only: snr, thingy => convolution2d
```
Algorithms (sympy.codegen.algorithms)

sympy.codegen.algorithms.newtons_method(expr, wrt, atol=1e-12, delta=None, debug=False, itermax=None, counter=None)

Generates an AST for Newton-Raphson method (a root-finding algorithm).

Parameters
expr : expression
  wrt : Symbol
    With respect to, i.e. what is the variable.
  atol : number or expr
    Absolute tolerance (stopping criterion)
  delta : Symbol
    Will be a Dummy if None.
  debug : bool
    Whether to print convergence information during iterations
  itermax : number or expr
    Maximum number of iterations.
  counter : Symbol
    Will be a Dummy if None.

Explanation
Returns an abstract syntax tree (AST) based on sympy.codegen.ast for Newton's method of root-finding.

Examples

```python
>>> from sympy import symbols, cos
>>> from sympy.codegen import Assignment
>>> from sympy.codegen.ast import newtons_method
>>> x, dx, atol = symbols('x dx atol')
>>> expr = cos(x) - x**3
>>> algo = newtons_method(expr, x, atol, dx)
>>> algo.has(Assignment(dx, -expr/expr.diff(x)))
True
```
References

[R40]
sympy.codegen.algorithms.newtons_method_function(expr, wrt, params=None,
func_name='newton', attrs=(), *,
delta=delta, **kwargs)

Generates an AST for a function implementing the Newton-Raphson method.

Parameters

- **expr**: expression
  - With respect to, i.e. what is the variable
- **wrt**: Symbol
  - Symbols appearing in expr that are taken as constants during the iterations (these will be accepted as parameters to the generated function).
- **params**: iterable of symbols
  - Name of the generated function.
- **func_name**: str
  - Attribute instances passed as attrs to FunctionDefinition.
- **kwargs**: Keyword arguments passed to sympy.codegen.algorithms.newtons_method() (page 1201).

Examples

```python
>>> from sympy import symbols, cos
cos
from sympy.codegen.algorithms import newtons_method_function
from sympy.codegen.pyutils import render_as_module
x = symbols('x')
expr = cos(x) - x**3
func = newtons_method_function(expr, x)
py_mod = render_as_module(func)  # source code as string
namespace = {}
exec(py_mod, namespace, namespace)
res = eval('newton(0.5)', namespace)
abs(res - 0.865474033102) < 1e-12
True
```

See also:

sympy.codegen.algorithms.newtons_method (page 1201)
**Python utilities (sympy.codegen.pyutils)**

`sympy.codegen.pyutils.render_as_module(content, standard='python3')`

Renders Python code as a module (with the required imports).

**Parameters**

`standard`

See the parameter `standard` in `sympy.printing.pycode.pycode()` (page 2251)

**C utilities (sympy.codegen.cutils)**

`sympy.codegen.cutils.render_as_source_file(content, Printer=class sympy.printing.c.C99CodePrinter, settings=None)`

Renders a C source file (with required #include statements)

**Fortran utilities (sympy.codegen.futils)**

`sympy.codegen.futils.render_as_module(definitions, name, declarations=(), printer_settings=None)`

Creates a Module instance and renders it as a string.

This generates Fortran source code for a module with the correct use statements.

**Parameters**

`definitions` : iterable

Passed to `sympy.codegen.fnodes.Module` (page 1195).

`name` : str

Passed to `sympy.codegen.fnodes.Module` (page 1195).

`declarations` : iterable

Passed to `sympy.codegen.fnodes.Module` (page 1195). It will be extended with use statements, ‘implicit none’ and public list generated from definitions.

`printer_settings` : dict

Passed to `FCodePrinter` (default: {
'standard': 2003,
'source_format': 'free'}).
5.8.3 Logic

Contents

Logic

Introduction

The logic module for SymPy allows to form and manipulate logic expressions using symbolic and Boolean values.

Forming logical expressions

You can build Boolean expressions with the standard python operators & (\texttt{And} (page 1210)), \texttt{|} (\texttt{Or} (page 1211)), \texttt{~} (\texttt{Not} (page 1211)):

```python
>>> from sympy import *
>>> x, y = symbols('x,y')
>>> y | (x & y)
>>> x | y
>>> ~x
```

You can also form implications with >> and <<:

```python
>>> x >> y
Implies(x, y)
>>> x << y
Implies(y, x)
```

Like most types in SymPy, Boolean expressions inherit from \texttt{Basic} (page 979):

```python
>>> (y & x).subs({x: True, y: True})
True
>>> (x | y).atoms()
{x, y}
```

The logic module also includes the following functions to derive boolean expressions from their truth tables:

\texttt{sympy.logic.boolalg.SOPform} (\texttt{variables, minterms, dontcares=None})

The SOPform function uses simplified pairs and a redundant group- eliminating algorithm to convert the list of all input combos that generate ‘1’ (the minterms) into the smallest sum-of-products form.

The variables must be given as the first argument.

Return a logical \texttt{Or} (page 1211) function (i.e., the “sum of products” or “SOP” form) that gives the desired outcome. If there are inputs that can be ignored, pass them as a list, too.

The result will be one of the (perhaps many) functions that satisfy the conditions.
Examples

```python
>>> from sympy.logic import SOPform
>>> from sympy import symbols

>>> w, x, y, z = symbols('w x y z')

>>> minterms = [[0, 0, 0, 1], [0, 0, 1, 1],
              [0, 1, 1, 1], [1, 0, 1, 1], [1, 1, 1, 1]]

>>> dontcares = [[0, 0, 0, 0], [0, 0, 1, 0], [0, 1, 0, 1]]

>>> SOPform([w, x, y, z], minterms, dontcares)
(y & z) | (~w & ~x)
```

The terms can also be represented as integers:

```python
>>> minterms = [1, 3, 7, 11, 15]

>>> dontcares = [0, 2, 5]

>>> SOPform([w, x, y, z], minterms, dontcares)
(y & z) | (~w & ~x)
```

They can also be specified using dicts, which does not have to be fully specified:

```python
>>> minterms = [{w: 0, x: 1}, {y: 1, z: 1, x: 0}]

>>> SOPform([w, x, y, z], minterms)
(x & ~w) | (y & z & ~x)
```

Or a combination:

```python
>>> minterms = [4, 7, 11, [1, 1, 1, 1]]

>>> dontcares = [{w : 0, x : 0, y: 0}, 5]

>>> SOPform([w, x, y, z], minterms, dontcares)
(w & y & z) | (~w & ~y) | (x & z & ~w)
```

See also:

POSform (page 1205)

References

[R572], [R573]

sympy.logic.boolalg.POSform(variables, minterms, dontcares=None)

The POSform function uses simplified_pairs and a redundant-group eliminating algorithm to convert the list of all input combinations that generate ‘1’ (the minterms) into the smallest product-of-sums form.

The variables must be given as the first argument.

Return a logical And (page 1210) function (i.e., the “product of sums” or “POS” form) that gives the desired outcome. If there are inputs that can be ignored, pass them as a list, too.

The result will be one of the (perhaps many) functions that satisfy the conditions.
Examples

```python
>>> from sympy.logic import POSform
>>> from sympy import symbols

>>> w, x, y, z = symbols('w x y z')

>>> minterms = [[0, 0, 0, 1], [0, 0, 1, 1], [0, 1, 1, 1],
              [1, 0, 1, 1], [1, 1, 1, 1]]
>>> dontcares = [[0, 0, 0, 0], [0, 0, 1, 0], [0, 1, 0, 1]]

>>> POSform([w, x, y, z], minterms, dontcares)
z & (y | ~w)
```

The terms can also be represented as integers:

```python
>>> minterms = [1, 3, 7, 11, 15]
>>> dontcares = [0, 2, 5]

>>> POSform([w, x, y, z], minterms, dontcares)
z & (y | ~w)
```

They can also be specified using dicts, which does not have to be fully specified:

```python
>>> minterms = [{w: 0, x: 1}, {y: 1, z: 1, x: 0}]

>>> POSform([w, x, y, z], minterms)
(x | y) & (x | z) & (~w | ~x)
```

Or a combination:

```python
>>> minterms = [4, 7, 11, [1, 1, 1, 1]]
>>> dontcares = [{w : 0, x : 0, y: 0}, 5]

>>> POSform([w, x, y, z], minterms, dontcares)
(w | x) & (y | ~w) & (z | ~y)
```

*SOPform* (page 1204)

References

[R574], [R575]

`sympy.logic.boolalg.ANFform(variables, truthvalues)`

The ANFform function converts the list of truth values to Algebraic Normal Form (ANF). The variables must be given as the first argument.

Return True, False, logical `And` (page 1210) function (i.e., the “Zhegalkin monomial”) or logical `Xor` (page 1212) function (i.e., the “Zhegalkin polynomial”). When True and False are represented by 1 and 0, respectively, then `And` (page 1210) is multiplication and `Xor` (page 1212) is addition.

Formally a “Zhegalkin monomial” is the product (logical `And`) of a finite set of distinct variables, including the empty set whose product is denoted 1 (True). A “Zhegalkin polynomial” is the sum (logical `Xor`) of a set of Zhegalkin monomials, with the empty set denoted by 0 (False).

**Parameters**

- `variables` : list of variables
**truthvalues**: list of 1’s and 0’s (result column of truth table)

**Examples**

```python
>>> from sympy.logic.boolalg import ANFform
>>> from sympy.abc import x, y
>>> ANFform([x], [1, 0])
x ^ True
>>> ANFform([x, y], [0, 1, 1, 1])
x ^ y ^ (x & y)
```

**References**

[R576]

**Boolean functions**

class sympy.logic.boolalg.Boolean(*args)
A Boolean object is an object for which logic operations make sense.

as_set()
Rewrites Boolean expression in terms of real sets.

**Examples**

```python
>>> from sympy import Symbol, Eq, Or, And
>>> x = Symbol('x', real=True)
>>> Eq(x, 0).as_set()
{0}
>>> (x > 0).as_set()
Interval.open(0, oo)
>>> And(-2 < x, x < 2).as_set()
Interval.open(-2, 2)
>>> Or(x < -2, 2 < x).as_set()
Union(Interval.open(-oo, -2), Interval.open(2, oo))
```

equals(other)
Returns True if the given formulas have the same truth table. For two formulas to be equal they must have the same literals.
Examples

```python
>>> from sympy.abc import A, B, C
>>> from sympy import And, Or, Not
>>> (A >> B).equals(~B >> ~A)
True
>>> Not(And(A, B, C)).equals(And(Not(A), Not(B), Not(C)))
False
>>> Not(And(A, Not(A))).equals(Or(B, Not(B)))
False
```

class sympy.logic.boolalg.BooleanTrue

SymPy version of True, a singleton that can be accessed via S.true.

This is the SymPy version of True, for use in the logic module. The primary advantage of using true instead of True is that shorthand Boolean operations like ~ and >> will work as expected on this class, whereas with True they act bitwise on 1. Functions in the logic module will return this class when they evaluate to true.

Notes

There is liable to be some confusion as to when True should be used and when S.true should be used in various contexts throughout SymPy. An important thing to remember is that sympify(True) returns S.true. This means that for the most part, you can just use True and it will automatically be converted to S.true when necessary, similar to how you can generally use 1 instead of S.One.

The rule of thumb is:

“If the boolean in question can be replaced by an arbitrary symbolic Boolean, like Or(x, y) or x > 1, use S.true. Otherwise, use True”

In other words, use S.true only on those contexts where the boolean is being used as a symbolic representation of truth. For example, if the object ends up in the .args of any expression, then it must necessarily be S.true instead of True, as elements of .args must be Basic. On the other hand, == is not a symbolic operation in SymPy, since it always returns True or False, and does so in terms of structural equality rather than mathematical, so it should return True. The assumptions system should use True and False. Aside from not satisfying the above rule of thumb, the assumptions system uses a three-valued logic (True, False, None), whereas S.true and S.false represent a two-valued logic. When in doubt, use True.

“S.true == True is True.”

While “S.true is True” is False, “S.true == True” is True, so if there is any doubt over whether a function or expression will return S.true or True, just use == instead of is to do the comparison, and it will work in either case. Finally, for boolean flags, it’s better to just use if x instead of if x is True. To quote PEP 8:

Do not compare boolean values to True or False using ==.

- Yes: if greeting:
- No: if greeting == True:
- Worse: if greeting is True:
Examples

```python
>>> from sympy import sympify, true, false, Or
>>> sympify(True)
True
>>> _ is True, _ is true
(False, True)
```

```python
>>> Or(true, false)
True
>>> _ is true
True
```

Python operators give a boolean result for true but a bitwise result for True

```python
>>> ~true, ~True
(False, -2)
>>> true >> true, True >> True
(True, 0)
```

See also:

`sympy.logic.boolalg.BooleanFalse` (page 1209)

```python
as_set()
```

Rewrite logic operators and relationals in terms of real sets.

Examples

```python
>>> from sympy import true
>>> true.as_set()
UniversalSet
```

**class sympy.logic.boolalg.BooleanFalse**

SymPy version of `False`, a singleton that can be accessed via `S.false`.

This is the SymPy version of `False`, for use in the logic module. The primary advantage of using `false` instead of `False` is that shorthand Boolean operations like `~` and `>>` will work as expected on this class, whereas with `False` they act bitwise on 0. Functions in the logic module will return this class when they evaluate to false.
**Notes**

See the notes section in `sympy.logic.boolalg.BooleanTrue` (page 1208)

**Examples**

```python
>>> from sympy import sympify, true, false, Or
>>> sympify(False)
False
>>> _ is False, _ is false
(True, False)
```

```python
>>> Or(true, false)
True
>>> _ is true
(True, True)
```

Python operators give a boolean result for false but a bitwise result for False

```python
>>> ~false, ~False
(True, False)
>>> false >> false, False >> False
(True, False)
```

**See also:**

`sympy.logic.boolalg.BooleanTrue` (page 1208)

**as_set()**

Rewrite logic operators and relationals in terms of real sets.

**Examples**

```python
>>> from sympy import false
>>> false.as_set()
EmptySet
```

**class** `sympy.logic.boolalg.And(*args)`

Logical AND function.

It evaluates its arguments in order, returning false immediately when an argument is false and true if they are all true.
Examples

```python
>>> from sympy.abc import x, y
>>> from sympy import And
>>> x & y
x & y
```

Notes

The & operator is provided as a convenience, but note that its use here is different from its normal use in Python, which is bitwise and. Hence, `And(a, b)` and `a & b` will produce different results if `a` and `b` are integers.

```python
>>> And(x, y).subs(x, 1)
y
```

```python
class sympy.logic.boolalg.Or(*args)
Logical OR function
```

It evaluates its arguments in order, returning true immediately when an argument is true, and false if they are all false.

Examples

```python
>>> from sympy.abc import x, y
>>> from sympy import Or
>>> x | y
x | y
```

Notes

The | operator is provided as a convenience, but note that its use here is different from its normal use in Python, which is bitwise or. Hence, `Or(a, b)` and `a | b` will return different things if `a` and `b` are integers.

```python
>>> Or(x, y).subs(x, 0)
y
```

```python
class sympy.logic.boolalg.Not(arg)
Logical Not function (negation)
```

Returns true if the statement is false or False. Returns false if the statement is true or True.
Examples

```python
>>> from sympy import Not, And, Or
>>> from sympy.abc import x, A, B
>>> Not(True)
False
>>> Not(False)
True
>>> Not(And(True, False))
True
>>> Not(Or(True, False))
False
>>> Not(And(And(True, x), Or(x, False)))
~x
>>> ~x
~x
>>> Not(And(Or(A, B), Or(~A, ~B)))
~((A | B) & (~A | ~B))
```

Notes

- The `~` operator is provided as a convenience, but note that its use here is different from its normal use in Python, which is bitwise not. In particular, `~a` and `Not(a)` will be different if `a` is an integer. Furthermore, since bools in Python subclass from `int`, `~True` is the same as `~1` which is `-2`, which has a boolean value of `True`. To avoid this issue, use the SymPy boolean types `true` and `false`.

```python
>>> from sympy import true
>>> ~true
False
```

class sympy.logic.boolalg.Xor(*args)

Logical XOR (exclusive OR) function.

Returns True if an odd number of the arguments are True and the rest are False.

Returns False if an even number of the arguments are True and the rest are False.

Examples

```python
>>> from sympy.logic.boolalg import Xor
>>> from sympy import symbols
>>> x, y = symbols('x y')
>>> Xor(True, False)
True
>>> Xor(True, True)
False
>>> Xor(True, False, True, True, False)
(continues on next page)
```
True
>>> Xor(True, False, True, False)
False
>>> x ^ y
x ^ y

Notes

The `^` operator is provided as a convenience, but note that its use here is different from its normal use in Python, which is bitwise xor. In particular, `a ^ b` and `Xor(a, b)` will be different if `a` and `b` are integers.

```python
>>> Xor(x, y).subs(y, 0)
x
```

class sympy.logic.boolalg.Nand(*args)
Logical NAND function.
It evaluates its arguments in order, giving True immediately if any of them are False, and False if they are all True.
Returns True if any of the arguments are False Returns False if all arguments are True

Examples

```python
>>> from sympy.logic.boolalg import Nand
>>> from sympy import symbols
>>> x, y = symbols('x y')
>>> Nand(False, True)
True
>>> Nand(True, True)
False
>>> Nand(x, y)
~(x & y)
```

class sympy.logic.boolalg.Nor(*args)
Logical NOR function.
It evaluates its arguments in order, giving False immediately if any of them are True, and True if they are all False.
Returns False if any argument is True Returns True if all arguments are False
Examples

```python
>>> from sympy.logic.boolalg import Nor
>>> from sympy import symbols
>>> x, y = symbols('x y')
```

```python
>>> Nor(True, False)
False
>>> Nor(True, True)
False
>>> Nor(False, True)
False
>>> Nor(False, False)
True
>>> Nor(x, y)
~(x | y)
```

class sympy.logic.boolalg.Xnor(*args)

Logical XNOR function.

Returns False if an odd number of the arguments are True and the rest are False.

Returns True if an even number of the arguments are True and the rest are False.

Examples

```python
>>> from sympy.logic.boolalg import Xnor
>>> from sympy import symbols
>>> x, y = symbols('x y')
>>> Xnor(True, False)
False
>>> Xnor(True, True)
True
>>> Xnor(True, False, True, True, False)
False
>>> Xnor(True, False, True, False)
True
```

class sympy.logic.boolalg.Implies(*args)

Logical implication.

A implies B is equivalent to if A then B. Mathematically, it is written as $A \Rightarrow B$ and is equivalent to $\neg A \lor B$ or $\neg A \mid B$.

Accepts two Boolean arguments; A and B. Returns False if A is True and B is False Returns True otherwise.
Examples

```python
>>> from sympy.logic.boolalg import Implies
>>> from sympy import symbols
>>> x, y = symbols('x y')

>>> Implies(True, False)
False
>>> Implies(False, False)
True
>>> Implies(True, True)
True
>>> Implies(False, True)
True
>>> x >> y
Implies(x, y)
>>> y << x
Implies(x, y)
```

Notes

The `>>` and `<<` operators are provided as a convenience, but note that their use here is different from their normal use in Python, which is bit shifts. Hence, `Implies(a, b)` and `a >> b` will return different things if `a` and `b` are integers. In particular, since Python considers `True` and `False` to be integers, `True >> True` will be the same as `1 >> 1`, i.e., `0`, which has a truth value of `False`. To avoid this issue, use the SymPy objects `true` and `false`.

```python
>>> from sympy import true, false
>>> True >> False
1
>>> true >> false
False
```

class sympy.logic.boolalg.Equivalent(*args)

Equivalence relation.

`Equivalent(A, B)` is True iff A and B are both True or both False.

Returns True if all of the arguments are logically equivalent. Returns False otherwise.

For two arguments, this is equivalent to `Xnor` (page 1214).
Examples

```python
>>> from sympy.logic.boolalg import Equivalent, And
>>> from sympy.abc import x
>>> Equivalent(False, False, False)
True
>>> Equivalent(True, False, False)
False
>>> Equivalent(x, And(x, True))
True
```

class sympy.logic.boolalg.ITE(*args)
If-then-else clause.

ITE(A, B, C) evaluates and returns the result of B if A is true else it returns the result of C. All args must be Booleans.

From a logic gate perspective, ITE corresponds to a 2-to-1 multiplexer, where A is the select signal.

Examples

```python
>>> from sympy.logic.boolalg import ITE, And, Xor, Or
>>> from sympy.abc import x, y, z
>>> ITE(True, False, True)
False
>>> ITE(Or(True, False), And(True, True), Xor(True, True))
True
>>> ITE(x, y, z)
ITE(x, y, z)
```

Trying to use non-Boolean args will generate a TypeError:

```python
>>> ITE(True, [], ())
Traceback (most recent call last):
...
TypeError: expecting bool, Boolean or ITE, not `[]`
```

class sympy.logic.boolalg.Exclusive(*args)
True if only one or no argument is true.

Exclusive(A, B, C) is equivalent to ~(A & B) & ~(A & C) & ~(B & C).

For two arguments, this is equivalent to Xor (page 1212).
Examples

```python
>>> from sympy.logic.boolalg import Exclusive
>>> Exclusive(False, False, False)
True
>>> Exclusive(False, True, False)
True
>>> Exclusive(False, True, True)
False
```

The following functions can be used to handle Algebraic, Conjunctive, Disjunctive, and Negated Normal forms:

**sympy.logic.boolalg.to_anf(expr, deep=True)**

Converts `expr` to Algebraic Normal Form (ANF).

ANF is a canonical normal form, which means that two equivalent formulas will convert to the same ANF.

A logical expression is in ANF if it has the form

\[ 1 \oplus a \oplus b \oplus ab \oplus abc \]

i.e. it can be:

- purely true,
- purely false,
- conjunction of variables,
- exclusive disjunction.

The exclusive disjunction can only contain true, variables or conjunction of variables. No negations are permitted.

If `deep` is `False`, arguments of the boolean expression are considered variables, i.e. only the top-level expression is converted to ANF.

**Examples**

```python
>>> from sympy.logic.boolalg import And, Or, Not, Implies, Equivalent
>>> from sympy.logic.boolalg import to_anf
>>> from sympy.abc import A, B, C
>>> to_anf(Not(A))
A ^ True
>>> to_anf(And(Or(A, B), Not(C)))
A ^ B ^ (A & B) ^ (A & C) ^ (B & C) ^ (A & B & C)
>>> to_anf(Implies(Not(A), Equivalent(B, C)), deep=False)
True ^ ~A ^ (~A & (Equivalent(B, C)))
```

**sympy.logic.boolalg.to_cnf(expr, simplify=False, force=False)**

Convert a propositional logical sentence `expr` to conjunctive normal form: \((A \mid \neg B \mid \ldots) \& (B \mid C \mid \ldots) \& \ldots\). If `simplify` is `True`, `expr` is evaluated to its simplest CNF form using the Quine-McCluskey algorithm; this may take a long time. If there are more than 8 variables the `force` flag must be set to `True` to simplify (default is `False`).
Examples

```python
>>> from sympy.logic.boolalg import to_cnf
>>> from sympy import A, B, D
>>> to_cnf(~(A | B) | D)
(D | ~A) & (D | ~B)
>>> to_cnf((A | B) & (A | ~A), True)
A | B
```

`sympy.logic.boolalg.to_dnf(expr, simplify=False, force=False)`

Convert a propositional logical sentence `expr` to disjunctive normal form: `((A & ~B & ...) | (B & C & ...) | ...)`. If `simplify` is `True`, `expr` is evaluated to its simplest DNF form using the Quine-McCluskey algorithm; this may take a long time. If there are more than 8 variables, the `force` flag must be set to `True` to simplify (default is `False`).

Examples

```python
>>> from sympy.logic.boolalg import to_dnf
>>> from sympy import A, B, C
>>> to_dnf(B & (A | C))
(A & B) | (B & C)
>>> to_dnf((A & B) | (A & ~B) | (B & C) | (~B & C), True)
A | C
```

`sympy.logic.boolalg.to_nnf(expr, simplify=True)`

Converts `expr` to Negation Normal Form (NNF).

A logical expression is in NNF if it contains only `And` (page 1210), `Or` (page 1211) and `Not` (page 1211), and `Not` (page 1211) is applied only to literals. If `simplify` is `True`, the result contains no redundant clauses.

Examples

```python
>>> from sympy.abc import A, B, C, D
>>> from sympy.logic.boolalg import Not, Equivalent, to_nnf
>>> to_nnf(Not(~(A & ~B) | (C & D)))
(A | B) & (~C | ~D)
>>> to_nnf(Equivalent(A >> B, B >> A))
(A | ~B | (A & ~B)) & (B | ~A | (B & ~A))
```

`sympy.logic.boolalg.is_anf(expr)`

Checks if `expr` is in Algebraic Normal Form (ANF).

A logical expression is in ANF if it has the form

```
1 \oplus a \oplus b \oplus ab \oplus abc
```

i.e. it is purely true, purely false, conjunction of variables or exclusive disjunction. The exclusive disjunction can only contain true, variables or conjunction of variables. No negations are permitted.
**Examples**

```python
>>> from sympy.logic.boolalg import And, Not, Xor, true, is_anf
>>> from sympy.abc import A, B, C
>>> is_anf(true)
True
>>> is_anf(A)
True
>>> is_anf(And(A, B, C))
True
>>> is_anf(Xor(A, Not(B)))
False
```

-symy.logic.boolalg.is_cnf(expr)-

Test whether or not an expression is in conjunctive normal form.

**Examples**

```python
>>> from sympy.logic.boolalg import is_cnf
>>> from sympy.abc import A, B, C
>>> is_cnf(A | B | C)
True
>>> is_cnf(A & B & C)
True
>>> is_cnf((A & B) | C)
False
```

-symy.logic.boolalg.is_dnf(expr)-

Test whether or not an expression is in disjunctive normal form.

**Examples**

```python
>>> from sympy.logic.boolalg import is_dnf
>>> from sympy.abc import A, B, C
>>> is_dnf(A | B | C)
True
>>> is_dnf(A & B & C)
True
>>> is_dnf((A & B) | C)
True
>>> is_dnf(A & (B | C))
False
```

-symy.logic.boolalg.is_nnf(expr, simplified=True)-

Checks if expr is in Negation Normal Form (NNF).

A logical expression is in NNF if it contains only `And` (page 1210), `Or` (page 1211) and `Not` (page 1211), and `Not` (page 1211) is applied only to literals. If `simplified` is `True`, checks if result contains no redundant clauses.
Examples

```python
>>> from sympy.abc import A, B, C
>>> from sympy.logic.boolalg import Not, is_nnf
>>> is_nnf(A & B | ~C)
True
>>> is_nnf((A | ~A) & (B | C))
False
>>> is_nnf((A | ~A) & (B | C), False)
True
>>> is_nnf(Not(A & B) | C)
False
>>> is_nnf((A >> B) & (B >> A))
False
```

`sympy.logic.boolalg.gateinputcount(expr)`

Return the total number of inputs for the logic gates realizing the Boolean expression.

**Returns**

`int`

Number of gate inputs

**Note**

Not all Boolean functions count as gate here, only those that are considered to be standard gates. These are: `And` (page 1210), `Or` (page 1211), `Xor` (page 1212), `Not` (page 1211), and `ITE` (page 1216) (multiplexer). `Nand` (page 1213), `Nor` (page 1213), and `Xnor` (page 1214) will be evaluated to `Not(And())` etc.

Examples

```python
>>> from sympy.logic import And, Or, Nand, Not, gateinputcount
>>> from sympy.abc import x, y, z
>>> expr = And(x, y)
>>> gateinputcount(expr)
2
>>> gateinputcount(Or(expr, z))
4
```

Note that `Nand` is automatically evaluated to `Not(And())` so

```python
>>> gateinputcount(Nand(x, y, z))
4
>>> gateinputcount(Not(And(x, y, z)))
4
```

Although this can be avoided by using `evaluate=False`

```python
>>> gateinputcount(Nand(x, y, z, evaluate=False))
3
```
Also note that a comparison will count as a Boolean variable:

```python
>>> gateinputcount(And(x > z, y >= 2))
2
```

As will a symbol: >>> gateinputcount(x) 0

### Simplification and equivalence-testing

`sympy.logic.boolalg.simplify_logic(expr, form=None, deep=True, force=False, dontcare=None)`

This function simplifies a boolean function to its simplified version in SOP or POS form. The return type is an `Or` (page 1211) or `And` (page 1210) object in SymPy.

**Parameters**

- `expr`: Boolean
- `form`: string ('cnf' or 'dnf') or None (default).
  - If 'cnf' or 'dnf', the simplest expression in the corresponding normal form is returned; if None, the answer is returned according to the form with fewest args (in CNF by default).
- `deep`: bool (default True)
  - Indicates whether to recursively simplify any non-boolean functions contained within the input.
- `force`: bool (default False)
  - As the simplifications require exponential time in the number of variables, there is by default a limit on expressions with 8 variables. When the expression has more than 8 variables only symbolical simplification (controlled by `deep`) is made. By setting `force` to True, this limit is removed. Be aware that this can lead to very long simplification times.
- `dontcare`: Boolean
  - Optimize expression under the assumption that inputs where this expression is true are don’t care. This is useful in e.g. Piecewise conditions, where later conditions do not need to consider inputs that are converted by previous conditions. For example, if a previous condition is `And(A, B)`, the simplification of `expr` can be made with don’t cares for `And(A, B)`.

**Examples**

```python
>>> from sympy.logic import simplify_logic
>>> from sympy.abc import x, y, z
>>> b = (~x & ~y & ~z) | (~x & ~y & z)
>>> simplify_logic(b)
~x & ~y
>>> simplify_logic(x | y, dontcare=y)
x
```
SymPy's `simplify()` function can also be used to simplify logic expressions to their simplest forms.

```
sympy.logic.boolalg.bool_map(bool1, bool2)
```

Return the simplified version of `bool1`, and the mapping of variables that makes the two expressions `bool1` and `bool2` represent the same logical behaviour for some correspondence between the variables of each. If more than one mappings of this sort exist, one of them is returned.

For example, `And(x, y)` is logically equivalent to `And(a, b)` for the mapping `{x: a, y: b}` or `{x: b, y: a}`. If no such mapping exists, return `False`.

**Examples**

```python
>>> from sympy import SOPform, bool_map, Or, And, Not, Xor
>>> from sympy.abc import w, x, y, z, a, b, c, d
>>> function1 = SOPform([x, z, y], [[1, 0, 1], [0, 0, 1]])
>>> function2 = SOPform([a, b, c], [[1, 0, 1], [1, 0, 0]])
>>> bool_map(function1, function2)
(y & ~z, {y: a, z: b})
```

The results are not necessarily unique, but they are canonical. Here, `(w, z)` could be `(a, d)` or `(d, a):

```python
>>> eq = Or(And(Not(y), w), And(Not(y), z), And(x, y))
>>> eq2 = Or(And(Not(c), a), And(Not(c), d), And(b, c))
>>> bool_map(eq, eq2)
((x & y) | (w & ~y) | (z & ~y), {w: a, x: b, y: c, z: d})
```

**Manipulating expressions**

The following functions can be used to manipulate Boolean expressions:

```
sympy.logic.boolalg.distribute_and_over_or(expr)
```

Given a sentence `expr` consisting of conjunctions and disjunctions of literals, return an equivalent sentence in CNF.
Examples

```python
>>> from sympy.logic.boolalg import distribute_and_over_or, And, Or, Not
>>> from sympy.abc import A, B, C
>>> distribute_and_over_or(Or(A, And(Not(B), Not(C))))
(A | ~B) & (A | ~C)
```

`sympy.logic.boolalg.distribute_or_over_and(expr)`

Given a sentence `expr` consisting of conjunctions and disjunctions of literals, return an equivalent sentence in DNF.

Note that the output is NOT simplified.

Examples

```python
>>> from sympy.logic.boolalg import distribute_or_over_and, And, Or, Not
>>> from sympy.abc import A, B, C
>>> distribute_or_over_and(And(Or(Not(A), B), C))
(B & C) | (C & ~A)
```

`sympy.logic.boolalg.distribute_xor_over_and(expr)`

Given a sentence `expr` consisting of conjunction and exclusive disjunctions of literals, return an equivalent exclusive disjunction.

Note that the output is NOT simplified.

Examples

```python
>>> from sympy.logic.boolalg import distribute_xor_over_and, And, Xor,
>>> from sympy.abc import A, B, C
>>> distribute_xor_over_and(And(Xor(Not(A), B), C))
(B & C) ^ (C & ~A)
```

`sympy.logic.boolalg.eliminate_implications(expr)`

Change `Implies` (page 1214) and `Equivalent` (page 1215) into `And` (page 1210), `Or` (page 1211), and `Not` (page 1211). That is, return an expression that is equivalent to `expr`, but has only `&`, `|`, and `~` as logical operators.

Examples

```python
>>> from sympy.logic.boolalg import Implies, Equivalent, Not
>>> eliminate_implications
>>> from sympy.abc import A, B, C
>>> eliminate_implications(Implies(A, B))
B | ~A
>>> eliminate_implications(Equivalent(A, B))
(A | ~B) & (B | ~A)
>>> eliminate_implications(Equivalent(A, B, C))
(A | ~C) & (B | ~A) & (C | ~B)
```
Truth tables and related functions

It is possible to create a truth table for a Boolean function with
sympy.logic.boolalg.truth_table(expr, variables, input=True)

Return a generator of all possible configurations of the input variables, and the result of the boolean expression for those values.

Parameters
  expr : Boolean expression
  variables : list of variables
  input : bool (default True)

Indicates whether to return the input combinations.

Examples

```python
>>> from sympy.logic.boolalg import truth_table
>>> from sympy.abc import x,y
>>> table = truth_table(x >> y, [x, y])
>>> for t in table:
...   print('{0} -> {1}'.format(*t))
[0, 0] -> True
[0, 1] -> True
[1, 0] -> False
[1, 1] -> True
```

If input is False, truth_table returns only a list of truth values. In this case, the corresponding input values of variables can be deduced from the index of a given output.

```python
>>> table = truth_table(x | y, [x, y])
>>> list(table)
[[[0, 0], False], [[0, 1], True], [[1, 0], True], [[1, 1], True]]
```

For mapping between integer representations of truth table positions, lists of zeros and ones and symbols, the following functions can be used:

```python
>>> from sympy.utilities.iterables import ibin
>>> vars = [y, x]
>>> values = truth_table(x >> y, vars, input=False)
>>> values = list(values)
>>> values
[True, False, True, True]

>>> for i, value in enumerate(values):
...   print('{0} -> {1}'.format(list(zip(...   vars, ibin(i, len(vars)))), value))
[(y, 0), (x, 0)] -> True
[(y, 0), (x, 1)] -> False
[(y, 1), (x, 0)] -> True
[(y, 1), (x, 1)] -> True
```
sympy.logic.boolalg.integer_to_term \( n, \text{bits=None, str=False} \)

Return a list of length \( \text{bits} \) corresponding to the binary value of \( n \) with small bits to the right (last). If \( \text{bits} \) is omitted, the length will be the number required to represent \( n \). If the bits are desired in reversed order, use the \([::-1]\) slice of the returned list.

If a sequence of all bits-length lists starting from \([0,0,...,0]\) through \([1,1,...,1]\) are desired, pass a non-integer for \( \text{bits} \), e.g. 'all'.

If the bit \textit{string} is desired pass \text{str=True}.

\section*{Examples}

\begin{verbatim}
>>> from sympy.utilities.iterables import ibin
>>> ibin(2)
[1, 0]
>>> ibin(2, 4)
[0, 0, 1, 0]
\end{verbatim}

If all lists corresponding to 0 to \( 2^n-1 \), pass a non-integer for \( \text{bits} \):

\begin{verbatim}
>>> bits = 2
>>> for i in ibin(2, 'all'):
...    print(i)
(0, 0)
(0, 1)
(1, 0)
(1, 1)
\end{verbatim}

If a bit string is desired of a given length, use \text{str=True}:

\begin{verbatim}
>>> n = 123
>>> bits = 10
>>> ibin(n, bits, \text{str=True})
'0001111011'
>>> ibin(n, bits, \text{str=True})[::-1]  # small bits left
'1101111000'
>>> list(ibin(3, 'all', \text{str=True}))
['000', '001', '010', '011', '100', '101', '110', '111']
\end{verbatim}

sympy.logic.boolalg.term_to_integer \( \text{term} \)

Return an integer corresponding to the base-2 digits given by \( \text{term} \).

\subsection*{Parameters}

\text{term} : a string or list of ones and zeros
**Examples**

```python
>>> from sympy.logic.boolalg import term_to_integer
>>> term_to_integer([1, 0, 0])
4
>>> term_to_integer('100')
4
```

```python
sympy.logic.boolalg.bool_maxterm(k, variables)
```

Return the k-th maxterm.

Each maxterm is assigned an index based on the opposite conventional binary encoding used for minterms. The maxterm convention assigns the value 0 to the direct form and 1 to the complemented form.

**Parameters**
- `k` : int or list of 1’s and 0’s (complementation pattern)
- `variables` : list of variables

**Examples**

```python
>>> from sympy.logic.boolalg import bool_maxterm
>>> from sympy.abc import x, y, z
>>> bool_maxterm([1, 0, 1], [x, y, z])
y | ~x | ~z
>>> bool_maxterm(6, [x, y, z])
z | ~x | ~y
```

**References**

[R578]

```python
sympy.logic.boolalg.bool_minterm(k, variables)
```

Return the k-th minterm.

Minterms are numbered by a binary encoding of the complementation pattern of the variables. This convention assigns the value 1 to the direct form and 0 to the complemented form.

**Parameters**
- `k` : int or list of 1’s and 0’s (complementation pattern)
- `variables` : list of variables
Examples

```python
>>> from sympy.logic.boolalg import bool_minterm
>>> from sympy.abc import x, y, z
>>> bool_minterm([1, 0, 1], [x, y, z])
x & z & ~y
>>> bool_minterm(6, [x, y, z])
x & y & ~z
```

References

[R579]

sympy.logic.boolalg.bool_monomial(k, variables)

Return the k-th monomial.

Monomials are numbered by a binary encoding of the presence and absences of the variables. This convention assigns the value 1 to the presence of variable and 0 to the absence of variable.

Each boolean function can be uniquely represented by a Zhegalkin Polynomial (Algebraic Normal Form). The Zhegalkin Polynomial of the boolean function with \( n \) variables can contain up to \( 2^n \) monomials. We can enumerate all the monomials. Each monomial is fully specified by the presence or absence of each variable.

For example, boolean function with four variables \((a, b, c, d)\) can contain up to \(2^4 = 16\) monomials. The 13-th monomial is the product \(a \& b \& d\), because 13 in binary is 1, 1, 0, 1.

Parameters

- \( k \): int or list of 1’s and 0’s
- `variables`: list of variables

Examples

```python
>>> from sympy.logic.boolalg import bool_monomial
>>> from sympy.abc import x, y, z
>>> bool_monomial([1, 0, 1], [x, y, z])
x & z
>>> bool_monomial(6, [x, y, z])
x & y
```

sympy.logic.boolalg.anf_coeffs(truthvalues)

Convert a list of truth values of some boolean expression to the list of coefficients of the polynomial mod 2 (exclusive disjunction) representing the boolean expression in ANF (i.e., the “Zhegalkin polynomial”).

There are \(2^n\) possible Zhegalkin monomials in \( n \) variables, since each monomial is fully specified by the presence or absence of each variable.

We can enumerate all the monomials. For example, boolean function with four variables \((a, b, c, d)\) can contain up to \(2^4 = 16\) monomials. The 13-th monomial is the product \(a \& b \& d\), because 13 in binary is 1, 1, 0, 1.
A given monomial’s presence or absence in a polynomial corresponds to that monomial’s coefficient being 1 or 0 respectively.

**Examples**

```python
>>> from sympy.logic.boolalg import anf_coeffs, bool_monomial, Xor
>>> from sympy import a, b, c
>>> truthvalues = [0, 1, 1, 0, 0, 1, 0, 1]
>>> coeffs = anf_coeffs(truthvalues)
>>> coeffs
[0, 1, 0, 0, 1, 0, 1, 0]
>>> polynomial = Xor(*
...     for k, coeff in enumerate(coeffs) if coeff == 1
...     bool_monomial(k, [a, b, c])
... )
>>> polynomial
b ^ c ^ (a & b)
```

**sympy.logic.boolalg.to_int_repr**(clauses, symbols)

Takes clauses in CNF format and puts them into an integer representation.

**Examples**

```python
>>> from sympy.logic.boolalg import to_intrepr
>>> from sympy import x, y
>>> to_intrepr([x | y, y]) == [{1, 2}, {2}]
True
```

**Inference**

This module implements some inference routines in propositional logic.

The function satisfiable will test that a given Boolean expression is satisfiable, that is, you can assign values to the variables to make the sentence True.

For example, the expression \(x \& \neg x\) is not satisfiable, since there are no values for \(x\) that make this sentence True. On the other hand, \((x \mid y) \& (x \mid \neg y) \& (\neg x \mid y)\) is satisfiable with both \(x\) and \(y\) being True.

```python
>>> from sympy.logic.inference import satisfiable
>>> from sympy import Symbol
>>> x = Symbol('x')
>>> y = Symbol('y')
>>> satisfiable(x & ~x)
False
>>> satisfiable((x | y) & (x | ~y) & (~x | y))
{x: True, y: True}
```

As you see, when a sentence is satisfiable, it returns a model that makes that sentence True. If it is not satisfiable it will return False.
sympy.logic.inference.satisfiable(expr, algorithm=None, all_models=False, minimal=False)

Checks satisfiability of a propositional sentence. Returns a model when it succeeds. Returns {true: true} for trivially true expressions.

On setting all_models to True, if given expr is satisfiable then returns a generator of models. However, if expr is unsatisfiable then returns a generator containing the single element False.

Examples

```python
>>> from sympy import A, B
>>> from sympy.logic.inference import satisfiable
>>> satisfiable(A & ~B)
{A: True, B: False}
>>> satisfiable(A & ~A)
False
>>> satisfiable(True)
{True: True}
>>> next(satisfiable(A & ~A, all_models=True))
False
>>> models = satisfiable((A >> B) & B, all_models=True)
>>> next(models)
{A: False, B: True}
>>> next(models)
{A: True, B: True}
>>> def use_models(models):
...     for model in models:
...         if model:
...             # Do something with the model.
...             print(model)
...         else:
...             # Given expr is unsatisfiable.
...             print("UNSAT")
>>> use_models(satisfiable(A >> ~A, all_models=True))
{A: False}
>>> use_models(satisfiable(A ^ A, all_models=True))
UNSAT
```

Sets

Basic Sets

```python
class sympy.sets.sets.Set(*args)
```

The base class for any kind of set.
**Explanation**

This is not meant to be used directly as a container of items. It does not behave like the built-in set; see `FiniteSet` (page 1241) for that.

Real intervals are represented by the `Interval` (page 1239) class and unions of sets by the `Union` (page 1241) class. The empty set is represented by the `EmptySet` (page 1245) class and available as a singleton as `S.EmptySet`.

**property boundary**

The boundary or frontier of a set.

**Explanation**

A point $x$ is on the boundary of a set $S$ if

1. $x$ is in the closure of $S$. I.e. Every neighborhood of $x$ contains a point in $S$.
2. $x$ is not in the interior of $S$. I.e. There does not exist an open set centered on $x$ contained entirely within $S$.

There are the points on the outer rim of $S$. If $S$ is open then these points need not actually be contained within $S$.

For example, the boundary of an interval is its start and end points. This is true regardless of whether or not the interval is open.

**Examples**

```python
>>> from sympy import Interval
>>> Interval(0, 1).boundary
{0, 1}
>>> Interval(0, 1, True, False).boundary
{0, 1}
```

**property closure**

Property method which returns the closure of a set. The closure is defined as the union of the set itself and its boundary.

**Examples**

```python
>>> from sympy import S, Interval
>>> S.Reals.closure
Reals
>>> Interval(0, 1).closure
Interval(0, 1)
```

**complement**(universe)

The complement of ‘self’ w.r.t the given universe.
Examples

```
>>> from sympy import Interval, S
>>> Interval(0, 1).complement(S.Reals)
Union(Interval.open(-oo, 0), Interval.open(1, oo))

>>> Interval(0, 1).complement(S.UniversalSet)
Complement(UniversalSet, Interval(0, 1))
```

`contains(other)`
Returns a SymPy value indicating whether other is contained in self: true if it is, false if it is not, else an unevaluated Contains expression (or, as in the case of ConditionSet and a union of FiniteSet/Intervals, an expression indicating the conditions for containment).

Examples

```
>>> from sympy import Interval, S
>>> from sympy.abc import x

>>> Interval(0, 1).contains(0.5)
True

As a shortcut it is possible to use the in operator, but that will raise an error unless an affirmative true or false is not obtained.

>>> Interval(0, 1).contains(x)
(0 <= x) & (x <= 1)
>>> x in Interval(0, 1)
 Traceback (most recent call last):
   ...
TypeError: did not evaluate to a bool: None
```

The result of ‘in’ is a bool, not a SymPy value

```
>>> 1 in Interval(0, 2)
True
>>> _ is S.true
False
```

`property inf`
The infimum of self.
Examples

```python
>>> from sympy import Interval, Union
>>> Interval(0, 1).inf
0
>>> Union(Interval(0, 1), Interval(2, 3)).inf
0
```

**property interior**

Property method which returns the interior of a set. The interior of a set S consists of all points of S that do not belong to the boundary of S.

Examples

```python
>>> from sympy import Interval
>>> Interval(0, 1).interior
Interval.open(0, 1)
>>> Interval(0, 1).boundary.interior
EmptySet
```

**intersect(other)**

Returns the intersection of ‘self’ and ‘other’.

Examples

```python
>>> from sympy import Interval
>>> Interval(1, 3).intersect(Interval(1, 2))
Interval(1, 2)
```

**intersection(other)**

Alias for `intersect()` (page 1232)

**property is_closed**

A property method to check whether a set is closed.
Explanation

A set is closed if its complement is an open set. The closedness of a subset of the reals is determined with respect to R and its standard topology.

Examples

```python
>>> from sympy import Interval
>>> Interval(0, 1).is_closed
True
```

is_disjoint(other)

Returns True if self and other are disjoint.

Examples

```python
>>> from sympy import Interval
>>> Interval(0, 2).is_disjoint(Interval(1, 2))
False
>>> Interval(0, 2).is_disjoint(Interval(3, 4))
True
```

References

[R769]

property is_open

Property method to check whether a set is open.

Explanation

A set is open if and only if it has an empty intersection with its boundary. In particular, a subset A of the reals is open if and only if each one of its points is contained in an open interval that is a subset of A.

Examples

```python
>>> from sympy import S
>>> S.Reals.is_open
True
>>> S.Rationals.is_open
False
```

is_proper_subset(other)

Returns True if self is a proper subset of other.
Examples

```python
>>> from sympy import Interval
>>> Interval(0, 0.5).is_proper_subset(Interval(0, 1))
True
>>> Interval(0, 1).is_proper_subset(Interval(0, 1))
False
```

**is_proper_superset(other)**

Returns True if self is a proper superset of other.

Examples

```python
>>> from sympy import Interval
>>> Interval(0, 1).is_proper_superset(Interval(0, 0.5))
True
>>> Interval(0, 1).is_proper_superset(Interval(0, 1))
False
```

**is_subset(other)**

Returns True if self is a subset of other.

Examples

```python
>>> from sympy import Interval
>>> Interval(0, 0.5).is_subset(Interval(0, 1))
True
>>> Interval(0, 1).is_subset(Interval(0, 1, left_open=True))
False
```

**is_superset(other)**

Returns True if self is a superset of other.

Examples

```python
>>> from sympy import Interval
>>> Interval(0, 0.5).is_superset(Interval(0, 1))
False
>>> Interval(0, 1).is_superset(Interval(0, 1, left_open=True))
True
```

**isdisjoint(other)**

Alias for `is_disjoint()` (page 1233)

**issubset(other)**

Alias for `is_subset()` (page 1234)

**issuperset(other)**

Alias for `is_superset()` (page 1234)
property kind

The kind of a Set

Explanation

Any Set (page 1229) will have kind SetKind (page 1259) which is parametrised by the kind of the elements of the set. For example most sets are sets of numbers and will have kind SetKind(NumberKind). If elements of sets are different in kind than their kind will SetKind(UndefinedKind). See sympy.core.kind.Kind (page 1118) for an explanation of the kind system.

Examples

```
>>> from sympy import Interval, Matrix, FiniteSet, EmptySet, 
    ProductSet, PowerSet

>>> FiniteSet(Matrix([1, 2])).kind
SetKind(MatrixKind(NumberKind))

>>> Interval(1, 2).kind
SetKind(NumberKind)

>>> EmptySet.kind
SetKind()

A sympy.sets.powerset.PowerSet (page 1256) is a set of sets:

>>> PowerSet({1, 2, 3}).kind
SetKind(SetKind(NumberKind))

A ProductSet (page 1242) represents the set of tuples of elements of other sets. Its kind is sympy.core.containers.TupleKind (page 1115) parametrised by the kinds of the elements of those sets:

```
>>> p = ProductSet(FiniteSet(1, 2), FiniteSet(3, 4))
>>> list(p)
[(1, 3), (2, 3), (1, 4), (2, 4)]
>>> p.kind
SetKind(TupleKind(NumberKind, NumberKind))
```

When all elements of the set do not have same kind, the kind will be returned as SetKind(UndefinedKind):

```
>>> FiniteSet(0, Matrix([[1, 2]])).kind
SetKind(UndefinedKind)
```

The kind of the elements of a set are given by the element_kind attribute of SetKind:

```
>>> Interval(1, 2).kind.element_kind
NumberKind
```
See also:

- `Integers` (page 1247), `sympy.sets.fancysets.ImageSet` (page 1248), `sympy.sets.fancysets.Range` (page 1249), `sympy.sets.fancysets.ComplexRegion` (page 1251),
- `sympy.sets.powerset.PowerSet` (page 1256), `sympy.sets.sets.ProductSet` (page 1242), `sympy.sets.sets.Interval` (page 1239),
- `sympy.sets.sets.Union` (page 1241), `sympy.sets.sets.Intersection` (page 1242), `sympy.sets.sets.Complement` (page 1244), `sympy.sets.sets.EmptySet` (page 1245),
- `sympy.sets.sets.UniversalSet` (page 1246), `sympy.sets.sets.FiniteSet` (page 1241),
- `sympy.sets.sets.SymmetricDifference` (page 1244), `sympy.sets.sets.DisjointUnion` (page 1245)

**property measure**

The (Lebesgue) measure of self.

**Examples**

```python
>>> from sympy import Interval, Union
>>> Interval(0, 1).measure
1
>>> Union(Interval(0, 1), Interval(2, 3)).measure
2
```

**powerset()**

Find the Power set of self.

**Examples**

```python
>>> from sympy import EmptySet, FiniteSet, Interval

A power set of an empty set:

```python
>>> A = EmptySet
>>> A.powerset()
{EmptySet}
```

A power set of a finite set:

```python
>>> A = FiniteSet(1, 2)
>>> a, b, c = FiniteSet(1), FiniteSet(2), FiniteSet(1, 2)
>>> A.powerset() == FiniteSet(a, b, c, EmptySet)
True
```

A power set of an interval:

```python
>>> Interval(1, 2).powerset()
PowerSet(Interval(1, 2))
```
property sup

The supremum of self.

Examples

```python
>>> from sympy import Interval, Union
>>> Interval(0, 1).sup
1
>>> Union(Interval(0, 1), Interval(2, 3)).sup
3
```

symmetric_difference(other)

Returns symmetric difference of self and other.

Examples

```python
>>> from sympy import Interval, S
>>> Interval(1, 3).symmetric_difference(S.Reals)
Union(Interval.open(-oo, 1), Interval.open(3, oo))
>>> Interval(1, 10).symmetric_difference(S.Reals)
Union(Interval.open(-oo, 1), Interval.open(10, oo))
```

References

[R771]

union(other)

Returns the union of self and other.

Examples

As a shortcut it is possible to use the + operator:

```python
>>> from sympy import Interval, FiniteSet
>>> Interval(0, 1).union(Interval(2, 3))
Union(Interval(0, 1), Interval(2, 3))
>>> Interval(0, 1) + Interval(2, 3)
Union(Interval(0, 1), Interval(2, 3))
>>> Interval(1, 2, True, True) + FiniteSet(2, 3)
Union({3}, Interval.Lopen(1, 2))
```
Similarly it is possible to use the - operator for set differences:

```
>>> Interval(0, 2) - Interval(0, 1)
Interval.Lopen(1, 2)
>>> Interval(1, 3) - FiniteSet(2)
Union(Interval.Ropen(1, 2), Interval.Lopen(2, 3))
```

`sympy.sets.sets.imageset(*args)`

Return an image of the set under transformation f.

**Explanation**

If this function cannot compute the image, it returns an unevaluated `ImageSet` object:

\[
\{f(x) \mid x \in \text{self}\}
\]

**Examples**

```python
>>> from sympy import S, Interval, imageset, sin, Lambda
>>> from sympy.abc import x

>>> imageset(x, 2*x, Interval(0, 2))
Interval(0, 4)

>>> imageset(lambda x: 2*x, Interval(0, 2))
Interval(0, 4)

>>> imageset(Lambda(x, sin(x)), Interval(-2, 1))
ImageSet(Lambda(x, sin(x)), Interval(-2, 1))

>>> imageset(sin, Interval(-2, 1))
ImageSet(Lambda(x, sin(x)), Interval(-2, 1))

>>> imageset('lambda y: x + y', Interval(-2, 1))
ImageSet(Lambda(y, x + y), Interval(-2, 1))
```

Expressions applied to the set of Integers are simplified to show as few negatives as possible and linear expressions are converted to a canonical form. If this is not desirable then the unevaluated `ImageSet` should be used.

```python
>>> imageset(x, -2*x + 5, S.Integers)
ImageSet(Lambda(x, 2*x + 1), Integers)
```

**See also:**

`sympy.sets.fancysets.ImageSet` (page 1248)
Elementary Sets

class sympy.sets.sets.Interval(start, end, left_open=False, right_open=False)
Represents a real interval as a Set.

Usage:
Returns an interval with end points start and end.
For left_open=True (default left_open is False) the interval will be open on the left. Similarly, for right_open=True the interval will be open on the right.

Examples

```python
>>> from sympy import Symbol, Interval
>>> Interval(0, 1)
Interval(0, 1)
>>> Interval.Ropen(0, 1)
Interval.Ropen(0, 1)
>>> Interval.Ropen(0, 1)
Interval.Ropen(0, 1)
>>> Interval.Lopen(0, 1)
Interval.Lopen(0, 1)
>>> Interval.open(0, 1)
Interval.open(0, 1)
>>> a = Symbol('a', real=True)
>>> Interval(0, a)
Interval(0, a)
```

Notes

- Only real end points are supported
- Interval(a, b) with a > b will return the empty set
- Use the evalf() method to turn an Interval into an mpmath mpi interval instance

References

[R772]
classmethod Lopen(a, b)
Return an interval not including the left boundary.
classmethod Ropen(a, b)
Return an interval not including the right boundary.
as_relational(x)
Rewrite an interval in terms of inequalities and logic operators.
property end

The right end point of the interval.
This property takes the same value as the sup property.

Examples

```python
from sympy import Interval
>>> Interval(0, 1).end
1
```

property is_left_unbounded

Return True if the left endpoint is negative infinity.

property is_right_unbounded

Return True if the right endpoint is positive infinity.

property left_open

True if interval is left-open.

Examples

```python
from sympy import Interval
>>> Interval(0, 1, left_open=True).left_open
True
>>> Interval(0, 1, left_open=False).left_open
False
```

classmethod open(a, b)

Return an interval including neither boundary.

property right_open

True if interval is right-open.

Examples

```python
from sympy import Interval
>>> Interval(0, 1, right_open=True).right_open
True
>>> Interval(0, 1, right_open=False).right_open
False
```

property start

The left end point of the interval.
This property takes the same value as the inf property.
Examples

```python
>>> from sympy import Interval
>>> Interval(0, 1).start
0
```

class sympy.sets.sets.FiniteSet(*args, **kwargs)

Represents a finite set of Sympy expressions.

Examples

```python
>>> from sympy import FiniteSet, Symbol, Interval, Naturals0
>>> FiniteSet(1, 2, 3, 4)
{1, 2, 3, 4}
>>> 3 in FiniteSet(1, 2, 3, 4)
True
>>> FiniteSet(1, (1, 2), Symbol('x'))
{1, x, (1, 2)}
>>> FiniteSet(Interval(1, 2), Naturals0, {1, 2})
FiniteSet({1, 2}, Interval(1, 2), Naturals0)
```

References

[R773]

as_relational(symbol)

Rewrite a FiniteSet in terms of equalities and logic operators.

Compound Sets

class sympy.sets.sets.Union(*args, **kwargs)

Represents a union of sets as a Set (page 1229).
Examples

```python
>>> from sympy import Union, Interval
>>> Union(Interval(1, 2), Interval(3, 4))
Union(Interval(1, 2), Interval(3, 4))
```

The Union constructor will always try to merge overlapping intervals, if possible. For example:

```python
>>> Union(Interval(1, 2), Interval(2, 3))
Interval(1, 3)
```

See also:

Intersection (page 1242)

References

[R774]

as_relnalional(symbol)

Rewrite a Union in terms of equalities and logic operators.

class sympy.sets.sets.Intersection(*args, **kwargs)

Represents an intersection of sets as a Set (page 1229).

Examples

```python
>>> from sympy import Intersection, Interval
>>> Intersection(Interval(1, 3), Interval(2, 4))
Interval(2, 3)
```

We often use the .intersect method

```python
>>> Interval(1,3).intersect(Interval(2,4))
Interval(2, 3)
```

See also:

Union (page 1241)

References

[R775]

as_relnalional(symbol)

Rewrite an Intersection in terms of equalities and logic operators.

class sympy.sets.sets.ProductSet(*sets, **assumptions)

Represents a Cartesian Product of Sets.
Explanation

Returns a Cartesian product given several sets as either an iterable or individual arguments.
Can use * operator on any sets for convenient shorthand.

Examples

```python
>>> from sympy import Interval, FiniteSet, ProductSet
>>> I = Interval(0, 5); S = FiniteSet(1, 2, 3)
>>> ProductSet(I, S)
ProductSet(Interval(0, 5), {1, 2, 3})

>>> (2, 2) in ProductSet(I, S)
True

>>> Interval(0, 1) * Interval(0, 1) # The unit square
ProductSet(Interval(0, 1), Interval(0, 1))

>>> coin = FiniteSet('H', 'T')
>>> set(coin**2)
{(H, H), (H, T), (T, H), (T, T)}
```

The Cartesian product is not commutative or associative e.g.:

```python
>>> I*S == S*I
False
>>> (I*I)*I == I*(I*I)
False
```

Notes

- Passes most operations down to the argument sets

References

[R776]

**property is_iterable**

A property method which tests whether a set is iterable or not. Returns True if set is iterable, otherwise returns False.
### Examples

```python
>>> from sympy import FiniteSet, Interval
>>> I = Interval(0, 1)
>>> A = FiniteSet(1, 2, 3, 4, 5)
>>> I.is_iterable
False
>>> A.is_iterable
True
```

```python
class sympy.sets.sets.Complement(a, b, evaluate=True)

Represents the set difference or relative complement of a set with another set.

\[
A - B = \{ x \in A \mid x \notin B \}
\]

### Examples

```python
>>> from sympy import Complement, FiniteSet
>>> Complement(FiniteSet(0, 1, 2), FiniteSet(1))
{0, 2}
```

**See also:**

*Intersection* (page 1242), *Union* (page 1241)

### References

[R777]

as_relational(symbol)

Rewrite a complement in terms of equalities and logic operators

static reduce(A, B)

Simplify a *Complement* (page 1244).

### SymmetricDifference

```python
class sympy.sets.sets.SymmetricDifference(a, b, evaluate=True)

Represents the set of elements which are in either of the sets and not in their intersection.

### Examples

```python```

```python
>>> from sympy import SymmetricDifference, FiniteSet
>>> SymmetricDifference(FiniteSet(1, 2, 3), FiniteSet(3, 4, 5))
{1, 2, 4, 5}
```

*Complement* (page 1244), *Union* (page 1241)
References

[R778]

`as_relational(symbol)`
Rewrite a symmetric_difference in terms of equalities and logic operators

```python
class sympy.sets.sets.DisjointUnion(*sets)
```
Represents the disjoint union (also known as the external disjoint union) of a finite number of sets.

Examples

```python
>>> from sympy import DisjointUnion, FiniteSet, Interval, Union, Symbol
>>> A = FiniteSet(1, 2, 3)
>>> B = Interval(0, 5)
>>> DisjointUnion(A, B)
DisjointUnion({1, 2, 3}, Interval(0, 5))
```

References

Singleton Sets

```python
class sympy.sets.sets.EmptySet
```
Represents the empty set. The empty set is available as a singleton as `S.EmptySet`.

Examples

```python
>>> from sympy import S, Interval
>>> S.EmptySet
EmptySet
```

See also:

UniversalSet (page 1246)
class sympy.sets.sets.UniversalSet

Represents the set of all things. The universal set is available as a singleton as S.UniversalSet.

Examples

```python
>>> from sympy import S, Interval
>>> S.UniversalSet
UniversalSet

>>> Interval(1, 2).intersect(S.UniversalSet)
Interval(1, 2)
```

See also:

EmptySet (page 1245)

References

[R780]

Special Sets

class sympy.sets.fancysets.Rationals

Represents the rational numbers. This set is also available as the singleton S.Rationals.

Examples

```python
>>> from sympy import S
>>> S.Half in S.Rationals
True
>>> iterable = iter(S.Rationals)
>>> [next(iterable) for i in range(12)]
[0, 1, -1, 1/2, 2, -1/2, -2, 1/3, 3, -1/3, -3, 2/3]
```

class sympy.sets.fancysets.Naturals

Represents the natural numbers (or counting numbers) which are all positive integers starting from 1. This set is also available as the singleton S.Naturals.
Examples

```
>>> from sympy import S, Interval, pprint
>>> 5 in S.Naturals
True
>>> iterable = iter(S.Naturals)
>>> next(iterable)
1
>>> next(iterable)
2
>>> next(iterable)
3
>>> pprint(S.Naturals.intersect(Interval(0, 10)))
{1, 2, ..., 10}
```

See also:

**Naturals0** *(page 1247)*

- non-negative integers (i.e. includes 0, too)

**Integers** *(page 1247)*

- also includes negative integers

**class** `sympy.sets.fancysets.Naturals0`

Represents the whole numbers which are all the non-negative integers, inclusive of zero.

See also:

**Naturals** *(page 1246)*

- positive integers; does not include 0

**Integers** *(page 1247)*

- also includes the negative integers

**class** `sympy.sets.fancysets.Integers`

Represents all integers: positive, negative and zero. This set is also available as the singleton `S.Integers`.

Examples

```
>>> from sympy import S, Interval, pprint
>>> 5 in S.Naturals
True
>>> iterable = iter(S.Integers)
>>> next(iterable)
0
>>> next(iterable)
1
>>> next(iterable)
-1
>>> next(iterable)
2
```
>>> pprint(S.Integers.intersect(Interval(-4, 4)))
{-4, -3, ..., 4}

See also:

*Naturals0* (page 1247)
on-negative integers

*Integers* (page 1247)
positive and negative integers and zero

class sympy.sets.fancysets.Reals
Represents all real numbers from negative infinity to positive infinity, including all integer, rational and irrational numbers. This set is also available as the singleton S.Reals.

Examples

```python
>>> from sympy import S, Rational, pi, I
>>> 5 in S.Reals
True
>>> Rational(-1, 2) in S.Reals
True
>>> pi in S.Reals
True
>>> 3*I in S.Reals
False
>>> S.Reals.contains(pi)
True
```

See also:

*ComplexRegion* (page 1251)

class sympy.sets.fancysets.Complexes
The Set of all complex numbers

Examples

```python
>>> from sympy import S, I
>>> S.Complexes
Complexes
>>> 1 + I in S.Complexes
True
```

See also:

*Reals* (page 1248), *ComplexRegion* (page 1251)

class sympy.sets.fancysets.ImageSet(*flambda, *sets*)
Image of a set under a mathematical function. The transformation must be given as a Lambda function which has as many arguments as the elements of the set upon which it operates, e.g. 1 argument when acting on the set of integers or 2 arguments when acting on a complex region.
This function is not normally called directly, but is called from `imageset`.

**Examples**

```python
>>> from sympy import Symbol, S, pi, Dummy, Lambda

>>> from sympy import FiniteSet, ImageSet, Interval

>>> x = Symbol('x')
>>> N = S.Naturals
>>> squares = ImageSet(Lambda(x, x**2), N)  # {x**2 for x in N}
>>> 4 in squares
True
>>> 5 in squares
False

>>> FiniteSet(0, 1, 2, 3, 4, 5, 6, 7, 9, 10).intersect(squares)
{1, 4, 9}

>>> square_iterable = iter(squares)
>>> for i in range(4):
...    next(square_iterable)
1
4
9
16
```

If you want to get value for $x = 2, 1/2$ etc. (Please check whether the $x$ value is in base_set or not before passing it as args)

```python
>>> squares.lamda(2)
4
>>> squares.lamda(S(1)/2)
1/4
```

```python
>>> n = Dummy('n')
>>> solutions = ImageSet(Lambda(n, n*pi), S.Integers)  # solutions of $\sin(x) = 0$
>>> dom = Interval(-1, 1)
>>> dom.intersect(solutions)
{0}
```

See also:

- `sympy.sets.sets.imageset` (page 1238)

**class** *sympy.sets.fancysets.Range(*args)*

Represents a range of integers. Can be called as `Range(stop)`, `Range(start, stop)`, or `Range(start, stop, step)`; when step is not given it defaults to 1.

`Range(stop)` is the same as `Range(0, stop, 1)` and the stop value (just as for Python ranges) is not included in the Range values.
>>> from sympy import Range
>>> list(Range(3))
[0, 1, 2]

The step can also be negative:

>>> list(Range(10, 0, -2))
[10, 8, 6, 4, 2]

The stop value is made canonical so equivalent ranges always have the same args:

>>> Range(0, 10, 3)
Range(0, 12, 3)

Infinite ranges are allowed. \( \infty \) and \(-\infty\) are never included in the set (Range is always a subset of Integers). If the starting point is infinite, then the final value is \( \text{stop} - \text{step} \). To iterate such a range, it needs to be reversed:

>>> from sympy import oo
>>> r = Range(-oo, 1)
>>> r[-1]
0
>>> next(iter(r))
Traceback (most recent call last):
...
TypeError: Cannot iterate over Range with infinite start
>>> next(iter(r.reversed))
0

Although Range is a Set (and supports the normal set operations) it maintains the order of the elements and can be used in contexts where range would be used.

>>> from sympy import Interval
>>> Range(0, 10, 2).intersect(Interval(3, 7))
Range(4, 8, 2)
>>> list(_)
[4, 6]

Although slicing of a Range will always return a Range – possibly empty – an empty set will be returned from any intersection that is empty:

>>> Range(3)[::]
Range(0, 0, 1)
>>> Range(3).intersect(Interval(4, oo))
EmptySet
>>> Range(3).intersect(Range(4, oo))
EmptySet

Range will accept symbolic arguments but has very limited support for doing anything other than displaying the Range:

>>> from sympy import Symbol, pprint
>>> from sympy.abc import i, j, k
>>> Range(i, j, k).start

(continues on next page)
Better success will be had when using integer symbols:

```python
>>> n = Symbol('n', integer=True)
>>> r = Range(n, n + 20, 3)
>>> r.inf
n
>>> pprint(r)
{n, n + 3, ..., n + 18}
```

`as_relational(x)`

Rewrite a Range in terms of equalities and logic operators.

**property reversed**

Return an equivalent Range in the opposite order.

**Examples**

```python
>>> from sympy import Range
>>> Range(10).reversed
Range(9, -1, -1)
```

**class sympy.sets.fancysets.ComplexRegion(sets, polar=False)**

Represents the Set of all Complex Numbers. It can represent a region of Complex Plane in both the standard forms Polar and Rectangular coordinates.

- **Polar Form**
  
  Input is in the form of the ProductSet or Union of ProductSets of the intervals of $r$ and $\theta$, and use the flag `polar=True`.

  $$Z = \{ z \in \mathbb{C} \mid z = r \times (\cos(\theta) + I \sin(\theta)), r \in [r], \theta \in [\theta] \}$$

- **Rectangular Form**
  
  Input is in the form of the ProductSet or Union of ProductSets of interval of $x$ and $y$, the real and imaginary parts of the Complex numbers in a plane. Default input type is in rectangular form.

  $$Z = \{ z \in \mathbb{C} \mid z = x + I y, x \in [\text{re}(z)], y \in [\text{im}(z)] \}$$
Examples

```python
>>> from sympy import ComplexRegion, Interval, S, I, Union

>>> a = Interval(2, 3)
>>> b = Interval(4, 6)
>>> c1 = ComplexRegion(a*b)  # Rectangular Form
>>> c1
CartesianComplexRegion(ProductSet(Interval(2, 3), Interval(4, 6)))

• c1 represents the rectangular region in complex plane surrounded by the coordinates (2, 4), (3, 4), (3, 6) and (2, 6), of the four vertices.

>>> c = Interval(1, 8)
>>> c2 = ComplexRegion(Union(a*b, b*c))
>>> c2
CartesianComplexRegion(Union(ProductSet(Interval(2, 3), Interval(4, 6)),
ProductSet(Interval(4, 6), Interval(1, 8))))

• c2 represents the Union of two rectangular regions in complex plane. One of them surrounded by the coordinates of c1 and other surrounded by the coordinates (4, 1), (6, 1), (6, 8) and (4, 8).

>>> 2.5 + 4.5*I in c1
True
>>> 2.5 + 6.5*I in c1
False

>>> r = Interval(0, 1)
>>> theta = Interval(0, 2*S.Pi)
>>> c2 = ComplexRegion(r*theta, polar=True)  # Polar Form
>>> c2  # unit Disk
PolarComplexRegion(ProductSet(Interval(0, 1), Interval.Ropen(0, 2*pi)))

• c2 represents the region in complex plane inside the Unit Disk centered at the origin.

>>> 0.5 + 0.5*I in c2
True
>>> 1 + 2*I in c2
False

>>> unit_disk = ComplexRegion(Interval(0, 1)*Interval(0, 2*S.Pi),
polar=True)
>>> upper_half_unit_disk = ComplexRegion(Interval(0, 1)*Interval(0, S.Pi),
polar=True)
>>> intersection = unit_disk.intersect(upper_half_unit_disk)
>>> intersection
PolarComplexRegion(ProductSet(Interval(0, 1), Interval(0, pi)))
>>> intersection == upper_half_unit_disk
True
```
property a_interval

Return the union of intervals of $x$ when, self is in rectangular form, or the union of intervals of $r$ when self is in polar form.

Examples

```python
>>> from sympy import Interval, ComplexRegion, Union
>>> a = Interval(2, 3)
>>> b = Interval(4, 5)
>>> c = Interval(1, 7)
>>> C1 = ComplexRegion(a*b)
>>> C1.a_interval
Interval(2, 3)
>>> C2 = ComplexRegion(Union(a*b, b*c))
>>> C2.a_interval
Union(Interval(2, 3), Interval(4, 5))
```

property b_interval

Return the union of intervals of $y$ when, self is in rectangular form, or the union of intervals of $\theta$ when self is in polar form.

Examples

```python
>>> from sympy import Interval, ComplexRegion, Union
>>> a = Interval(2, 3)
>>> b = Interval(4, 5)
>>> c = Interval(1, 7)
>>> C1 = ComplexRegion(a*b)
>>> C1.b_interval
Interval(4, 5)
>>> C2 = ComplexRegion(Union(a*b, b*c))
>>> C2.b_interval
Interval(1, 7)
```

classmethod from_real(sets)

Converts given subset of real numbers to a complex region.
Examples

```python
from sympy import Interval, ComplexRegion

unit = Interval(0, 1)
ComplexRegion.from_real(unit)
CartesianComplexRegion(ProductSet(Interval(0, 1), {0}))
```

**property psets**

Return a tuple of sets (ProductSets) input of the self.

Examples

```python
from sympy import Interval, ComplexRegion, Union

a = Interval(2, 3)
b = Interval(4, 5)
c = Interval(1, 7)
C1 = ComplexRegion(a*b)
C1.psets
(ProductSet(Interval(2, 3), Interval(4, 5)),)
C2 = ComplexRegion(Union(a*b, b*c))
C2.psets
(ProductSet(Interval(2, 3), Interval(4, 5)), ProductSet(Interval(4, 5), Interval(1, 7)))
```

**property sets**

Return raw input sets to the self.

Examples

```python
from sympy import Interval, ComplexRegion, Union

a = Interval(2, 3)
b = Interval(4, 5)
c = Interval(1, 7)
C1 = ComplexRegion(a*b)
C1.sets
ProductSet(Interval(2, 3), Interval(4, 5))
C2 = ComplexRegion(Union(a*b, b*c))
C2.sets
Union(ProductSet(Interval(2, 3), Interval(4, 5)),
     ProductSet(Interval(4, 5), Interval(1, 7)))
```

class sympy.sets.fancysets.CartesianComplexRegion(sets)

Set representing a square region of the complex plane.

\[
Z = \{ z \in \mathbb{C} \mid z = x + iy, x \in [\text{re}(z)], y \in [\text{im}(z)] \}\]
Examples

```python
>>> from sympy import ComplexRegion, I, Interval
>>> region = ComplexRegion(Interval(1, 3) * Interval(4, 6))
>>> 2 + 5*I in region
True
>>> 5*I in region
False
```

See also:

- `ComplexRegion` (page 1251), `PolarComplexRegion` (page 1255), `Complexes` (page 1248)

```python
class sympy.sets.fancysets.PolarComplexRegion(sets)
```

Set representing a polar region of the complex plane.

\[ Z = \{ z \in \mathbb{C} \mid z = r \times (\cos(\theta) + I\sin(\theta)), r \in [r], \theta \in [\theta] \}\]

Examples

```python
>>> from sympy import ComplexRegion, Interval, oo, pi, I
>>> rset = Interval(0, oo)
>>> thetaset = Interval(0, pi)
>>> upper_half_plane = ComplexRegion(rset * thetaset, polar=True)
>>> 1 + I in upper_half_plane
True
>>> 1 - I in upper_half_plane
False
```

See also:

- `ComplexRegion` (page 1251), `CartesianComplexRegion` (page 1254), `Complexes` (page 1248)

```python
sympy.sets.fancysets.normalize_theta_set(theta)
```

Normalize a Real Set \( \theta \) in the interval \([0, 2\pi)\). It returns a normalized value of \( \theta \) in the Set. For Interval, a maximum of one cycle \([0, 2\pi]\), is returned i.e. for \( \theta \) equal to \([0, 10\pi]\), returned normalized value would be \([0, 2\pi]\). As of now intervals with end points as non-multiples of \( \pi \) is not supported.

Raises

- `NotImplementedError`
  The algorithms for Normalizing theta Set are not yet implemented.

- `ValueError`
  The input is not valid, i.e. the input is not a real set.

- `RuntimeError`
  It is a bug, please report to the github issue tracker.
Examples

```python
>>> from sympy.sets.fancysets import normalize_theta_set
>>> from sympy import Interval, FiniteSet, pi
>>> normalize_theta_set(Interval(9*pi/2, 5*pi))
Interval(pi/2, pi)
>>> normalize_theta_set(Interval(-3*pi/2, pi/2))
Interval.Ropen(0, 2*pi)
>>> normalize_theta_set(Interval(-pi/2, pi/2))
Union(Interval(0, pi/2), Interval.Ropen(3*pi/2, 2*pi))
>>> normalize_theta_set(Interval(-4*pi, 3*pi))
Interval.Ropen(0, 2*pi)
>>> normalize_theta_set(Interval(-3*pi/2, -pi/2))
Interval(pi/2, 3*pi/2)
>>> normalize_theta_set(FiniteSet(0, pi, 3*pi))
{0, pi}
```

Power sets

class sympy.sets.powerset.PowerSet(arg, evaluate=None)

A symbolic object representing a power set.

Parameters

arg : Set
    The set to take power of.

evaluate : bool
    The flag to control evaluation.

If the evaluation is disabled for finite sets, it can take advantage of using subset test as a membership test.

Notes

Power set \( \mathcal{P}(S) \) is defined as a set containing all the subsets of \( S \).
If the set \( S \) is a finite set, its power set would have \( 2^{|S|} \) elements, where \( |S| \) denotes the cardinality of \( S \).

Examples

```python
>>> from sympy import PowerSet, S, FiniteSet

A power set of a finite set:

```
>>> PowerSet(S.EmptySet)
PowerSet(EmptySet)
>>> PowerSet(PowerSet(S.EmptySet))
PowerSet(PowerSet(EmptySet))

A power set of an infinite set:

>>> PowerSet(S.Reals)
PowerSet(Reals)

Evaluating the power set of a finite set to its explicit form:

>>> PowerSet(FiniteSet(1, 2, 3)).rewrite(FiniteSet)
FiniteSet(EmptySet, {1}, {2}, {3}, {1, 2}, {1, 3}, {2, 3}, {1, 2, 3})

References

[R781], [R782]

Condition Sets

class sympy.sets.conditionset.ConditionSet(sym, condition, base_set=UniversalSet)
Set of elements which satisfies a given condition.

\{x \mid \text{condition}(x) = \text{True}, x \in S\}

Examples

>>> from sympy import Symbol, S, ConditionSet, pi, Eq, sin, Interval
>>> from sympy.abc import x, y, z

>>> sin_sols = ConditionSet(x, Eq(sin(x), 0), Interval(0, 2*pi))
>>> 2*pi in sin_sols
True
>>> pi/2 in sin_sols
False
>>> 3*pi in sin_sols
False
>>> 5 in ConditionSet(x, x**2 > 4, S.Reals)
True

If the value is not in the base set, the result is false:

>>> 5 in ConditionSet(x, x**2 > 4, Interval(2, 4))
False
Notes

Symbols with assumptions should be avoided or else the condition may evaluate without consideration of the set:

```python
>>> n = Symbol('n', negative=True)
>>> cond = (n > 0); cond
False
>>> ConditionSet(n, cond, S.Integers)
EmptySet
```

Only free symbols can be changed by using `subs`:

```python
>>> c = ConditionSet(x, x < 1, {x, z})
>>> c.subs(x, y)
ConditionSet(x, x < 1, {y, z})
```

To check if pi is in c use:

```python
>>> pi in c
False
```

If no base set is specified, the universal set is implied:

```python
>>> ConditionSet(x, x < 1).base_set
UniversalSet
```

Only symbols or symbol-like expressions can be used:

```python
>>> ConditionSet(x + 1, x + 1 < 1, S.Integers)
Traceback (most recent call last):
  ...
ValueError: non-symbol dummy not recognized in condition
```

When the base set is a ConditionSet, the symbols will be unified if possible with preference for the outermost symbols:

```python
>>> ConditionSet(x, x < y, ConditionSet(z, z + y < 2, S.Integers))
ConditionSet(x, (x < y) & (x + y < 2), Integers)
```

class sympy.sets.conditionset.Contains(x, s)

Asserts that `x` is an element of the set `S`.

Examples

```python
>>> from sympy import Symbol, Integer, S, Contains
>>> Contains(Integer(2), S.Integers)
True
>>> Contains(Integer(-2), S.Naturals)
False
>>> i = Symbol('i', integer=True)
>>> Contains(i, S.Naturals)
Contains(i, Naturals)
```
SetKind

class sympy.sets.conditionset.SetKind(element_kind=None)

SetKind is kind for all Sets

Every instance of Set will have kind SetKind parametrised by the kind of the elements of the Set. The kind of the elements might be NumberKind, or TupleKind or something else. When not all elements have the same kind then the kind of the elements will be given as UndefinedKind.

Parameters

element_kind: Kind (optional)

The kind of the elements of the set. In a well defined set all elements will have the same kind. Otherwise the kind should sympy.core.kind.UndefinedKind (page 1118). The element_kind argument is optional but should only be omitted in the case of EmptySet whose kind is simply SetKind()

Examples

```python
>>> from sympy import Interval
>>> Interval(1, 2).kind
SetKind(NumberKind)
```

See also:
sympy.core.kind.NumberKind (page 1118), sympy.matrices.common.MatrixKind (page 1405), sympy.core.containers.TupleKind (page 1115)

Iteration over sets

For set unions, \{a, b\} ∪ \{x, y\} can be treated as \{a, b, x, y\} for iteration regardless of the distinctiveness of the elements, however, for set intersections, assuming that \{a, b\} ∩ \{x, y\} is ∅ or \{a, b\} would not always be valid, since some of a, b, x or y may or may not be the elements of the intersection.

Iterating over the elements of a set involving intersection, complement, or symmetric difference yields (possibly duplicate) elements of the set provided that all elements are known to be the elements of the set. If any element cannot be determined to be a member of a set then the iteration gives TypeError. This happens in the same cases where x in y would give an error.

There are some reasons to implement like this, even if it breaks the consistency with how the python set iterator works. We keep in mind that sympy set comprehension like FiniteSet(*s) from a existing sympy sets could be a common usage. And this approach
would make `FiniteSet(*s)` to be consistent with any symbolic set processing methods like `FiniteSet(*simplify(s))`.

### 5.8.4 Matrices

**Contents**

**Matrices**

A module that handles matrices. Includes functions for fast creating matrices like zero, one/eye, random matrix, etc. Contents:

**Matrices (linear algebra)**

**Creating Matrices**

The linear algebra module is designed to be as simple as possible. First, we import and declare our first `Matrix` object:

```python
>>> from sympy.interactive.printing import init_printing
>>> init_printing(use_unicode=False, wrap_line=False)
>>> from sympy.matrices import Matrix, eye, zeros, ones, diag, GramSchmidt
>>> M = Matrix([[1,0,0], [0,0,0]]); M
[1 0 0]
[ ]
[0 0 0]
>>> Matrix([[M, (0, 0, -1)]])
[1 0 0 ]
[ ]
[0 0 0 ]
[ ]
[0 0 -1]
>>> Matrix([[1, 2, 3]])
[1 2 3]
>>> Matrix([[1, 2, 3]])
[1]
[ ]
[2]
[ ]
[3]
```

In addition to creating a matrix from a list of appropriately-sized lists and/or matrices, SymPy also supports more advanced methods of matrix creation including a single list of values and dimension inputs:

```python
>>> Matrix(2, 3, [1, 2, 3, 4, 5, 6])
[1 2 3]
(continues on next page)```
More interesting (and useful), is the ability to use a 2-variable function (or lambda) to create a matrix. Here we create an indicator function which is 1 on the diagonal and then use it to make the identity matrix:

```python
>>> def f(i,j):
...     if i == j:
...         return 1
...     else:
...         return 0
...

>>> Matrix(4, 4, f)
[1 0 0 0]
[0 1 0 0]
[0 0 1 0]
[0 0 0 1]
```

Finally let’s use lambda to create a 1-line matrix with 1’s in the even permutation entries:

```python
>>> Matrix(3, 4, lambda i,j: 1 - (i+j) % 2)
[1 0 1 0]
[0 1 0 1]
[1 0 1 0]
```

There are also a couple of special constructors for quick matrix construction: eye is the identity matrix, zeros and ones for matrices of all zeros and ones, respectively, and diag to put matrices or elements along the diagonal:

```python
>>> eye(4)
[1 0 0 0]
[0 1 0 0]
[0 0 1 0]
[0 0 0 1]

>>> zeros(2)
[0 0]
[0 0]

>>> zeros(2, 5)
[0 0 0 0 0]
[0 0 0 0 0]

>>> ones(3)
[1 1 1]
```
Basic Manipulation

While learning to work with matrices, let’s choose one where the entries are readily identifiable. One useful thing to know is that while matrices are 2-dimensional, the storage is not and so it is allowable - though one should be careful - to access the entries as if they were a 1-d list.

```python
>>> M = Matrix(2, 3, [1, 2, 3, 4, 5, 6])
>>> M[4]
5
```

Now, the more standard entry access is a pair of indices which will always return the value at the corresponding row and column of the matrix:

```python
>>> M[1, 2]
6
>>> M[0, 0]
1
>>> M[1, 1]
5
```

Since this is Python we’re also able to slice submatrices; slices always give a matrix in return, even if the dimension is 1 x 1:

```python
>>> M[0:2, 0:2]
[1 2]
[4 5]
>>> M[2:2, 2]
[]
>>> M[:, 2]
[3]
[6]
>>> M[1:2]
[3]
```

In the second example above notice that the slice 2:2 gives an empty range. Note also (in keeping with 0-based indexing of Python) the first row/column is 0.
You cannot access rows or columns that are not present unless they are in a slice:

```python
>>> M[:, 10]  # the 10-th column (not there)
Traceback (most recent call last):
...
IndexError: Index out of range: a[[0, 10]]
>>> M[:, 10:11]  # the 10-th column (if there)
[]
>>> M[:, :10]  # all columns up to the 10-th
[1 2 3]
[4 5 6]
```

Slicing an empty matrix works as long as you use a slice for the coordinate that has no size:

```python
>>> Matrix(0, 3, []).[:, 1]
[]
```

Slicing gives a copy of what is sliced, so modifications of one object do not affect the other:

```python
>>> M2 = M[:, :]
>>> M2[0, 0] = 100
>>> M[0, 0] == 100
False
```

Notice that changing M2 didn’t change M. Since we can slice, we can also assign entries:

```python
>>> M = Matrix(((1, 2, 3, 4), [5, 6, 7, 8], [9, 10, 11, 12], [13, 14, 15, 16]))
>>> M
[1 2 3 4]
[5 6 7 8]
[9 10 11 12]
[13 14 15 16]
>>> M[2, 2] = M[0, 3] = 0
>>> M
[1 2 3 0]
[5 6 7 8]
[9 10 0 12]
[13 14 15 16]
```

as well as assign slices:

```python
>>> M = Matrix(((1, 2, 3, 4), [5, 6, 7, 8], [9, 10, 11, 12], [13, 14, 15, 16]))
>>> M[2:, 2:] = Matrix(2, 2, lambda i, j: 0)
>>> M
[1 2 3 4]
[5 6 7 8]
(continues on next page)```
All the standard arithmetic operations are supported:

```python
>>> M = Matrix([[1, 2, 3], [4, 5, 6], [7, 8, 9]])
>>> M - M
[0 0 0]
[0 0 0]
[0 0 0]
>>> M + M
[2  4  6 ]
[ 8 10 12]
[14 16 18]
>>> M * M
[30 36 42]
[66 81 96]
[102 126 150]
>>> M2 = Matrix([3, 1, [1, 5, 0]])
>>> M * M2
[11]
[29]
[47]
>>> M ** 2
[30 36 42]
[66 81 96]
[102 126 150]
```

As well as some useful vector operations:

```python
>>> M.row_del(0)
>>> M
[4 5 6]
[7 8 9]
>>> M.col_del(1)
>>> M
[4 6]
[7 9]
```
Recall that the `row_del()` and `col_del()` operations don't return a value - they simply change the matrix object. We can also "glue" together matrices of the appropriate size:

```
>>> M1 = eye(3)
>>> M2 = zeros(3, 4)
>>> M1.row_join(M2)
[1 0 0 0 0 0 0]
[0 1 0 0 0 0 0]
[0 0 1 0 0 0 0]
>>> M3 = zeros(4, 3)
>>> M1.col_join(M3)
[1 0 0]
[0 1 0]
[0 0 1]
[0 0 0]
[0 0 0]
[0 0 0]
[0 0 0]
[0 0 0]
```

**Operations on entries**

We are not restricted to having multiplication between two matrices:

```
>>> M = eye(3)
>>> 2*M
[2 0 0]
[0 2 0]
[0 0 2]
>>> 3*M
[3 0 0]
[0 0 0]
```

(continues on next page)
but we can also apply functions to our matrix entries using applyfunc(). Here we’ll declare a function that double any input number. Then we apply it to the 3x3 identity matrix:

```python
>>> f = lambda x: 2*x
>>> eye(3).applyfunc(f)
[2 0 0]  
[ ]    
[0 2 0]
[ ]
[0 0 2]
```

If you want to extract a common factor from a matrix you can do so by applying gcd to the data of the matrix:

```python
>>> from sympy.abc import x, y
>>> from sympy import gcd
>>> m = Matrix([[x, y], [1, x*y]]).inv('ADJ'); m
  [ x*y    -y ]
[------------------------]
  [ 2    2 ]
  [ x*y - y x*y - y ]
  [ ]
  [ -1    x ]
  [------------------------]
  [ 2    2 ]
  [ x*y - y x*y - y ]
```

```python
>>> gcd(tuple(_))
1

--------
2
x*y - y
```

```python
>>> m/_
  [x*y    -y]  
[ ]    
[-1    x ]
```

One more useful matrix-wide entry application function is the substitution function. Let’s declare a matrix with symbolic entries then substitute a value. Remember we can substitute anything - even another symbol!:

```python
>>> from sympy import Symbol
>>> x = Symbol('x')
>>> M = eye(3) * x
>>> M
  [x 0 0 ]
[ ]    
[0 x 0 ]
[ ]
[0 0 x]
```

(continues on next page)
Linear algebra

Now that we have the basics out of the way, let’s see what we can do with the actual matrices. Of course, one of the first things that comes to mind is the determinant:

```python
>>> M = Matrix(((1, 2, 3), [3, 6, 2], [2, 0, 1]))
>>> M.det()
-28
>>> M2 = eye(3)
>>> M2.det()
1
>>> M3 = Matrix(((1, 0, 0), [1, 0, 0], [1, 0, 0]))
>>> M3.det()
0
```

Another common operation is the inverse: In SymPy, this is computed by Gaussian elimination by default (for dense matrices) but we can specify it be done by $LU$ decomposition as well:

```python
>>> M2.inv()
[1 0 0]
[0 1 0]
[0 0 1]
>>> M2.inv(method="LU")
[1 0 0]
[0 1 0]
[0 0 1]
>>> M.inv(method="LU")
[-3/14 1/14 1/2]
[ ]
[-1/28 5/28 -1/4]
[ ]
[3/7 -1/7 0]
>>> M * M.inv(method="LU")
```
We can perform a $QR$ factorization which is handy for solving systems:

```python
>>> A = Matrix([[1, 1, 1], [1, 1, 3], [2, 3, 4]])
>>> Q, R = A.QRdecomposition()
>>> Q
[\sqrt{6} -\sqrt{3} -\sqrt{2}]
[6 3 2]
[\sqrt{6} -\sqrt{3} \sqrt{2}]
[6 3 2]
[\sqrt{6} \sqrt{3}]
[6 3 0]
[3 3]
>>> R
[4*\sqrt{6}]
[\sqrt{6} 2*\sqrt{6}]
[3]
[\sqrt{3}]
[0 0]
[0]
>>> Q*R
[1 1 1]
[1 1 3]
[2 3 4]
```

In addition to the solvers in the `solver.py` file, we can solve the system $Ax=b$ by passing the $b$ vector to the matrix $A$'s LU$\text{solve}$ function. Here we'll cheat a little choose $A$ and $x$ then multiply to get $b$. Then we can solve for $x$ and check that it's correct:

```python
>>> A = Matrix([ [2, 3, 5], [3, 6, 2], [8, 3, 6] ])  
>>> x = Matrix([3, 1, [3, 7, 5]])  
>>> b = A*x
```
There's also a nice Gram-Schmidt orthogonalizer which will take a set of vectors and orthogonalize them with respect to another. There is an optional argument which specifies whether or not the output should also be normalized, it defaults to False. Let's take some vectors and orthogonalize them - one normalized and one not:

```python
>>> L = [Matrix([2, 3, 5]), Matrix([3, 6, 2]), Matrix([8, 3, 6])]
>>> out1 = GramSchmidt(L)
>>> out2 = GramSchmidt(L, True)
```

Let's take a look at the vectors:

```python
>>> for i in out1:
...     print(i)
...
Matrix([[2], [3], [5]])
Matrix([[23/19], [63/19], [-47/19]])
Matrix([[1692/353], [-1551/706], [-423/706]])
>>> for i in out2:
...     print(i)
...
Matrix([[sqrt(38)/19], [3*sqrt(38)/38], [5*sqrt(38)/38]])
Matrix([[23*sqrt(6707)/6707], [63*sqrt(6707)/6707], [-47*sqrt(6707)/6707]])
Matrix([[12*sqrt(706)/353], [-11*sqrt(706)/706], [-3*sqrt(706)/706]])
```

We can spot-check their orthogonality with dot() and their normality with norm():

```python
>>> out1[0].dot(out1[1])
0
>>> out1[0].dot(out1[2])
0
>>> out1[1].dot(out1[2])
0
>>> out2[0].norm()
1
>>> out2[1].norm()
1
>>> out2[2].norm()
1
```

So there is quite a bit that can be done with the module including eigenvalues, eigenvectors, nullspace calculation, cofactor expansion tools, and so on. From here one might want to look over the `matrices.py` file for all functionality.
Matrix Base Classes

The Matrix classes are built from functionality in various base classes. Every method and attribute of Matrix is implemented on one of these base classes. See also Common Matrices (page 1373), Dense Matrices (page 1406), and Sparse Matrices (page 1409).

class sympy.matrices.matrices.MatrixDeterminant

Provides basic matrix determinant operations. Should not be instantiated directly. See determinant.py for their implementations.

adjugate(method='berkowitz')

Returns the adjugate, or classical adjoint, of a matrix. That is, the transpose of the matrix of cofactors.

Parameters

method : string, optional

Method to use to find the cofactors, can be “bareiss”, “berkowitz” or “lu”.

Examples

```python
>>> from sympy import Matrix
>>> M = Matrix([[1, 2], [3, 4]])
>>> M.adjugate()
Matrix([[4, -2], [-3, 1]])
```

See also:

cofactor_matrix (page 1272), sympy.matrices.common.MatrixCommon.
transpose (page 1400)

charpoly(x='lambda', simplify=<function_simplify>,

Computes characteristic polynomial det(x*I - M) where I is the identity matrix.

A PurePoly is returned, so using different variables for x does not affect the comparison or the polynomials:

Parameters

x : string, optional

Name for the “lambda” variable, defaults to “lambda”.

simplify : function, optional

Simplification function to use on the characteristic polynomial calculated. Defaults to simplify.
Examples

```python
>>> from sympy import Matrix
>>> from sympy.abc import x, y
>>> M = Matrix([[1, 3], [2, 0]])
>>> M.charpoly()
PurePoly(lambda**2 - lambda - 6, lambda, domain='ZZ')
>>> M.charpoly(x) == M.charpoly(y)
True
>>> M.charpoly(x) == M.charpoly(y)
True
```

Specifying x is optional; a symbol named lambda is used by default (which looks good when pretty-printed in unicode):

```python
>>> M.charpoly().as_expr()
lambda**2 - lambda - 6
```

And if x clashes with an existing symbol, underscores will be prepended to the name to make it unique:

```python
>>> M = Matrix([[1, 2], [x, 0]])
>>> M.charpoly(x).as_expr()
_x**2 - _x - 2*x
```

Whether you pass a symbol or not, the generator can be obtained with the gen attribute since it may not be the same as the symbol that was passed:

```python
>>> M.charpoly(x).gen
_x
>>> M.charpoly(x).gen == x
False
```

Notes

The Samuelson-Berkowitz algorithm is used to compute the characteristic polynomial efficiently and without any division operations. Thus the characteristic polynomial over any commutative ring without zero divisors can be computed.

If the determinant \( \det(xI - M) \) can be found out easily as in the case of an upper or a lower triangular matrix, then instead of Samuelson-Berkowitz algorithm, eigenvalues are computed and the characteristic polynomial with their help.

See also:

- `det` (page 1272)
- `cofactor(i, j, method='berkowitz')`

Calculate the cofactor of an element.

Parameters

- `method` : string, optional

  Method to use to find the cofactors, can be “bareiss”, “berkowitz” or “lu”.

5.8. Topics 1271
Examples

```python
>>> from sympy import Matrix
>>> M = Matrix([[1, 2], [3, 4]])
>>> M.cofactor(0, 1)
-3
```

See also:

cofactor_matrix (page 1272), minor (page 1273), minor_submatrix (page 1274)

cofactor_matrix(method='berkowitz')

Return a matrix containing the cofactor of each element.

Parameters

method : string, optional

Method to use to find the cofactors, can be “bareiss”, “berkowitz” or “lu”.

Examples

```python
>>> from sympy import Matrix
>>> M = Matrix([[1, 2], [3, 4]])
>>> M.cofactor_matrix()
Matrix([[4, -3], [-2, 1]])
```

See also:

cofactor (page 1271), minor (page 1273), minor_submatrix (page 1274)

det(method='bareiss', iszerofunc=None)

Computes the determinant of a matrix if M is a concrete matrix object otherwise return an expressions Determinant(M) if M is a MatrixSymbol or other expression.

Parameters

method : string, optional

Specifies the algorithm used for computing the matrix determinant.

If the matrix is at most 3x3, a hard-coded formula is used and the specified method is ignored. Otherwise, it defaults to 'bareiss'.

Also, if the matrix is an upper or a lower triangular matrix, determinant is computed by simple multiplication of diagonal elements, and the specified method is ignored.

If it is set to 'domain-ge', then Gaussian elimination method will be used via using DomainMatrix.

If it is set to 'bareiss', Bareiss' fraction-free algorithm will be used.

If it is set to 'berkowitz', Berkowitz' algorithm will be used.

Otherwise, if it is set to 'lu', LU decomposition will be used.
Note: For backward compatibility, legacy keys like “bareis” and “det_lu” can still be used to indicate the corresponding methods. And the keys are also case-insensitive for now. However, it is suggested to use the precise keys for specifying the method.

**iszerofunc** : FunctionType or None, optional

If it is set to None, it will be defaulted to _iszero if the method is set to 'bareiss', and _is_zero_after_expand_mul if the method is set to 'lu'.

It can also accept any user-specified zero testing function, if it is formatted as a function which accepts a single symbolic argument and returns True if it is tested as zero and False if it tested as non-zero, and also None if it is undecidable.

**Returns**

- **det** : Basic
  Result of determinant.

**Raises**

- **ValueError**
  If unrecognized keys are given for method or iszerofunc.

- **NonSquareMatrixError**
  If attempted to calculate determinant from a non-square matrix.

**Examples**

```python
>>> from sympy import Matrix, eye, det
>>> I3 = eye(3)
>>> det(I3)
1
>>> M = Matrix([[1, 2], [3, 4]])
>>> det(M)
-2
>>> det(M) == M.det()
True
>>> M.det(method="domain-ge")
-2
```

**minor** *(i, j, method='berkowitz')*

Return the (i,j) minor of M. That is, return the determinant of the matrix obtained by deleting the *ith row and jth column from M*.

**Parameters**

- **i, j** : int
  The row and column to exclude to obtain the submatrix.

- **method** : string, optional
  Method to use to find the determinant of the submatrix, can be “bareiss”, “berkowitz” or “lu”.
Examples

```python
>>> from sympy import Matrix
>>> M = Matrix([[1, 2, 3], [4, 5, 6], [7, 8, 9]])
>>> M.minor(1, 1)
-12
```

See also:

- `minor_submatrix` (page 1274), `cofactor` (page 1271), `det` (page 1272)

**minor_submatrix**

Return the submatrix obtained by removing the \textit{i}'th row and \textit{j}'th column from 'M' (works with Pythonic negative indices).

**Parameters**

- \textit{i}, \textit{j}: int

  The row and column to exclude to obtain the submatrix.

Examples

```python
>>> from sympy import Matrix
>>> M = Matrix([[1, 2, 3], [4, 5, 6], [7, 8, 9]])
>>> M.minor_submatrix(1, 1)
Matrix([[1, 3],
       [7, 9]])
```

See also:

- `minor` (page 1273), `cofactor` (page 1271)

**per()**

Returns the permanent of a matrix. Unlike determinant, permanent is defined for both square and non-square matrices.

For an \textit{m} \times \textit{n} matrix, with \textit{m} less than or equal to \textit{n}, it is given as the sum over the permutations \textit{s} of size less than or equal to \textit{m} on \{1, 2, ... \textit{n}\} of the product from \textit{i} = 1 to \textit{m} of \textit{M}[\textit{i}, \textit{s}[\textit{i}]]. Taking the transpose will not affect the value of the permanent.

In the case of a square matrix, this is the same as the permutation definition of the determinant, but it does not take the sign of the permutation into account. Computing the permanent with this definition is quite inefficient, so here the Ryser formula is used.
Examples

```python
>>> from sympy import Matrix
>>> M = Matrix([[1, 2, 3], [4, 5, 6], [7, 8, 9]])
>>> M.per()
450
>>> M = Matrix([1, 5, 7])
>>> M.per()
13
```

References

class sympy.matrices.matrices.MatrixReductions

Provides basic matrix row/column operations. Should not be instantiated directly. See reductions.py for some of their implementations.

echelon_form(iszerofunc=<function _iszero>, simplify=False, with_pivots=False)

Returns a matrix row-equivalent to \( M \) that is in echelon form. Note that echelon form of a matrix is not unique, however, properties like the row space and the null space are preserved.

Examples

```python
>>> from sympy import Matrix
>>> M = Matrix([[1, 2], [3, 4]])
>>> M.echelon_form()
Matrix([[1, 2], [0, -2]])
```

elementary_col_op(op='n->kn', col=None, k=None, col1=None, col2=None)

Performs the elementary column operation \( op \).

\( op \) may be one of

- "n->kn" (column \( n \) goes to \( k*n \))
- "n<->m" (swap column \( n \) and column \( m \))
- "n->n+km" (column \( n \) goes to column \( n + k*column \))

Parameters

- **op**: string; the elementary row operation
- **col**: the column to apply the column operation
- **k**: the multiple to apply in the column operation
- **col1**: one column of a column swap
- **col2**: second column of a column swap or column "m" in the column operation
"n->n+km"

**elementary_row_op** *(op='n->kn', row=None, k=None, row1=None, row2=None)*

Performs the elementary row operation *op*.

*op* may be one of

- "n->kn" (row n goes to k*n)
- "n<->m" (swap row n and row m)
- "n->n+km" (row n goes to row n + k*row m)

**Parameters**

- **op** : string; the elementary row operation
- **row** : the row to apply the row operation
- **k** : the multiple to apply in the row operation
- **row1** : one row of a row swap
- **row2** : second row of a row swap or row “m” in the row operation

**property is_echelon**

Returns *True* if the matrix is in echelon form. That is, all rows of zeros are at the bottom, and below each leading non-zero in a row are exclusively zeros.

**rank** *(iszerofunc=<function _iszero>, simplify=False)*

Returns the rank of a matrix.

**Examples**

```python
>>> from sympy import Matrix
>>> from sympy.abc import x
>>> m = Matrix([[1, 2], [x, 1 - 1/x]])
>>> m.rank()
2
>>> n = Matrix(3, 3, range(1, 10))
>>> n.rank()
2
```

**rref** *(iszerofunc=<function _iszero>, simplify=False, pivots=True, normalize_last=True)*

Return reduced row-echelon form of matrix and indices of pivot vars.

**Parameters**

- **iszerofunc** : Function
  A function used for detecting whether an element can act as a pivot.
  `lambda x: x.is_zero` is used by default.

- **simplify** : Function
  A function used to simplify elements when looking for a pivot. By default SymPy’s `simplify` is used.
**pivots** : True or False

If **True**, a tuple containing the row-reduced matrix and a tuple of pivot columns is returned. If **False** just the row-reduced matrix is returned.

**normalize_last** : True or False

If **True**, no pivots are normalized to 1 until after all entries above and below each pivot are zeroed. This means the row reduction algorithm is fraction free until the very last step. If **False**, the naive row reduction procedure is used where each pivot is normalized to be 1 before row operations are used to zero above and below the pivot.

**Examples**

```python
>>> from sympy import Matrix
>>> from sympy.abc import x
>>> m = Matrix([[1, 2], [x, 1 - 1/x]])
>>> m.rref()
(Matrix([[1, 0],
          [0, 1]]), (0, 1))
```

```python
>>> rref_matrix, rref_pivots = m.rref()
>>> rref_matrix
Matrix([[1, 0],
         [0, 1]])
>>> rref_pivots
(0, 1)
```

**iszerofunc** can correct rounding errors in matrices with float values. In the following example, calling **rref()** leads to floating point errors, incorrectly row reducing the matrix. **iszerofunc = lambda x: abs(x)<1e-9** sets sufficiently small numbers to zero, avoiding this error:

```python
>>> m = Matrix([[0.9, -0.1, -0.2, 0], [-0.8, 0.9, -0.4, 0], [-0.1, -0.8, 0.6, 0]])
>>> m.rref()
(Matrix([[1, 0, 0, 0],
         [0, 1, 0, 0],
         [0, 0, 1, 0]]), (0, 1, 2))
```

```python
>>> m.rref(iszerofunc=lambda x: abs(x)<1e-9)
(Matrix([[1, 0, -0.301369863013699, 0],
         [0, 1, -0.712328767123288, 0],
         [0, 0, 0, 0]]), (0, 1))
```
Notes

The default value of `normalize_last=True` can provide significant speedup to row reduction, especially on matrices with symbols. However, if you depend on the form row reduction algorithm leaves entries of the matrix, set `noramlize_last=False`

```python
class sympy.matrices.matrices.MatrixSubspaces
    Provides methods relating to the fundamental subspaces of a matrix. Should not be instantiated directly. See subspaces.py for their implementations.

columnspace(simplify=False)
    Returns a list of vectors (Matrix objects) that span columnspace of M
```

Examples

```python
>>> from sympy import Matrix
>>> M = Matrix(3, 3, [1, 3, 0, -2, -6, 0, 3, 9, 6])
>>> M
Matrix([ 1, 3, 0],
[-2, -6, 0],
[ 3, 9, 6])
>>> M.columnspace()
[Matrix([[ 1],
    [-2],
    [ 3]]), Matrix([[ 0],
    [0],
    [6]])]
```

See also:

`nullspace` (page 1278), `rowspace` (page 1279)

```python
nullspace(simplify=False, iszerofunc=<function iszero>)
    Returns list of vectors (Matrix objects) that span nullspace of M
```

Examples

```python
>>> from sympy import Matrix
>>> M = Matrix(3, 3, [1, 3, 0, -2, -6, 0, 3, 9, 6])
>>> M
Matrix([ 1, 3, 0],
[-2, -6, 0],
[ 3, 9, 6])
>>> M.nullspace()
[Matrix([[-3],
    [ 1],
    [ 0]])]
```
See also:

columnspace (page 1278), rowspace (page 1279)

classmethod orthogonalize(*vecs, **kwargs)

Apply the Gram-Schmidt orthogonalization procedure to vectors supplied in vecs.

**Parameters**

- **vecs**
  - vectors to be made orthogonal
- **normalize** : bool
  - If True, return an orthonormal basis.
- **rankcheck** : bool
  - If True, the computation does not stop when encountering linearly dependent vectors.
  - If False, it will raise ValueError when any zero or linearly dependent vectors are found.

**Returns**

- list
  - List of orthogonal (or orthonormal) basis vectors.

**Examples**

```python
>>> from sympy import I, Matrix
>>> v = [Matrix([[1, I]]), Matrix([[1, -I]])]
>>> Matrix.orthogonalize(*v)
[Matrix([[1], [I]]), Matrix([[1], [-I]])]
```

See also:

MatrixBase.QRdecomposition (page 1328)

**References**

[R588]

rowspace(simplify=False)

Returns a list of vectors that span the row space of M.
Examples

```python
>>> from sympy import Matrix
>>> M = Matrix(3, 3, [1, 3, 0, -2, -6, 0, 3, 9, 6])
>>> M
Matrix([[1, 3, 0], [-2, -6, 0], [3, 9, 6]])
```

```python
>>> M.rowspace()
[Matrix([[1, 3, 0]]), Matrix([[0, 0, 6]]))]
```

class sympy.matrices.matrices.MatrixEigen

Provides basic matrix eigenvalue/vector operations. Should not be instantiated directly. See eigen.py for their implementations.

    bidiagonal_decomposition(upper=True)

Returns \((U, B, V.H)\) for

\[ A = U B V^H \]

where \(A\) is the input matrix, and \(B\) is its Bidiagonalized form

Note: Bidiagonal Computation can hang for symbolic matrices.

Parameters

    upper : bool. Whether to do upper bidiagonalization or lower.

                        True for upper and False for lower.

References

[R589], [R590]

bidimensionalize(upper=True)

Returns \(B\), the Bidiagonalized form of the input matrix.

Note: Bidiagonal Computation can hang for symbolic matrices.

Parameters

    upper : bool. Whether to do upper bidiagonalization or lower.

                        True for upper and False for lower.

References

diagonalize(reals_only=False, sort=False, normalize=False)

Return \((P, D)\), where \(D\) is diagonal and

\[ D = P^{-1} \ast M \ast P \]

where \(M\) is current matrix.
Parameters

- **reals_only**: bool. Whether to throw an error if complex numbers are need
to diagonalize. (Default: False)

- **sort**: bool. Sort the eigenvalues along the diagonal. (Default: False)

- **normalize**: bool. If True, normalize the columns of P. (Default: False)

Examples

```python
>>> from sympy import Matrix
>>> M = Matrix(3, 3, [1, 2, 0, 0, 3, 0, 2, -4, 2])
>>> M
Matrix([[1, 2, 0],
[0, 3, 0],
[2, -4, 2]])
>>> (P, D) = M.diagonalize()
>>> D
Matrix([[1, 0, 0],
[0, 2, 0],
[0, 0, 3]])
>>> P
Matrix([[-1, 0, -1],
[0, 0, -1],
[2, 1, 2]])
>>> P.inv() * M * P
Matrix([[1, 0, 0],
[0, 2, 0],
[0, 0, 3]])
```

See also:

- `is_diagonal` (page 1383), `is_diagonalizable` (page 1284)

- `eigenvals` (`error_when_incomplete=True`, `**flags`)

  Compute eigenvalues of the matrix.

Parameters

- **error_when_incomplete**: bool, optional
  If it is set to True, it will raise an error if not all eigenvalues are computed. This is caused by roots not returning a full list of eigenvalues.

- **simplify**: bool or function, optional
  If it is set to True, it attempts to return the most simplified form of expressions returned by applying default simplification method in every routine.

  If it is set to False, it will skip simplification in this particular routine to save computation resources.
If a function is passed to, it will attempt to apply the particular function as simplification method.

**rational** : bool, optional

If it is set to True, every floating point numbers would be replaced with rationals before computation. It can solve some issues of roots routine not working well with floats.

**multiple** : bool, optional

If it is set to True, the result will be in the form of a list.

If it is set to False, the result will be in the form of a dictionary.

**Returns**

**eigs** : list or dict

Eigenvalues of a matrix. The return format would be specified by the key multiple.

**Raises**

**MatrixError**

If not enough roots had got computed.

**NonSquareMatrixError**

If attempted to compute eigenvalues from a non-square matrix.

**Examples**

```python
>>> from sympy import Matrix
>>> M = Matrix([0, 1, 1, 0, 0, 1, 1, 1])
>>> M.eigenvals()
{-1: 1, 0: 1, 2: 1}
```

**Notes**

Eigenvalues of a matrix $A$ can be computed by solving a matrix equation $\det(A - \lambda I) = 0$.

It’s not always possible to return radical solutions for eigenvalues for matrices larger than 4,4 shape due to Abel-Ruffini theorem.

If there is no radical solution is found for the eigenvalue, it may return eigenvalues in the form of `sympy.polys.rootoftools.ComplexRootOf` (page 2507).

**See also:**

`MatrixDeterminant.charpoly` (page 1270), `eigenvects` (page 1282)

**eigenvects** *(error_when_incomplete=True, iszerofunc=<function iszero>, **flags)*

Compute eigenvectors of the matrix.

**Parameters**

**error_when_incomplete** : bool, optional

Raise an error when not all eigenvalues are computed. This is caused by roots not returning a full list of eigenvalues.
iszerofunc : function, optional

Specifies a zero testing function to be used in rref.

Default value is _iszero, which uses SymPy’s naive and fast default assumption handler.

It can also accept any user-specified zero testing function, if it is formatted as a function which accepts a single symbolic argument and returns True if it is tested as zero and False if it is tested as non-zero, and None if it is undecidable.

simplify : bool or function, optional

If True, as_content_primitive() will be used to tidy up normalization artifacts.

It will also be used by the nullspace routine.

chop : bool or positive number, optional

If the matrix contains any Floats, they will be changed to Rationals for computation purposes, but the answers will be returned after being evaluated with evalf. The chop flag is passed to evalf. When chop=True a default precision will be used; a number will be interpreted as the desired level of precision.

Returns

ret : [(eigenval, multiplicity, eigenspace), ...]

A ragged list containing tuples of data obtained by eigenvals and nullspace.

eigenspace is a list containing the eigenvector for each eigenvalue.

eigenvector is a vector in the form of a Matrix. e.g. a vector of length 3 is returned as Matrix([a_1, a_2, a_3]).

Raises

NotImplementedError

If failed to compute nullspace.

Examples

```python
>>> from sympy import Matrix
>>> M = Matrix(3, 3, [0, 1, 1, 0, 0, 1, 1, 1, 1])
>>> M.eigenvects()
[(-1, 1, [Matrix([[ -1],
 [ 1],
 [ 0]])]), (0, 1, [Matrix([[ 0],
 [-1],
 [ 1]])]), (2, 1, [Matrix([[2/3],
 [1/3],
 [ 1]])])]
```
See also:

eigenvals (page 1281), MatrixSubspaces.nullspace (page 1278)

is_diagonalizable(\texttt{reals\_only=False}, **\texttt{kwargs})

Returns True if a matrix is diagonalizable.

Parameters

\texttt{reals\_only} : bool, optional

If True, it tests whether the matrix can be diagonalized to contain only real numbers on the diagonal.

If False, it tests whether the matrix can be diagonalized at all, even with numbers that may not be real.

Examples

Example of a diagonalizable matrix:

\begin{verbatim}
>>> from sympy import Matrix
>>> M = Matrix([[1, 2, 0], [0, 3, 0], [2, -4, 2]])
>>> M.is_diagonalizable()
True
\end{verbatim}

Example of a non-diagonalizable matrix:

\begin{verbatim}
>>> M = Matrix([[0, 1], [0, 0]])
>>> M.is_diagonalizable()
False
\end{verbatim}

Example of a matrix that is diagonalized in terms of non-real entries:

\begin{verbatim}
>>> M = Matrix([[\theta, 1], [-1, \theta]])
>>> M.is_diagonalizable(\texttt{reals\_only=False})
True
>>> M.is_diagonalizable(\texttt{reals\_only=True})
False
\end{verbatim}

property is_indefinite

Finds out the definiteness of a matrix.

Explanation

A square real matrix $A$ is:

- A positive definite matrix if $x^T A x > 0$ for all non-zero real vectors $x$.
- A positive semidefinite matrix if $x^T A x \geq 0$ for all non-zero real vectors $x$.
- A negative definite matrix if $x^T A x < 0$ for all non-zero real vectors $x$.
- A negative semidefinite matrix if $x^T A x \leq 0$ for all non-zero real vectors $x$. 
• An indefinite matrix if there exists non-zero real vectors $x, y$ with $x^T A x > 0 > y^T A y$.

A square complex matrix $A$ is:

• A positive definite matrix if $\text{re}(x^H A x) > 0$ for all non-zero complex vectors $x$.
• A positive semidefinite matrix if $\text{re}(x^H A x) \geq 0$ for all non-zero complex vectors $x$.
• A negative definite matrix if $\text{re}(x^H A x) < 0$ for all non-zero complex vectors $x$.
• A negative semidefinite matrix if $\text{re}(x^H A x) \leq 0$ for all non-zero complex vectors $x$.
• An indefinite matrix if there exists non-zero complex vectors $x, y$ with $\text{re}(x^H A x) > 0 > \text{re}(y^H A y)$.

A matrix need not be symmetric or hermitian to be positive definite.

• A real non-symmetric matrix is positive definite if and only if $\frac{A + A^T}{2}$ is positive definite.
• A complex non-hermitian matrix is positive definite if and only if $\frac{A + A^H}{2}$ is positive definite.

And this extension can apply for all the definitions above.

However, for complex cases, you can restrict the definition of $\text{re}(x^H A x) > 0$ to $x^H A x > 0$ and require the matrix to be hermitian. But we do not present this restriction for computation because you can check $M.is\_hermitian$ independently with this and use the same procedure.

**Examples**

An example of symmetric positive definite matrix:

```python
>>> from sympy import Matrix, symbols
>>> from sympy.plotting import plot3d
>>> a, b = symbols('a b')
>>> x = Matrix([a, b])

>>> A = Matrix([[1, 0], [0, 1]])
>>> A.is_positive_definite
True
>>> A.is_positive_semidefinite
True

>>> p = plot3d((x.T*A*x)[0, 0], (a, -1, 1), (b, -1, 1))
```

An example of symmetric positive semidefinite matrix:

```python
>>> A = Matrix([[1, -1], [-1, 1]])
>>> A.is_positive_definite
False
>>> A.is_positive_semidefinite
True
```
f(a, b)
An example of symmetric negative definite matrix:

```python
>>> A = Matrix([[[-1, 0], [0, -1]]])
>>> A.is_negative_definite
True
>>> A.is_negative_semidefinite
True
>>> A.is_indefinite
False
```

An example of symmetric indefinite matrix:

```python
>>> A = Matrix([[1, 2], [2, -1]])
>>> A.is_indefinite
True
```

An example of non-symmetric positive definite matrix:

```python
>>> p = plot3d((x.T*A*x)[0, 0], (a, -1, 1), (b, -1, 1))
```
$f(a, b)$
>>> A = Matrix([[1, 2], [-2, 1]])
>>> A.is_positive_definite
True
>>> A.is_positive_semidefinite
True

>>> p = plot3d((x.T*Ax)[0, 0], (a, -1, 1), (b, -1, 1))

Notes

Although some people trivialize the definition of positive definite matrices only for symmetric or hermitian matrices, this restriction is not correct because it does not classify all instances of positive definite matrices from the definition \(x^TAx > 0\) or \(\text{re}(x^HAx) > 0\).

For instance, \(\text{Matrix}([[1, 2], [-2, 1]])\) presented in the example above is an example of real positive definite matrix that is not symmetric.

However, since the following formula holds true;

\[
\text{re}(x^HAx) > 0 \iff \text{re}(x^HA + A^Hx) > 0
\]
We can classify all positive definite matrices that may or may not be symmetric or hermitian by transforming the matrix to $\frac{A + A^T}{2}$ or $\frac{A + A^H}{2}$ (which is guaranteed to be always real symmetric or complex hermitian) and we can defer most of the studies to symmetric or hermitian positive definite matrices.

But it is a different problem for the existance of Cholesky decomposition. Because even though a non symmetric or a non hermitian matrix can be positive definite, Cholesky or LDL decomposition does not exist because the decompositions require the matrix to be symmetric or hermitian.
