We can classify all positive definite matrices that may or may not be symmetric or hermitian by transforming the matrix to \( \frac{A + A^T}{2} \) or \( \frac{A + A^H}{2} \) (which is guaranteed to be always real symmetric or complex hermitian) and we can defer most of the studies to symmetric or hermitian positive definite matrices.

But it is a different problem for the existence of Cholesky decomposition. Because even though a non symmetric or a non hermitian matrix can be positive definite, Cholesky or LDL decomposition does not exist because the decompositions require the matrix to be symmetric or hermitian.

**References**

[R599], [R600], [R601]

**property is_positive_definite**

Finds out the definiteness of a matrix.

**Explanation**

A square real matrix \( A \) is:

- A positive definite matrix if \( x^T Ax > 0 \) for all non-zero real vectors \( x \).
- A positive semidefinite matrix if \( x^T Ax \geq 0 \) for all non-zero real vectors \( x \).
- A negative definite matrix if \( x^T Ax < 0 \) for all non-zero real vectors \( x \).
- A negative semidefinite matrix if \( x^T Ax \leq 0 \) for all non-zero real vectors \( x \).
- An indefinite matrix if there exists non-zero real vectors \( x, y \) with \( x^T Ax > 0 > y^T Ay \).

A square complex matrix \( A \) is:

- A positive definite matrix if \( \text{re}(x^H Ax) > 0 \) for all non-zero complex vectors \( x \).
- A positive semidefinite matrix if \( \text{re}(x^H Ax) \geq 0 \) for all non-zero complex vectors \( x \).
- A negative definite matrix if \( \text{re}(x^H Ax) < 0 \) for all non-zero complex vectors \( x \).
- A negative semidefinite matrix if \( \text{re}(x^H Ax) \leq 0 \) for all non-zero complex vectors \( x \).
- An indefinite matrix if there exists non-zero complex vectors \( x, y \) with \( \text{re}(x^H Ax) > 0 > \text{re}(y^H Ay) \).

A matrix need not be symmetric or hermitian to be positive definite.

- A real non-symmetric matrix is positive definite if and only if \( \frac{A + A^T}{2} \) is positive definite.
- A complex non-hermitian matrix is positive definite if and only if \( \frac{A + A^H}{2} \) is positive definite.
And this extension can apply for all the definitions above.

However, for complex cases, you can restrict the definition of $\text{re}(x^HAx) > 0$ to $x^HAx > 0$ and require the matrix to be hermitian. But we do not present this restriction for computation because you can check $M$.is_hermitian independently with this and use the same procedure.

**Examples**

An example of symmetric positive definite matrix:

```python
>>> from sympy import Matrix, symbols
>>> from sympy.plotting import plot3d
>>> a, b = symbols('a b')
>>> x = Matrix([a, b])

>>> A = Matrix([[1, 0], [0, 1]])
>>> A.is_positive_definite
True
>>> A.is_positive_semidefinite
True

>>> p = plot3d((x.T*A*x)[0, 0], (a, -1, 1), (b, -1, 1))
```

An example of symmetric positive semidefinite matrix:

```python
>>> A = Matrix([[1, -1], [-1, 1]])
>>> A.is_positive_definite
False
>>> A.is_positive_semidefinite
True

>>> p = plot3d((x.T*A*x)[0, 0], (a, -1, 1), (b, -1, 1))
```

An example of symmetric negative definite matrix:

```python
>>> A = Matrix([[-1, 0], [0, -1]])
>>> A.is_negative_definite
True
>>> A.is_negative_semidefinite
True
>>> A.is_indefinite
False

>>> p = plot3d((x.T*A*x)[0, 0], (a, -1, 1), (b, -1, 1))
```

An example of symmetric indefinite matrix:

```python
>>> A = Matrix([[1, 2], [2, -1]])
>>> A.is_indefinite
True
```
$f(a, b)$
$f(a, b)$

The figure shows a 3D graph of the function $f(a, b)$ over the ranges of $a$ and $b$.
An example of non-symmetric positive definite matrix.

```python
>>> A = Matrix([[1, 2], [-2, 1]])
>>> A.is_positive_definite
True
>>> A.is_positive_semidefinite
True
```

Notes

Although some people trivialize the definition of positive definite matrices only for symmetric or hermitian matrices, this restriction is not correct because it does not classify all instances of positive definite matrices from the definition $x^T A x > 0$ or $\text{re}(x^H A x) > 0$.

For instance, `Matrix([[1, 2], [-2, 1]])` presented in the example above is an example of real positive definite matrix that is not symmetric.
\[ f(a, b) \]
However, since the following formula holds true;

\[
\text{re}(x^H Ax) > 0 \iff \text{re}\left(\frac{x^H \left( A + A^H \right)x}{2}\right) > 0
\]

We can classify all positive definite matrices that may or may not be symmetric or hermitian by transforming the matrix to \( \frac{A + A^T}{2} \) or \( \frac{A + A^H}{2} \) (which is guaranteed to be always real symmetric or complex hermitian) and we can defer most of the studies to symmetric or hermitian positive definite matrices.

But it is a different problem for the existence of Cholesky decomposition. Because even though a non symmetric or a non hermitian matrix can be positive definite, Cholesky or LDL decomposition does not exist because the decompositions require the matrix to be symmetric or hermitian.

**jordan_form** *(calc_transform=True, **kwargs)*

Return \((P, J)\) where \(J\) is a Jordan block matrix and \(P\) is a matrix such that \(M = PJP^{-1}\)

**Parameters**

- **calc_transform** : bool
  - If False, then only \(J\) is returned.
- **chop** : bool
  - All matrices are converted to exact types when computing eigenvalues and eigenvectors. As a result, there may be approximation errors. If chop==True, these errors will be truncated.

**Examples**

```python
>>> from sympy import Matrix
>>> M = Matrix([[ 6,  5, -2, -3], [-3, -1,  3,  3], [ 2,  1, -2, -3], [-1,  1,  5,  5]])
>>> P, J = M.jordan_form()
>>> J
Matrix([[2, 1, 0, 0],
        [0, 2, 0, 0],
        [0, 0, 2, 1],
        [0, 0, 0, 2]])
```

**See also:**

- **jordan_block** (page 1391)
- **left_eigenvects** (**flags**)
  - Returns left eigenvectors and eigenvalues.
  
  This function returns the list of triples (eigenval, multiplicity, basis) for the left eigenvectors. Options are the same as for eigenvects(), i.e. the **flags** arguments gets passed directly to eigenvects().
Examples

```python
>>> from sympy import Matrix
>>> M = Matrix([[0, 1, 1], [1, 0, 0], [1, 1, 1]])
>>> M.eigenvects()
[(-1, 1, [Matrix([[-1],
                   [1],
                   [0]])]), (0, 1, [Matrix([[0],
                                  [-1],
                                  [1]])]), (2, 1, [Matrix([[2/3],
                                             [1/3],
                                             [1]])]])]

singualar_values()
Compute the singular values of a Matrix

Examples

```python
>>> from sympy import Matrix, Symbol
>>> x = Symbol('x', real=True)
>>> M = Matrix([[0, 1, 0], [0, x, 0], [-1, 0, 0]])
>>> M.singular_values()
[sqrt(x**2 + 1), 1, 0]

See also:
```
condition_number (page 1333)
```
See also:

integrate (page 1320), limit (page 1321)

`integrate(*args, **kwargs)`
Integrate each element of the matrix. args will be passed to the integrate function.

Examples

```python
>>> from sympy import Matrix
>>> from sympy import x, y
>>> M = Matrix([[x, y], [1, 0]])
>>> M.integrate((x, ))
Matrix([[x**2/2, x*y], [x, 0]])
>>> M.integrate((x, 0, 2))
Matrix([[2, 2*y], [2, 0]])
```

See also:

limit (page 1321), diff (page 1319)

`jacobian(X)`
Calculates the Jacobian matrix (derivative of a vector-valued function).

Parameters

```
```

```

Both `self` and X can be a row or a column matrix in any order (i.e., jacobian() should always work).

Examples

```python
>>> from sympy import sin, cos, Matrix
>>> from sympy import rho, phi
>>> X = Matrix([rho*cos(phi), rho*sin(phi), rho**2])
>>> Y = Matrix([rho, phi])
>>> X.jacobian(Y)
Matrix([[cos(phi), -rho*sin(phi)], [sin(phi), rho*cos(phi)], [2*rho, 0]])
>>> X = Matrix([rho*cos(phi), rho*sin(phi)])
>>> Y = X.jacobian(Y)
Matrix([[cos(phi), -rho*sin(phi)], [sin(phi), rho*cos(phi)]])
```
See also:

*hessian* (page 1361), *wronskian* (page 1362)

**limit(*args*)**

Calculate the limit of each element in the matrix. *args* will be passed to the limit function.

**Examples**

```python
>>> from sympy import Matrix
>>> from sympy.abc import x, y
>>> M = Matrix([[x, y], [1, 0]])
>>> M.limit(x, 2)
Matrix([[2, y], [1, 0]])
```

See also:

*integrate* (page 1320), *diff* (page 1319)

class sympy.matrices.matrices.MatrixBase

Base class for matrix objects.

**property D**

Return Dirac conjugate (if self.rows == 4).

**Examples**

```python
>>> from sympy import Matrix, I, eye
>>> m = Matrix((0, 1 + I, 2, 3))
>>> m.D
Matrix([[0, 1 - I, -2, -3]])
>>> m = (eye(4) + I*eye(4))
>>> m[0, 3] = 2
>>> m.D
Matrix([[1 - I, 0, 0, 0],
[0, 1 - I, 0, 0],
[0, 0, -1 + I, 0],
[2, 0, 0, -1 + I]])
```

If the matrix does not have 4 rows an AttributeError will be raised because this property is only defined for matrices with 4 rows.

```python
>>> Matrix(eye(2)).D
Traceback (most recent call last):
... AttributeError: Matrix has no attribute D.
```

See also:
```python
>>> from sympy import Matrix, eye
>>> A = Matrix(((25, 15, -5), (15, 18, 0), (-5, 0, 11)))
>>> L, D = A.LDLdecomposition()

L
Matrix([[1, 0, 0],
[3/5, 1, 0],
[-1/5, 1/3, 1]])

D
Matrix([[25, 0, 0],
[0, 9, 0],
[0, 0, 9]])

>>> L * D * L.T * A.inv() == eye(A.rows)
True
```

The matrix can have complex entries:

```python
>>> from sympy import I
>>> A = Matrix(((9, 3*I), (-3*I, 5)))
>>> L, D = A.LDLdecomposition()

L
Matrix([[1, 0],
[-I/3, 1]])

D
Matrix([[9, 0],
[0, 4]])

>>> L*D*L.H == A
True
```

See also:

LDLsolve(rhs)
Solves \( Ax = B \) using LDL decomposition, for a general square and non-singular matrix.
For a non-square matrix with rows > cols, the least squares solution is returned.

Examples

```python
>>> from sympy import Matrix, eye
>>> A = eye(2)*2
>>> B = Matrix([[1, 2], [3, 4]])
>>> A.LDLsolve(B) == B/2
True
```

LUdecomposition(iszerofunc=<function _iszero>, simpfunc=None, rankcheck=False)
Returns \((L, U, perm)\) where \(L\) is a lower triangular matrix with unit diagonal, \(U\) is an upper triangular matrix, and \(perm\) is a list of row swap index pairs. If \(A\) is the original matrix, then \(A = (L*U).permuteBkwd(perm)\), and the row permutation matrix \(P\) such that \(PA = LU\) can be computed by \(P = eye(A.rows).permuteFwd(perm)\).

See documentation for LUCombined for details about the keyword argument rankcheck, iszerofunc, and simpfunc.

Parameters

**rankcheck** : bool, optional
Determines if this function should detect the rank deficiency of the matrix and should raise a ValueError.

**iszerofunc** : function, optional
A function which determines if a given expression is zero.
The function should be a callable that takes a single SymPy expression and returns a 3-valued boolean value True, False, or None.
It is internally used by the pivot searching algorithm. See the notes section for a more information about the pivot searching algorithm.

**simpfunc** : function or None, optional
A function that simplifies the input.
If this is specified as a function, this function should be a callable that takes a single SymPy expression and returns an another SymPy expression that is algebraically equivalent.
If None, it indicates that the pivot search algorithm should not attempt to simplify any candidate pivots.
It is internally used by the pivot searching algorithm. See the notes section for a more information about the pivot searching algorithm.
Examples

```python
>>> from sympy import Matrix
>>> a = Matrix([[4, 3], [6, 3]])
>>> L, U, _ = a.LUdecomposition()
>>> L
Matrix([[1, 0], [3/2, 1]])
>>> U
Matrix([[4, 3], [0, -3/2]])
```

- `LUdecompositionFF` (page 1324),
- `LUsolve` (page 1328)

**LUdecompositionFF()**

Compute a fraction-free LU decomposition.

Returns 4 matrices P, L, D, U such that PA = L D**-1 U. If the elements of the matrix belong to some integral domain I, then all elements of L, D and U are guaranteed to belong to I.

See also:

- `sympy.matrices.matrices.MatrixBase.LUdecomposition` (page 1323),

**References**

[R608]

**LUdecomposition_Simple**

```
(iszerofunc=<function _iszero>, simpfunc=None,
 rankcheck=False)
```

Compute the PLU decomposition of the matrix.

Parameters

- `rankcheck` : bool, optional
  Determines if this function should detect the rank deficiency of the matrix and should raise a ValueError.
- `iszerofunc` : function, optional
  A function which determines if a given expression is zero.
  The function should be a callable that takes a single SymPy expression and returns a 3-valued boolean value True, False, or None.
  It is internally used by the pivot searching algorithm. See the notes section for a more information about the pivot searching algorithm.
- `simpfunc` : function or None, optional
A function that simplifies the input.

If this is specified as a function, this function should be a callable that takes a single SymPy expression and returns another SymPy expression that is algebraically equivalent.

If None, it indicates that the pivot search algorithm should not attempt to simplify any candidate pivots.

It is internally used by the pivot searching algorithm. See the notes section for more information about the pivot searching algorithm.

**Returns**

**lu, row_swaps** : (Matrix, list)

If the original matrix is a \( m \times n \) matrix:

- \( lu \) is a \( m \times n \) matrix, which contains result of the decomposition in a compressed form. See the notes section to see how the matrix is compressed.

- \( row\_swaps \) is a \( m \)-element list where each element is a pair of row exchange indices.

\[ A = (L*U).\text{permute\_backward}(perm), \] and the row permutation matrix \( P \) from the formula \( PA = LU \) can be computed by \( P=\text{eye}(A.row)\). \( \text{permute\_forward}(perm) \).

**Raises**

---

**ValueError**

Raised if rankcheck=True and the matrix is found to be rank deficient during the computation.

---

**Notes**

About the PLU decomposition:

PLU decomposition is a generalization of a LU decomposition which can be extended for rank-deficient matrices.

It can further be generalized for non-square matrices, and this is the notation that SymPy is using.

PLU decomposition is a decomposition of a \( m \times n \) matrix \( A \) in the form of \( PA = LU \) where

- \( L \) is a \( m \times m \) lower triangular matrix with unit diagonal entries.

- \( U \) is a \( m \times n \) upper triangular matrix.

- \( P \) is a \( m \times m \) permutation matrix.

So, for a square matrix, the decomposition would look like:

\[
L = \begin{bmatrix}
1 & 0 & 0 & \cdots & 0 \\
L_{1,0} & 1 & 0 & \cdots & 0 \\
L_{2,0} & L_{2,1} & 1 & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
L_{n-1,0} & L_{n-1,1} & L_{n-1,2} & \cdots & 1
\end{bmatrix}
\]
\[
U = \begin{bmatrix}
U_{0,0} & U_{0,1} & U_{0,2} & \cdots & U_{0,n-1} \\
0 & U_{1,1} & U_{1,2} & \cdots & U_{1,n-1} \\
0 & 0 & U_{2,2} & \cdots & U_{2,n-1} \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & U_{n-1,n-1}
\end{bmatrix}
\]

And for a matrix with more rows than the columns, the decomposition would look like:

\[
L = \begin{bmatrix}
1 & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 \\
L_{1,0} & 1 & 0 & \cdots & 0 & 0 & \cdots & 0 \\
L_{2,0} & L_{2,1} & 1 & \cdots & 0 & 0 & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\
L_{n-1,0} & L_{n-1,1} & L_{n-1,2} & \cdots & 1 & 0 & \cdots & 0 \\
L_{n,0} & L_{n,1} & L_{n,2} & \cdots & L_{n,n-1} & 1 & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\
L_{m-1,0} & L_{m-1,1} & L_{m-1,2} & \cdots & L_{m-1,n-1} & 0 & \cdots & 1
\end{bmatrix}
\]

\[
U = \begin{bmatrix}
U_{0,0} & U_{0,1} & U_{0,2} & \cdots & U_{0,n-1} \\
0 & U_{1,1} & U_{1,2} & \cdots & U_{1,n-1} \\
0 & 0 & U_{2,2} & \cdots & U_{2,n-1} \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & U_{n-1,n-1} \\
0 & 0 & 0 & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & 0 
\end{bmatrix}
\]

Finally, for a matrix with more columns than the rows, the decomposition would look like:

\[
L = \begin{bmatrix}
1 & 0 & 0 & \cdots & 0 \\
L_{1,0} & 1 & 0 & \cdots & 0 \\
L_{2,0} & L_{2,1} & 1 & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
L_{m-1,0} & L_{m-1,1} & L_{m-1,2} & \cdots & 1
\end{bmatrix}
\]

\[
U = \begin{bmatrix}
U_{0,0} & U_{0,1} & U_{0,2} & \cdots & U_{0,m-1} & \cdots & U_{0,n-1} \\
0 & U_{1,1} & U_{1,2} & \cdots & U_{1,m-1} & \cdots & U_{1,n-1} \\
0 & 0 & U_{2,2} & \cdots & U_{2,m-1} & \cdots & U_{2,n-1} \\
\vdots & \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & U_{m-1,m-1} & \cdots & U_{m-1,n-1}
\end{bmatrix}
\]

About the compressed LU storage:

The results of the decomposition are often stored in compressed forms rather than returning \( L \) and \( U \) matrices individually.

It may be less intuitive, but it is commonly used for a lot of numeric libraries because of the efficiency.

The storage matrix is defined as following for this specific method:

- The subdiagonal elements of \( L \) are stored in the subdiagonal portion of \( LU \), that is \( LU_{i,j} = L_{i,j} \) whenever \( i > j \).
• The elements on the diagonal of $L$ are all 1, and are not explicitly stored.

• $U$ is stored in the upper triangular portion of $LU$, that is $LU_{i,j} = U_{i,j}$ whenever $i \leq j$.

• For a case of $m > n$, the right side of the $L$ matrix is trivial to store.

• For a case of $m < n$, the below side of the $U$ matrix is trivial to store.

So, for a square matrix, the compressed output matrix would be:

$$LU = \begin{bmatrix} U_{0,0} & U_{0,1} & U_{0,2} & \cdots & U_{0,n-1} \\ L_{1,0} & U_{1,1} & U_{1,2} & \cdots & U_{1,n-1} \\ L_{2,0} & L_{2,1} & U_{2,2} & \cdots & U_{2,n-1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ L_{n-1,0} & L_{n-1,1} & L_{n-1,2} & \cdots & U_{n-1,n-1} \end{bmatrix}$$

For a matrix with more rows than the columns, the compressed output matrix would be:

$$LU = \begin{bmatrix} U_{0,0} & U_{0,1} & U_{0,2} & \cdots & U_{0,n-1} \\ L_{1,0} & U_{1,1} & U_{1,2} & \cdots & U_{1,n-1} \\ L_{2,0} & L_{2,1} & U_{2,2} & \cdots & U_{2,n-1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ L_{n-1,0} & L_{n-1,1} & L_{n-1,2} & \cdots & U_{n-1,n-1} \\ L_{m-1,0} & L_{m-1,1} & L_{m-1,2} & \cdots & L_{m-1,n-1} \end{bmatrix}$$

For a matrix with more columns than the rows, the compressed output matrix would be:

$$LU = \begin{bmatrix} U_{0,0} & U_{0,1} & U_{0,2} & \cdots & U_{0,m-1} & \cdots & U_{0,n-1} \\ L_{1,0} & U_{1,1} & U_{1,2} & \cdots & U_{1,m-1} & \cdots & U_{1,n-1} \\ L_{2,0} & L_{2,1} & U_{2,2} & \cdots & U_{2,m-1} & \cdots & U_{2,n-1} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ L_{m-1,0} & L_{m-1,1} & L_{m-1,2} & \cdots & U_{m-1,m-1} & \cdots & U_{m-1,n-1} \end{bmatrix}$$

About the pivot searching algorithm:

When a matrix contains symbolic entries, the pivot search algorithm differs from the case where every entry can be categorized as zero or nonzero. The algorithm searches column by column through the submatrix whose top left entry coincides with the pivot position. If it exists, the pivot is the first entry in the current search column that iszerofunc guarantees is nonzero. If no such candidate exists, then each candidate pivot is simplified if iszerofunc is not None. The search is repeated, with the difference that a candidate may be the pivot if iszerofunc() cannot guarantee that it is nonzero. In the second search the pivot is the first candidate that iszerofunc can guarantee is nonzero. If no such candidate exists, then the pivot is the first candidate for which iszerofunc returns None. If no such candidate exists, then the search is repeated in the next column to the right. The pivot search algorithm differs from the one in rref(), which relies on rref(). Future versions of LUdecomposition_simple() may use rref().

LUdecompositionFF (page 1324), LUsolve (page 1328)

LUsolve(rhs, iszerofunc=<function _iszero>)
Solve the linear system $Ax = rhs$ for $x$ where $A = M$.
This is for symbolic matrices, for real or complex ones use mpmath.lu_solve or mpmath.qr_solve.

LUdecomposition (page 1323)

QRdecomposition()
Returns a QR decomposition.

Explanation

A QR decomposition is a decomposition in the form $A = QR$ where

- $Q$ is a column orthogonal matrix.
- $R$ is a upper triangular (trapezoidal) matrix.

A column orthogonal matrix satisfies $I = Q^H Q$ while a full orthogonal matrix satisfies relation $I = QQ^H = Q^HQ$ where $I$ is an identity matrix with matching dimensions.

For matrices which are not square or are rank-deficient, it is sufficient to return a column orthogonal matrix because augmenting them may introduce redundant computations. And an another advantage of this is that you can easily inspect the matrix rank by counting the number of columns of $Q$.

If you want to augment the results to return a full orthogonal decomposition, you should use the following procedures.

- Augment the $Q$ matrix with columns that are orthogonal to every other columns and make it square.
- Augment the $R$ matrix with zero rows to make it have the same shape as the original matrix.

The procedure will be illustrated in the examples section.
Examples

A full rank matrix example:

```python
>>> from sympy import Matrix
>>> A = Matrix([[12, -51, 4], [6, 167, -68], [-4, 24, -41]])
>>> Q, R = A.QRdecomposition()
>>> Q
Matrix([[6/7, -69/175, -58/175],
        [3/7, 158/175, 6/175],
        [-2/7, 6/35, -33/35]])
>>> R
Matrix([[14, 21, -14],
        [0, 175, -70],
        [0, 0, 35]])
```

If the matrix is square and full rank, the $Q$ matrix becomes orthogonal in both directions, and needs no augmentation.

```python
>>> Q * Q.H
Matrix([[1, 0, 0],
        [0, 1, 0],
        [0, 0, 1]])
>>> Q.H * Q
Matrix([[1, 0, 0],
        [0, 1, 0],
        [0, 0, 1]])
```

```python
>>> A == Q*R
True
```

A rank deficient matrix example:

```python
>>> A = Matrix([[12, -51, 0], [6, 167, 0], [-4, 24, 0]])
>>> Q, R = A.QRdecomposition()
>>> Q
Matrix([[6/7, -69/175],
        [3/7, 158/175],
        [-2/7, 6/35]])
>>> R
Matrix([[14, 21, 0],
        [0, 175, 0]])
```

QR decomposition might return a matrix $Q$ that is rectangular. In this case the orthogonality condition might be satisfied as $I = Q.H * Q$ but not in the reversed product $I = Q * Q.H$. 

If you want to augment the results to be a full orthogonal decomposition, you should augment $Q$ with an another orthogonal column.

You are able to append an arbitrary standard basis that are linearly independent to every other columns and you can run the Gram-Schmidt process to make them augmented as orthogonal basis.

Augmenting the $R$ matrix with zero row is straightforward.

A zero matrix example:
As the same augmentation rule described above, $Q$ can be augmented with columns of an identity matrix and $R$ can be augmented with rows of a zero matrix.

```
>>> Q_aug = Q.row_join(Matrix.eye(3))
>>> R_aug = R.col_join(Matrix.zeros(3, 4))
>>> Q_aug * R_aug == A
True
```

See also:

**QRsolve(b)**

Solve the linear system $Ax = b$.

$M$ is the matrix $A$, the method argument is the vector $b$. The method returns the solution vector $x$. If $b$ is a matrix, the system is solved for each column of $b$ and the return value is a matrix of the same shape as $b$.

This method is slower (approximately by a factor of 2) but more stable for floating-point arithmetic than the LUsolve method. However, LUsolve usually uses an exact arithmetic, so you do not need to use QRsolve.

This is mainly for educational purposes and symbolic matrices, for real (or complex) matrices use mpmath.qr_solve.

See also:

- `sympy.matrices.dense.DenseMatrix.lower_triangular_solve` (page 1408), `sympy.matrices.dense.DenseMatrix.upper_triangular_solve` (page 1408), `gauss_jordan_solve` (page 1338), `cholesky_solve` (page 1333), `diagonal_solve` (page 1336), `LDLSolve` (page 1322), `LUsolve` (page 1328), `pinv_solve` (page 1347), `QRdecomposition` (page 1328)
add(b)
    Return self + b.

analytic_func(f, x)
    Computes f(A) where A is a Square Matrix and f is an analytic function.

    Parameters
    f : Expr
        Analytic Function
    x : Symbol
        parameter of f

Examples

>>> from sympy import Symbol, Matrix, S, log

>>> x = Symbol('x')
>>> m = Matrix([[S(5)/4, S(3)/4], [S(3)/4, S(5)/4]])
>>> f = log(x)
>>> m.analytic_func(f, x)
Matrix([[0, log(2)],
       [log(2), 0]])

cholesky(hermitian=True)
    Returns the Cholesky-type decomposition L of a matrix A such that L * L.H == A if
hermitian flag is True, or L * L.T == A if hermitian is False.

    A must be a Hermitian positive-definite matrix if hermitian is True, or a symmetric
matrix if it is False.

Examples

>>> from sympy import Matrix

>>> A = Matrix(((25, 15, -5), (15, 18, 0), (-5, 0, 11)))
>>> A.cholesky()
Matrix([[5, 0, 0],
       [3, 3, 0],
       [-1, 1, 3]])

>>> A.cholesky() * A.cholesky().T
Matrix([[25, 15, -5],
       [15, 18, 0],
       [-5, 0, 11]])

    The matrix can have complex entries:
```python
>>> from sympy import I
>>> A = Matrix(((9, 3*I), (-3*I, 5)))
>>> A.cholesky()
Matrix([ [ 3, 0], [-I, 2]])
>>> A.cholesky() * A.cholesky().H
Matrix([ [ 9, 3*I], [-3*I, 5]])
```

Non-hermitian Cholesky-type decomposition may be useful when the matrix is not positive-definite.

```python
>>> A = Matrix([[1, 2], [2, 1]])
>>> L = A.cholesky(hermitian=False)
>>> L
Matrix([ [1, 0], [2, sqrt(3)*I]])
>>> L*L.T == A
True
```

**See also:**

**cholesky_solve**(rhs)

Solves $Ax = B$ using Cholesky decomposition, for a general square non-singular matrix. For a non-square matrix with rows $> cols$, the least squares solution is returned.

**See also:**

- `sympy.matrices.dense.DenseMatrix.lower_triangular_solve` (page 1408), `sympy.matrices.dense.DenseMatrix.upper_triangular_solve` (page 1408), `gauss_jordan_solve` (page 1338), `diagonal_solve` (page 1336), `LDLsolve` (page 1322), `LUsolve` (page 1328), `QRsolve` (page 1331), `pinv_solve` (page 1347)

**condition_number()**

Returns the condition number of a matrix.

This is the maximum singular value divided by the minimum singular value

**Examples**

```python
>>> from sympy import Matrix, S
>>> A = Matrix([[1, 0, 0], [0, 10, 0], [0, 0, S.One/10]])
>>> A.condition_number()
100
```

**See also:**

- `singular_values` (page 1319)
**connected_components()**

Returns the list of connected vertices of the graph when a square matrix is viewed as a weighted graph.

**Examples**

```python
>>> from sympy import Matrix
>>> A = Matrix([...
  ... [66, 0, 0, 68, 0, 0, 0, 67],
  ... [0, 55, 0, 0, 0, 0, 54, 53, 0],
  ... [0, 0, 0, 0, 1, 2, 0, 0, 0],
  ... [86, 0, 88, 0, 0, 0, 0, 87],
  ... [0, 0, 10, 0, 11, 12, 0, 0, 0],
  ... [0, 0, 20, 0, 21, 22, 0, 0, 0],
  ... [0, 45, 0, 0, 0, 0, 44, 43, 0],
  ... [0, 35, 0, 0, 0, 0, 34, 33, 0],
  ... [76, 0, 78, 0, 0, 0, 0, 77]])
>>> A.connected_components()
[[0, 3, 8], [1, 6, 7], [2, 4, 5]]
```

**Notes**

Even if any symbolic elements of the matrix can be indeterminate to be zero mathematically, this only takes the account of the structural aspect of the matrix, so they will considered to be nonzero.

**connected_components_decomposition()**

Decomposes a square matrix into block diagonal form only using the permutations.

**Returns**

\( P, B : \text{PermutationMatrix}, \text{BlockDiagMatrix} \)

\( P \) is a permutation matrix for the similarity transform as in the explanation. And \( B \) is the block diagonal matrix of the result of the permutation.

If you would like to get the diagonal blocks from the BlockDiagMatrix, see `get_diag_blocks()` (page 1430).

**Explanation**

The decomposition is in a form of \( A = P^{-1}BP \) where \( P \) is a permutation matrix and \( B \) is a block diagonal matrix.
Examples

```python
>>> from sympy import Matrix, pprint
>>> A = Matrix([...       [66, 0, 0, 68, 0, 0, 0, 0, 67],...       [0, 55, 0, 0, 0, 54, 53, 0],...       [0, 0, 0, 1, 2, 0, 0, 0],...       [86, 0, 0, 88, 0, 0, 0, 87],...       [0, 0, 10, 11, 12, 0, 0, 0],...       [0, 0, 20, 0, 21, 22, 0, 0],...       [0, 45, 0, 0, 0, 44, 43, 0],...       [0, 35, 0, 0, 0, 34, 33, 0],...       [76, 0, 0, 78, 0, 0, 0, 77]])
```

```python
>>> P, B = A.connected_components_decomposition()
>>> pprint(P)
PermutationMatrix((1 3)(2 8 5 7 4 6))
```

```python
>>> pprint(B)
[[66 68 67]]
[[0 0 0]]
[[86 88 87]]
[[0 0 0]]
[[76 78 77]]
[[55 54 53]]
[[45 44 43]]
[[35 34 33]]
[[0 1 2]]
[[0 0 0]]
[[10 11 12]]
[[0 0 0]]
```

```python
>>> P = P.as_explicit()
>>> B = B.as_explicit()
>>> P.T*B*P == A
True
```

Notes

This problem corresponds to the finding of the connected components of a graph, when a matrix is viewed as a weighted graph.

`copy()`

Returns the copy of a matrix.
Examples

```python
>>> from sympy import Matrix
>>> A = Matrix([2, 2, 1, 2, 3, 4])
>>> A.copy()
Matrix([
    [1, 2],
    [3, 4]])
```

cross(b)

Return the cross product of self and b relaxing the condition of compatible dimensions: if each has 3 elements, a matrix of the same type and shape as self will be returned. If b has the same shape as self then common identities for the cross product (like \(a \times b = -b \times a\)) will hold.

Parameters
- **b**: 3x1 or 1x3 Matrix

See also:
- `dot` (page 1336), `multiply` (page 1392), `multiply_elementwise` (page 1393)

diagonal_solve(rhs)

Solves \(Ax = B\) efficiently, where A is a diagonal Matrix, with non-zero diagonal entries.

Examples

```python
>>> from sympy import Matrix, eye
>>> A = eye(2)*2
>>> B = Matrix([[1, 2], [3, 4]])
>>> A.diagonal_solve(B) == B/2
True
```

See also:
- `sympy.matrices.dense.DenseMatrix.lower_triangular_solve` (page 1408),
- `sympy.matrices.dense.DenseMatrix.upper_triangular_solve` (page 1408),
- `gauss_jordan_solve` (page 1338),
- `cholesky_solve` (page 1333),
- `LDLsolve` (page 1322),
- `LUsolve` (page 1328),
- `QRsolve` (page 1331),
- `pinv_solve` (page 1347)

dot(b, hermitian=None, conjugate_convention=None)

Return the dot or inner product of two vectors of equal length. Here self must be a Matrix of size 1 x n or n x 1, and b must be either a matrix of size 1 x n, n x 1, or a list/tuple of length n. A scalar is returned.

By default, dot does not conjugate self or b, even if there are complex entries. Set hermitian=True (and optionally a conjugate_convention) to compute the hermitian inner product.

Possible kwargs are hermitian and conjugate_convention.

If conjugate_convention is "left", "math" or "maths", the conjugate of the first vector (self) is used. If "right" or "physics" is specified, the conjugate of the second vector b is used.
Examples

```python
>>> from sympy import Matrix
>>> M = Matrix([[1, 2, 3], [4, 5, 6], [7, 8, 9]])
>>> v = Matrix([1, 1, 1])
>>> M.row(0).dot(v)
6
>>> M.col(0).dot(v)
12
>>> v = [3, 2, 1]
>>> M.row(0).dot(v)
10
```

```python
>>> from sympy import I
>>> q = Matrix([1*I, 1*I, 1*I])
>>> q.dot(q, hermitian=False)
-3
```

```python
>>> q.dot(q, hermitian=True)
3
```

```python
>>> q1 = Matrix([1, 1, 1*I])
>>> q.dot(q1, hermitian=True, conjugate_convention="maths")
1 - 2*I
```

```python
>>> q.dot(q1, hermitian=True, conjugate_convention="physics")
1 + 2*I
```

See also:

cross (page 1336), multiply (page 1392), multiply_elementwise (page 1393)

dual()

Returns the dual of a matrix.

A dual of a matrix is:

\[
(1/2) \text{levicivita}(i, j, k, l) \times M(k, l) \text{ summed over indices } k \text{ and } l
\]

Since the levicivita method is anti_symmetric for any pairwise exchange of indices, the dual of a symmetric matrix is the zero matrix. Strictly speaking the dual defined here assumes that the 'matrix' \( M \) is a contravariant anti_symmetric second rank tensor, so that the dual is a covariant second rank tensor.

exp()

Return the exponential of a square matrix.
Examples

```python
>>> from sympy import Symbol, Matrix

>>> t = Symbol('t')
>>> m = Matrix([[0, 1], [-1, 0]]) * t
>>> m.exp()
Matrix([
    [exp(I*t)/2 + exp(-I*t)/2, -I*exp(I*t)/2 + I*exp(-I*t)/2],
    [I*exp(I*t)/2 - I*exp(-I*t)/2, exp(I*t)/2 + exp(-I*t)/2]])
```

gauss_jordan_solve(B, freevar=False)

Solves $Ax = B$ using Gauss Jordan elimination.

There may be zero, one, or infinite solutions. If one solution exists, it will be returned. If infinite solutions exist, it will be returned parametrically. If no solutions exist, it will throw ValueError.

**Parameters**

- **B**: Matrix
  
The right hand side of the equation to be solved for. Must have the same number of rows as matrix A.

- **freevar**: boolean, optional
  
  Flag, when set to True will return the indices of the free variables in the solutions (column Matrix), for a system that is underdetermined (e.g. A has more columns than rows), for which infinite solutions are possible, in terms of arbitrary values of free variables. Default False.

**Returns**

- **x**: Matrix
  
The matrix that will satisfy $Ax = B$. Will have as many rows as matrix A has columns, and as many columns as matrix B.

- **params**: Matrix
  
  If the system is underdetermined (e.g. A has more columns than rows), infinite solutions are possible, in terms of arbitrary parameters. These arbitrary parameters are returned as params Matrix.

- **free_var_index**: List, optional
  
  If the system is underdetermined (e.g. A has more columns than rows), infinite solutions are possible, in terms of arbitrary values of free variables. Then the indices of the free variables in the solutions (column Matrix) are returned by free_var_index, if the flag freevar is set to True.
Examples

```python
>>> from sympy import Matrix
>>> A = Matrix([[1, 2, 1, 1], [1, 2, 2, -1], [2, 4, 0, 6]])
>>> B = Matrix([7, 12, 4])
>>> sol, params = A.gauss_jordan_solve(B)
>>> sol
Matrix([[-2*tau0 - 3*tau1 + 2],
          [tau0],
          [2*tau1 + 5],
          [tau1]])
>>> params
Matrix([tau0, tau1])
```

```python
>>> taus_zeroes = { tau: 0 for tau in params }
>>> sol_unique = sol.xreplace(taus_zeroes)
>>> sol_unique
Matrix([[2],
        [0],
        [5],
        [0]])
```

```python
>>> A = Matrix([[1, 2, 3], [4, 5, 6], [7, 8, 10]])
>>> B = Matrix([3, 6, 9])
>>> sol, params = A.gauss_jordan_solve(B)
>>> sol
Matrix([[-1],
        [2],
        [0]])
>>> params
Matrix(0, 1, [])
```

```python
>>> A = Matrix([[2, -7], [-1, 4]])
>>> B = Matrix([[-21, 3], [12, -2]])
>>> sol, params = A.gauss_jordan_solve(B)
>>> sol
Matrix([[0, -2],
        [3, -1]])
>>> params
Matrix(0, 2, [])
```

```python
>>> from sympy import Matrix
>>> A = Matrix([[1, 2, 1, 1], [1, 2, 2, -1], [2, 4, 0, 6]])
>>> B = Matrix([7, 12, 4])
>>> sol, params, freevars = A.gauss_jordan_solve(B, freevar=True)
>>> sol
Matrix([[-2*tau0 - 3*tau1 + 2],
          [tau0],
          [2*tau1 + 5],
          [tau1]])
```

(continues on next page)
[-2*tau0 - 3*tau1 + 2],
[ tau0],
[ 2*tau1 + 5],
[ tau1])

>>> params
Matrix([tau0],
[tau1])

>>> freevars
[1, 3]

inv(method=None, iszerofunc=<function_iszero>, try_block_diag=False)
Return the inverse of a matrix using the method indicated. Default for dense matrices is Gauss elimination, default for sparse matrices is LDL.

Parameters

- method : ('GE', 'LU', 'ADJ', 'CH', 'LDL')
- iszerofunc : function, optional
  Zero-testing function to use.
- try_block_diag : bool, optional
  If True then will try to form block diagonal matrices using the method get_diag_blocks(), invert these individually, and then reconstruct the full inverse matrix.

Raises

ValueError
If the determinant of the matrix is zero.

Examples

>>> from sympy import SparseMatrix, Matrix
>>> A = SparseMatrix([...
... [ 2, -1,  0],
... [-1,  2, -1],
... [ 0,  0,  2]])
>>> A.inv('CH')
Matrix([...[2/3, 1/3, 1/6],
... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ... ......
>>> A.inv(method='LDL')  # use of 'method=' is optional
Matrix([  
    [2/3, 1/3, 1/6],  
    [1/3, 2/3, 1/3],  
    [ 0, 0, 1/2]  
])

>>> A._ * _
Matrix([  
    [1, 0, 0],  
    [0, 1, 0],  
    [0, 0, 1]  
])

>>> A = Matrix(A)

>>> A.inv('CH')
Matrix([  
    [2/3, 1/3, 1/6],  
    [1/3, 2/3, 1/3],  
    [ 0, 0, 1/2]  
])

>>> A.inv('ADJ') == A.inv('GE') == A.inv('LU') == A.inv('CH') == A.
... .inv('LDL') == A.inv('QR')
True

**Notes**

According to the method keyword, it calls the appropriate method:

GE .... inverse_GE(); default for dense matrices
LU .... inverse_LU() ADJ ...
inverse_ADJ(); CH ... inverse_CH() LDL .... inverse_LDL(); default for sparse
matrices QR ... inverse_QR()

Note, the GE and LU methods may require the matrix to be simplified before it is
inverted in order to properly detect zeros during pivoting. In difficult cases a custom
zero detection function can be provided by setting the iszerofunc argument to a
function that should return True if its argument is zero. The ADJ routine computes
the determinant and uses that to detect singular matrices in addition to testing for
zeros on the diagonal.

inverse_CH (page 1342), inverse_LDL (page 1342)

**inv_mod(m)**

Returns the inverse of the matrix $K \mod m$, if it exists.

Method to find the matrix inverse of $K \mod m$ implemented in this function:

- Compute $\text{adj}(K) = \text{cof}(K)^\dagger$, the adjoint matrix of $K$.
- Compute $r = 1/\det(K) \mod m$.
- $K^{-1} = r \cdot \text{adj}(K) \mod m$. 

---

5.8. Topics 1341
Examples

```python
>>> from sympy import Matrix
>>> A = Matrix(2, 2, [1, 2, 3, 4])
>>> A.inv_mod(5)
Matrix([[3, 1],
        [4, 2]])
>>> A.inv_mod(3)
Matrix([[1, 1],
        [0, 1]])
```

**inverse_ADJ**

Calculates the inverse using the adjugate matrix and a determinant.

**See also:**

**inverse_BLOCK**

Calculates the inverse using BLOCKWISE inversion.

**See also:**

**inverse_CH**

Calculates the inverse using cholesky decomposition.

**See also:**

**inverse_GE**

Calculates the inverse using Gaussian elimination.

**See also:**

**inverse_LDL**

Calculates the inverse using LDL decomposition.

**See also:**

**inverse_LU**

Calculates the inverse using LU decomposition.

**See also:**

inverse_QR(iszerofunc=<function iszero>)
Calculates the inverse using QR decomposition.

See also:
inv (page 1340), inverse_ADJ (page 1342), inverse_GE (page 1342), inverse_CH (page 1342), inverse_LDL (page 1342)

classmethod irregular(ntop, *matrices, **kwargs)
Return a matrix filled by the given matrices which are listed in order of appearance from left to right, top to bottom as they first appear in the matrix. They must fill the matrix completely.

Examples

```python
>>> from sympy import ones, Matrix
>>> Matrix.irregular(3, ones(2,1), ones(3,3)*2, ones(2,2)*3, ...
    ones(1,1)*4, ones(2,2)*5, ones(1,2)*6, ones(1,2)*7)
Matrix([[1, 2, 2, 2, 3, 3],
        [1, 2, 2, 2, 3, 3],
        [4, 2, 2, 2, 5, 5],
        [6, 6, 7, 7, 5, 5]])
```

is_nilpotent()
Checks if a matrix is nilpotent.

A matrix B is nilpotent if for some integer k, B**k is a zero matrix.

Examples

```python
>>> from sympy import Matrix
>>> a = Matrix([[0, 0, 0], [1, 0, 0], [1, 1, 0]])
>>> a.is_nilpotent()
True

>>> a = Matrix([[1, 0, 1], [1, 0, 0], [1, 1, 0]])
>>> a.is_nilpotent()
False
```

key2bounds(keys)
Converts a key with potentially mixed types of keys (integer and slice) into a tuple of ranges and raises an error if any index is out of self’s range.

See also:
key2ij (page 1343)

key2ij(key)
Converts key into canonical form, converting integers or indexable items into valid integers for self’s range or returning slices unchanged.

See also:
key2bounds (page 1343)
\texttt{log(simplify=<function cancel>)}

Return the logarithm of a square matrix.

**Parameters**

\texttt{simplify} : function, bool

The function to simplify the result with.

Default is cancel, which is effective to reduce the expression growing for taking reciprocals and inverses for symbolic matrices.

**Examples**

```python
>>> from sympy import S, Matrix

Examples for positive-definite matrices:

```python
>>> m = Matrix([[1, 1], [0, 1]])
>>> m.log()
Matrix([[0, 1],
        [0, 0]])
```  

```python
>>> m = Matrix([[S(5)/4, S(3)/4], [S(3)/4, S(5)/4]])
>>> m.log()
Matrix([[0, log(2)],
        [log(2), 0]])
```  

Examples for non positive-definite matrices:

```python
>>> m = Matrix([[S(3)/4, S(5)/4], [S(5)/4, S(3)/4]])
>>> m.log()
Matrix([[I*pi/2, log(2) - I*pi/2],
        [log(2) - I*pi/2, I*pi/2]])
```  

```python
>>> m = Matrix(...[[0, 0, 1, 0],
...               [0, 0, 1, 0],
...               [0, 1, 0, 0],
...               [1, 0, 0, 0]])
>>> m.log()
Matrix([[I*pi/2, 0, 0, -I*pi/2],
        [0, I*pi/2, -I*pi/2, 0],
        [0, -I*pi/2, I*pi/2, 0],
        [-I*pi/2, 0, 0, I*pi/2]])
```  

**lower_triangular_solve**(\texttt{rhs})

Solves \(Ax = B\), where \(A\) is a lower triangular matrix.

**See also:**

\texttt{upper_triangular_solve} (page 1359), \texttt{gauss_jordan_solve} (page 1338)
**norm** (ord=None)

Return the Norm of a Matrix or Vector.

In the simplest case this is the geometric size of the vector. Other norms can be specified by the ord parameter.

<table>
<thead>
<tr>
<th>ord</th>
<th>norm for matrices</th>
<th>norm for vectors</th>
</tr>
</thead>
<tbody>
<tr>
<td>None</td>
<td>Frobenius norm</td>
<td>2-norm</td>
</tr>
<tr>
<td>‘fro’</td>
<td>Frobenius norm</td>
<td>• does not exist</td>
</tr>
<tr>
<td>inf</td>
<td>maximum row sum</td>
<td>max(abs(x))</td>
</tr>
<tr>
<td>-inf</td>
<td>–</td>
<td>min(abs(x))</td>
</tr>
<tr>
<td>1</td>
<td>maximum column sum</td>
<td>as below</td>
</tr>
<tr>
<td>-1</td>
<td>–</td>
<td>as below</td>
</tr>
<tr>
<td>2</td>
<td>2-norm (largest sing.</td>
<td>as below</td>
</tr>
<tr>
<td>-2</td>
<td>smallest singular value</td>
<td>as below</td>
</tr>
<tr>
<td>other</td>
<td>• does not exist</td>
<td>sum(abs(x)<strong>ord)</strong>(1./ord)</td>
</tr>
</tbody>
</table>

**Examples**

```python
>>> from sympy import Matrix, Symbol, trigsimp, cos, sin, oo
>>> x = Symbol('x', real=True)
>>> v = Matrix([[cos(x), sin(x)]])
>>> trigsimp( v.norm() )
1
>>> v.norm(10)
(cos(x)**10 + sin(x)**10)**(1/10)
>>> A = Matrix([[1, 1], [1, 1]])
>>> A.norm(1) # maximum sum of absolute values of A is 2
2
>>> A.norm(2) # Spectral norm (max of |Ax|/|x| under 2-vector-norm)
2
>>> A.norm(-2) # Inverse spectral norm (smallest singular value)
0
>>> A.norm() # Frobenius Norm
2
>>> A.norm(oo) # Infinity Norm
2
>>> Matrix([[1, -2]]).norm(oo)
2
>>> Matrix([-1, 2]).norm(-oo)
1
```
See also:

normalized (page 1346)

`normalized(iszerofunc=<function_iszero>)`

Return the normalized version of self.

Parameters

- `iszerofunc`: Function, optional
  A function to determine whether `self` is a zero vector. The default `_iszero` tests to see if each element is exactly zero.

Returns

Matrix

Normalized vector form of `self`. It has the same length as a unit vector. However, a zero vector will be returned for a vector with norm 0.

Raises

- `ShapeError`
  If the matrix is not in a vector form.

See also:

`norm` (page 1345)

`pinv(method='RD')`

Calculate the Moore-Penrose pseudoinverse of the matrix.

The Moore-Penrose pseudoinverse exists and is unique for any matrix. If the matrix is invertible, the pseudoinverse is the same as the inverse.

Parameters

- `method`: String, optional
  Specifies the method for computing the pseudoinverse.
  If 'RD', Rank-Decomposition will be used.
  If 'ED', Diagonalization will be used.

Examples

Computing pseudoinverse by rank decomposition:

```python
>>> from sympy import Matrix
>>> A = Matrix([[1, 2, 3], [4, 5, 6]])
>>> A.pinv()
Matrix([[-17/18, 4/9], [-1/9, 1/9], [13/18, -2/9]])
```

Computing pseudoinverse by diagonalization:
>>> B = A.pinv(method='ED')
>>> B.simplify()
>>> B
Matrix([[-17/18, 4/9],
         [-1/9, 1/9],
         [13/18, -2/9]])

See also:

inv (page 1340), pinv_solve (page 1347)

References

[R610]

pinv_solve(B, arbitrary_matrix=None)

Solve \( Ax = B \) using the Moore-Penrose pseudoinverse.

There may be zero, one, or infinite solutions. If one solution exists, it will be
returned. If infinite solutions exist, one will be returned based on the value of arbi-
trary_matrix. If no solutions exist, the least-squares solution is returned.

Parameters

B : Matrix

The right hand side of the equation to be solved for. Must have the
same number of rows as matrix A.

arbitrary_matrix : Matrix

If the system is underdetermined (e.g. \( A \) has more columns than
rows), infinite solutions are possible, in terms of an arbitrary matrix.
This parameter may be set to a specific matrix to use for that purpose;
if so, it must be the same shape as \( x \), with as many rows as matrix \( A \)
has columns, and as many columns as matrix \( B \). If left as None, an ap-
propriate matrix containing dummy symbols in the form of \( w_n \_m \) will
be used, with \( n \) and \( m \) being row and column position of each symbol.

Returns

x : Matrix

The matrix that will satisfy \( Ax = B \). Will have as many rows as matrix
\( A \) has columns, and as many columns as matrix \( B \).

Examples

>>> from sympy import Matrix
>>> A = Matrix([[1, 2, 3], [4, 5, 6]])
>>> B = Matrix([7, 8])
>>> A.pinv_solve(B)
Matrix([[ _w0_0/6 - _w1_0/3 + _w2_0/6 - 55/18],
        [-_w0_0/3 + 2*_w1_0/3 - _w2_0/3 + 1/9],
        [ _w0_0/6 - _w1_0/3 + _w2_0/6 - 55/18]]

(continues on next page)
Notes

This may return either exact solutions or least squares solutions. To determine which, check $A \times A.pinv() \times B == B$. It will be True if exact solutions exist, and False if only a least-squares solution exists. Be aware that the left hand side of that equation may need to be simplified to correctly compare to the right hand side.

References

[R611]

`print_nonzero(symb='X')`

Shows location of non-zero entries for fast shape lookup.

Examples

```python
>>> from sympy import Matrix, eye
>>> m = Matrix(2, 3, lambda i, j: i*3+j)
>>> m
Matrix([[0, 1, 2],
        [3, 4, 5]])
>>> m.print_nonzero()
[ XX]
[XXX]
>>> m = eye(4)
>>> m.print_nonzero("x")
[x   ]
[x   ]
[x   ]
[x   ]
```

`project(v)`

Return the projection of self onto the line containing v.
Examples

```python
>>> from sympy import Matrix, S, sqrt
>>> V = Matrix([[sqrt(3)/2, S.Half]])
>>> x = Matrix([[1], [0]])
>>> V.project(x)
Matrix([[sqrt(3)/2], [0]])
>>> V.project(-x)
Matrix([[sqrt(3)/2], [0]])
```

`rank_decomposition(iszerofunc=<function _iszero>, simplify=False)`

Returns a pair of matrices \((C, F)\) with matching rank such that \(A = CF\).

**Parameters**

- **iszerofunc**: Function, optional
  
  A function used for detecting whether an element can act as a pivot. `lambda x: x.is_zero` is used by default.

- **simplify**: Bool or Function, optional
  
  A function used to simplify elements when looking for a pivot. By default SymPy’s `simplify` is used.

**Returns**

\((C, F)\) : Matrices

\(C\) and \(F\) are full-rank matrices with rank as same as \(A\), whose product gives \(A\).

See Notes for additional mathematical details.

Examples

```python
>>> from sympy import Matrix
>>> A = Matrix([...
... [1, 3, 1, 4],
... [2, 7, 3, 9],
... [1, 5, 3, 1],
... [1, 2, 0, 8]
... ])
>>> C, F = A.rank_decomposition()
>>> C
Matrix([[1, 3, 4], [2, 7, 9], [1, 5, 1], [1, 2, 8]])
>>> F
Matrix([[1, 0, -2, 0], [0, 1, 1, 0], [0, 0, 0, 1]])
>>> C * F == A
True
```
**Notes**

Obtaining \( F \), an RREF of \( A \), is equivalent to creating a product

\[
E_n E_{n-1} \ldots E_1 A = F
\]

where \( E_n, E_{n-1}, \ldots, E_1 \) are the elimination matrices or permutation matrices equivalent to each row-reduction step.

The inverse of the same product of elimination matrices gives \( C \):

\[
C = (E_n E_{n-1} \ldots E_1)^{-1}
\]

It is not necessary, however, to actually compute the inverse: the columns of \( C \) are those from the original matrix with the same column indices as the indices of the pivot columns of \( F \).

`sympy.matrices.matrices.MatrixReductions.rref` (page 1276)

**References**

[R612], [R613]

`singular_value_decomposition()`

Returns a Condensed Singular Value decomposition.

**Explanation**

A Singular Value decomposition is a decomposition in the form \( A = U \Sigma V \) where

- \( U, V \) are column orthogonal matrix.
- \( \Sigma \) is a diagonal matrix, where the main diagonal contains singular values of matrix \( A \).

A column orthogonal matrix satisfies \( I = U^H U \) while a full orthogonal matrix satisfies relation \( I = U U^H = U^H U \) where \( I \) is an identity matrix with matching dimensions.

For matrices which are not square or are rank-deficient, it is sufficient to return a column orthogonal matrix because augmenting them may introduce redundant computations. In condensed Singular Value Decomposition we only return column orthogonal matrices because of this reason.

If you want to augment the results to return a full orthogonal decomposition, you should use the following procedures.

- Augment the \( U, V \) matrices with columns that are orthogonal to every other columns and make it square.
- Augment the \( \Sigma \) matrix with zero rows to make it have the same shape as the original matrix.

The procedure will be illustrated in the examples section.
Examples

We take a full rank matrix first:

```python
>>> from sympy import Matrix
>>> A = Matrix([[1, 2],[2,1]])
>>> U, S, V = A.singular_value_decomposition()
>>> U
Matrix([[sqrt(2)/2, sqrt(2)/2], [-sqrt(2)/2, sqrt(2)/2]])
>>> S
Matrix([[1, 0], [0, 3]])
>>> V
Matrix([[sqrt(2)/2, sqrt(2)/2], [-sqrt(2)/2, sqrt(2)/2]])
```

If a matrix is square and full rank both U, V are orthogonal in both directions

```python
>>> U * U.H
Matrix([[1, 0], [0, 1]])
>>> U.H * U
Matrix([[1, 0], [0, 1]])
>>> V * V.H
Matrix([[1, 0], [0, 1]])
```

```python
>>> A == U * S * V.H
True
```

```python
>>> C = Matrix([... [1, 0, 0, 0, 2],... [0, 0, 3, 0, 0],... [0, 0, 0, 0, 0],... [0, 2, 0, 0, 0],... ])
>>> U, S, V = C.singular_value_decomposition()
```

```python
>>> V.H * V
Matrix([[1, 0, 0],
         [0, 2, 0],
         [0, 0, 3]])
```
If you want to augment the results to be a full orthogonal decomposition, you should augment \( V \) with another orthogonal column.

You are able to append an arbitrary standard basis that are linearly independent to every other columns and you can run the Gram-Schmidt process to make them augmented as orthogonal basis.

Similarly we augment \( U \)

```python
>>> U_aug = U.row_join(Matrix([[0, 0, 1, 0]]))
>>> U_aug = U_aug.QRdecomposition()[0]
>>> U_aug
Matrix([ [0, 1, 0, 0], [0, 0, 1, 0], [0, 0, 0, 1], [1, 0, 0, 0]])
```
We add 2 zero columns and one row to S

```python
>>> S_aug = S.col_join(Matrix([[0, 0, 0]]))
>>> S_aug = S_aug.row_join(Matrix([[0, 0, 0, 0], [0, 0, 0, 0], ...
... [0, 0, 0, 0]]).H)
>>> S_aug
Matrix([%
[2, 0, 0, 0, 0],
[0, sqrt(5), 0, 0, 0],
[0, 0, 3, 0, 0],
[0, 0, 0, 0, 0]])
```

>>> U_aug * S_aug * V_aug.H == C
True

**solve**(*rhs*, *method='GJ'* )

Solves linear equation where the unique solution exists.

**Parameters**

- **rhs** : Matrix
  Vector representing the right hand side of the linear equation.

- **method** : string, optional
  If set to 'GJ' or 'GE', the Gauss-Jordan elimination will be used, which is implemented in the routine `gauss_jordan_solve`. If set to 'LU', LU solve routine will be used.
  If set to 'QR', QR solve routine will be used.
  If set to 'PINV', pinv solve routine will be used.
  It also supports the methods available for special linear systems
  For positive definite systems:
  If set to 'CH', cholesky solve routine will be used.
  If set to 'LDL', LDL solve routine will be used.

  To use a different method and to compute the solution via the inverse, use a method defined in the .inv() docstring.

**Returns**

- **solutions** : Matrix
Vector representing the solution.

Raises

ValueError

If there is not a unique solution then a ValueError will be raised.

If M is not square, a ValueError and a different routine for solving
the system will be suggested.

solve_least_squares(rhs, method='CH')

Return the least-square fit to the data.

Parameters

rhs : Matrix

Vector representing the right hand side of the linear equation.

method : string or boolean, optional

If set to 'CH', cholesky_solve routine will be used.

If set to 'LDL', LDLsolve routine will be used.

If set to 'QR', QRsolve routine will be used.

If set to 'PINV', pinv_solve routine will be used.

Otherwise, the conjugate of M will be used to create a system of equa-
tions that is passed to solve along with the hint defined by method.

Returns

solutions : Matrix

Vector representing the solution.

Examples

>>> from sympy import Matrix, ones

>>> A = Matrix([[1, 2, 3]])

>>> B = Matrix([[2, 3, 4]])

>>> S = Matrix(A.row_join(B))

>>> S

Matrix([ [1, 2],
          [2, 3],
          [3, 4]])

If each line of S represent coefficients of Ax + By and x and y are [2, 3] then S*xy is:

>>> r = S*Matrix([[2, 3]]); r

Matrix([ [ 8],
          [13],
          [18]])

But let’s add 1 to the middle value and then solve for the least-squares value of xy:
```python
>>> xy = S.solve_least_squares(Matrix([[8, 14, 18]])); xy
Matrix([[5/3],
        [10/3]])
```

The error is given by \( S \cdot xy - r \):

```python
>>> S*xy - r
Matrix([[1/3],
        [1/3],
        [1/3]])
```

If a different \( xy \) is used, the norm will be higher:

```python
>>> xy += ones(2, 1)/10
>>> (S*xy - r).norm().n(2)
1.5
```

### strongly_connected_components()

Returns the list of strongly connected vertices of the graph when a square matrix is viewed as a weighted graph.

### Examples

```python
>>> from sympy import Matrix
>>> A = Matrix([...
              [44, 0, 0, 0, 43, 0, 45, 0, 0],
              [0, 66, 62, 61, 0, 68, 0, 60, 67],
              [0, 0, 22, 21, 0, 0, 0, 20, 0],
              [0, 0, 12, 11, 0, 0, 0, 10, 0],
              [34, 0, 0, 0, 33, 0, 35, 0, 0],
              [0, 86, 82, 81, 0, 88, 0, 80, 87],
              [54, 0, 0, 0, 53, 0, 55, 0, 0],
              [0, 0, 2, 1, 0, 0, 0, 0, 0],
              [0, 76, 72, 71, 0, 78, 0, 70, 77]])
```

```python
>>> A.strongly_connected_components()
[[0, 4, 6], [2, 3, 7], [1, 5, 8]]
```

### strongly_connected_components_decomposition(lower=True)

Decomposes a square matrix into block triangular form only using the permutations.

**Parameters**

- **lower** : bool

  Makes \( B \) lower block triangular when True. Otherwise, makes \( B \) upper block triangular.

**Returns**

- \( P, B \) : PermutationMatrix, BlockMatrix
$P$ is a permutation matrix for the similarity transform as in the explanation. And $B$ is the block triangular matrix of the result of the permutation.

**Explanation**

The decomposition is in a form of $A = P^{-1}BP$ where $P$ is a permutation matrix and $B$ is a block diagonal matrix.

**Examples**

```python
>>> from sympy import Matrix, pprint
>>> A = Matrix([...
... [44, 0, 0, 0, 43, 0, 45, 0, 0],
... [0, 66, 62, 61, 0, 68, 0, 60, 67],
... [0, 0, 22, 21, 0, 0, 0, 20, 0],
... [0, 0, 12, 11, 0, 0, 0, 10, 0],
... [34, 0, 0, 0, 33, 0, 35, 0, 0],
... [0, 86, 82, 81, 0, 88, 0, 80, 87],
... [54, 0, 0, 0, 53, 0, 55, 0, 0],
... [0, 0, 2, 1, 0, 0, 0, 0, 0],
... [0, 76, 72, 71, 0, 78, 0, 70, 77]])

A lower block triangular decomposition:

```python
>>> P, B = A.strongly_connected_components_decomposition()
>>> pprint(P)
PermutationMatrix((8)(1 4 3 2 6)(5 7))

>>> pprint(B)
[[44 43 45] [0 0 0] [0 0 0] ]
[[ ] [ ] [ ] ]
[[34 33 35] [0 0 0] [0 0 0] ]
[[ ] [ ] [ ] ]
[[54 53 55] [0 0 0] [0 0 0] ]
[[ ] [ ] [ ] ]
[[0 0 0] [22 21 20] [0 0 0] ]
[[ ] [ ] [ ] ]
[[0 0 0] [12 11 10] [0 0 0] ]
[[ ] [ ] [ ] ]
[[0 0 0] [2 1 0] [0 0 0] ]
[[ ] [ ] [ ] ]
[[0 0 0] [62 61 60] [66 68 67]]
[[ ] [ ] [ ] ]
[[0 0 0] [82 81 80] [86 88 87]]
[[ ] [ ] [ ] ]
[[0 0 0] [72 71 70] [76 78 77]]
```
An upper block triangular decomposition:

```python
>>> P, B = A.strongly_connected_components_decomposition(lower=False)
>>> pprint(P)
PermutationMatrix((0 1 5 7 4 3 2 8 6))
>>> pprint(B)
[[66 68 67] [62 61 60] [0 0 0] ]
[[ ] [ ] [ ] ]
[[66 88 87] [82 81 80] [0 0 0] ]
[[ ] [ ] [ ] ]
[[76 78 77] [72 71 70] [0 0 0] ]
[ ]
[ [0 0 0] [22 21 20] [0 0 0] ]
[ [ ] [ ] [ ] ]
[ [0 0 0] [12 11 10] [0 0 0] ]
[ [ ] [ ] [ ] ]
[ [0 0 0] [2 1 0] [0 0 0] ]
[ ]
[ [0 0 0] [0 0 0] [44 43 45]]
[ [ ] [ ] [ ] ]
[ [0 0 0] [0 0 0] [34 33 35]]
[ [ ] [ ] [ ] ]
[ [0 0 0] [0 0 0] [54 53 55]]
```

```python
>>> P = P.as_explicit()
>>> B = B.as_explicit()
>>> P.T * B * P == A
True
```

`table(printer, rowstart='[', rowend=']', rowsep='\n', colsep=', ', align='right')`

String form of Matrix as a table.

- `printer` is the printer to use for on the elements (generally something like StrPrinter())
- `rowstart` is the string used to start each row (by default '[').
- `rowend` is the string used to end each row (by default ']').
- `rowsep` is the string used to separate rows (by default a newline).
- `colsep` is the string used to separate columns (by default ',', '.').
- `align` defines how the elements are aligned. Must be one of 'left', 'right', or 'center'. You can also use '<', '>', and '^' to mean the same thing, respectively.

This is used by the string printer for Matrix.
Examples

```python
>>> from sympy import Matrix, StrPrinter
>>> M = Matrix([[1, 2], [-33, 4]])
>>> printer = StrPrinter()
>>> M.table(printer)
'[[ 1, 2]
 [-33, 4]]

>>> print(M.table(printer))
[ 1, 2]
[-33, 4]

>>> print(M.table(printer, rowsep=',\n'))
[ 1, 2],
[-33, 4]

>>> print('[' + M.table(printer, rowsep=',\n') + '])
[[ 1, 2],
 [-33, 4]]

>>> print(M.table(printer, colsep=' '))
[ 1 2]
[-33 4]

>>> print(M.table(printer, align='center'))
[ 1 , 2]
[-33 , 4]

>>> print(M.table(printer, rowstart='{', rowend='}'))
{ 1, 2}
{ -33, 4}
```

**upper_hessenberg_decomposition()**

Converts a matrix into Hessenberg matrix H.

Returns 2 matrices H, P s.t. \(PH^T = A\), where H is an upper hessenberg matrix and P is an orthogonal matrix

Examples

```python
>>> from sympy import Matrix
>>> A = Matrix([...[1,2,3],...
[-3,5,6],...
[4,-8,9],...
])
>>> H, P = A.upper_hessenberg_decomposition()
>>> H
Matrix([[1, 6/5, 17/5],
        [5, 213/25, -134/25],
        [0, 216/25, 137/25]])

>>> P
Matrix([[1, 0, 0],
        [0, -3/5, 4/5],
        [0, 4/5, 3/5]])
```

(continues on next page)

Matrix Exceptions

```python
class sympy.matrices.matrices.MatrixError
class sympy.matrices.matrices.ShapeError
    Wrong matrix shape
class sympy.matrices.matrices.NonSquareMatrixError
```

Matrix Functions

```python
sympy.matrices.dense.matrix_multiply_elementwise(A, B)
    Return the Hadamard product (elementwise product) of A and B
```

```python
>>> from sympy import Matrix, matrix_multiply_elementwise
>>> A = Matrix([[0, 1, 2], [3, 4, 5]])
>>> B = Matrix([[1, 10, 100], [100, 10, 1]])
>>> matrix_multiply_elementwise(A, B)
Matrix([[0, 10, 200],
        [300, 40, 5]])
```

- `ones` (page 1359), `eye` (page 1360), `diag` (page 1360)

5.8. Topics 1359
sympy.matrices.dense.ones(*args, **kwargs)

Returns a matrix of ones with rows rows and cols columns; if cols is omitted a square matrix will be returned.

See also:
zeros (page 1359), eye (page 1360), diag (page 1360)

sympy.matrices.dense.eye(*args, **kwargs)

Create square identity matrix n x n

See also:
diag (page 1360), zeros (page 1359), ones (page 1359)

sympy.matrices.dense.diag(*values, strict=True, unpack=False, **kwargs)

Returns a matrix with the provided values placed on the diagonal. If non-square matrices are included, they will produce a block-diagonal matrix.

Examples

This version of diag is a thin wrapper to Matrix.diag that differs in that it treats all lists like matrices – even when a single list is given. If this is not desired, either put a * before the list or set unpack = True.

```python
>>> from sympy import diag
>>> diag([1, 2, 3], unpack=True)  # = diag(1,2,3) or diag(*[1,2,3])
Matrix([[1, 0, 0],
       [0, 2, 0],
       [0, 0, 3]])

>>> diag([1, 2, 3])  # a column vector
Matrix([[1],
        [2],
        [3]])
```

See also:
common.MatrixCommon.eye (page 1381), common.MatrixCommon.diagonal (page 1379),
common.MatrixCommon.diag (page 1377), expressions.blockmatrix.BlockMatrix (page 1424)

sympy.matrices.dense.jordan_cell(eigenval, n)

Create a Jordan block:
Examples

```python
>>> from sympy import jordan_cell
>>> from sympy.abc import x
>>> jordan_cell(x, 4)
Matrix([[x, 1, 0, 0],
       [0, x, 1, 0],
       [0, 0, x, 1],
       [0, 0, 0, x]])
```

`sympy.matrices.dense.hessian(f, varlist, constraints=())`

Compute Hessian matrix for a function f wrt parameters in varlist which may be given as a sequence or a row/column vector. A list of constraints may optionally be given.

Examples

```python
>>> from sympy import Function, hessian, pprint
>>> from sympy.abc import x, y
>>> f = Function('f')(x, y)
>>> g1 = Function('g')(x, y)
>>> g2 = x**2 + 3*y
>>> pprint(hessian(f, (x, y), [g1, g2]))
```

```
[ d  d
[ 0 0 --(g(x, y)) --(g(x, y)) ]
[ dx dy ]
[ ]
[ 0 0 2*x 3 ]
[ ]
[ d  d 2 2
[d -(-g(x, y)) 2*x ---(f(x, y)) -----(f(x, y))]
[dx 2 2 2
[ dy dx ]
[ ]
[ ]
[d  d 2 2
 [d -(-g(x, y)) 3 -----(f(x, y)) ---(f(x, y))]
[dy 2 2
[ dy dx dy ]
```

`sympy.matrices.matrices.MatrixCalculus.jacobian` (page 1320), `wronskian` (page 1362)
References

[R614]
sympy.matrices.dense.GramSchmidt(vlist, orthonormal=False)
Apply the Gram-Schmidt process to a set of vectors.

Parameters

vlist : List of Matrix
Vectors to be orthogonalized for.

orthonormal : Bool, optional
If true, return an orthonormal basis.

Returns

vlist : List of Matrix
Orthogonalized vectors

Notes

This routine is mostly duplicate from Matrix.orthogonalize, except for some difference that this always raises error when linearly dependent vectors are found, and the keyword normalize has been named as orthonormal in this function.

See also:

matrices.MatrixSubspaces.orthogonalize (page 1279)

References

[R615]
sympy.matrices.dense.wronskian(functions, var, method='bareiss')
Compute Wronskian for [] of functions

\[
W(f_1, \ldots, f_n) = \begin{vmatrix}
f_1 & f_2 & \cdots & f_n \\
f_1' & f_2' & \cdots & f_n' \\
\vdots & \vdots & \ddots & \vdots \\
\vdots & \vdots & \ddots & \vdots \\
(n) & (n) & (n) & \cdots \\
D (f_1) & D (f_2) & \cdots & D (f_n)
\end{vmatrix}
\]

see: https://en.wikipedia.org/wiki/Wronskian

See also:

sympy.matrices.matrices.MatrixCalculus.jacobian (page 1320), hessian (page 1361)
sympy.matrices.dense.casoratian(seqs, n, zero=True)
Given linear difference operator L of order ‘k’ and homogeneous equation Ly = 0 we want to compute kernel of L, which is a set of ‘k’ sequences: a(n), b(n), ... z(n).
Solutions of L are linearly independent iff their Casoratian, denoted as C(a, b, ..., z), do not vanish for n = 0.

Casoratian is defined by k x k determinant:

\[
\begin{vmatrix}
  a(n) & b(n) & \ldots & z(n) \\
  a(n+1) & b(n+1) & \ldots & z(n+1) \\
  \vdots & \vdots & \ddots & \vdots \\
  \vdots & \vdots & \ddots & \vdots \\
  a(n+k-1) & b(n+k-1) & \ldots & z(n+k-1)
\end{vmatrix}
\]

It proves very useful in \texttt{rsolve_hyper()} where it is applied to a generating set of a recurrence to factor out linearly dependent solutions and return a basis:

```python
>>> from sympy import Symbol, casoratian, factorial
>>> n = Symbol('n', integer=True)
```

Exponential and factorial are linearly independent:

```python
>>> casoratian([2**n, factorial(n)], n) != 0
True
```

\texttt{sympy.matrices.dense.randMatrix}(r, c=None, min=0, max=99, seed=None, symmetric=False, percent=100, prng=None)

Create random matrix with dimensions r x c. If c is omitted the matrix will be square. If symmetric is True the matrix must be square. If percent is less than 100 then only approximately the given percentage of elements will be non-zero.

The pseudo-random number generator used to generate matrix is chosen in the following way.

- If \texttt{prng} is supplied, it will be used as random number generator. It should be an instance of \texttt{random.Random}, or at least have \texttt{randint} and \texttt{shuffle} methods with same signatures.
- if \texttt{prng} is not supplied but \texttt{seed} is supplied, then new \texttt{random.Random} with given seed will be created;
- otherwise, a new \texttt{random.Random} with default seed will be used.

**Examples**

```python
>>> from sympy import randMatrix
>>> randMatrix(3)
[25, 45, 27]
[44, 54, 9]
[23, 96, 46]
```

(continues on next page)
>>> randMatrix(3, symmetric=True)
[85, 26, 29]
[26, 71, 43]
[29, 43, 57]
>>> A = randMatrix(3, seed=1)
>>> B = randMatrix(3, seed=2)
>>> A == B
False
>>> A == randMatrix(3, seed=1)
True
>>> randMatrix(3, symmetric=True, percent=50)
[77, 70, 0],
[70, 0, 0],
[ 0, 0, 88]

Rotation matrices

```
sympy.matrices.dense.rot_givens(i, j, theta, dim=3)
```

Returns a a Givens rotation matrix, a a rotation in the plane spanned by two coordinates axes.

**Parameters**

- **i**: int between 0 and dim - 1
  
  Represents first axis

- **j**: int between 0 and dim - 1
  
  Represents second axis

- **dim**: int bigger than 1
  
  Number of dimensions. Defaults to 3.

**Explanation**

The Givens rotation corresponds to a generalization of rotation matrices to any number of dimensions, given by:

\[
G(i, j, \theta) = \begin{bmatrix}
1 & \cdots & 0 & \cdots & 0 & \cdots & 0 \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\
0 & \cdots & c & \cdots & -s & \cdots & 0 \\
\vdots & \vdots & \ddots & \ddots & \ddots & \ddots & \vdots \\
0 & \cdots & s & \cdots & c & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \ddots & \ddots & \vdots \\
0 & \cdots & 0 & \cdots & 0 & \cdots & 1
\end{bmatrix}
\]

Where \(c = \cos(\theta)\) and \(s = \sin(\theta)\) appear at the intersections ith and jth rows and columns.

For fixed \(i > j\), the non-zero elements of a Givens matrix are given by:

- \(g_{kk} = 1\) for \(k \neq i, j\)
• \( g_{kk} = c \) for \( k = i, j \)
• \( g_{ji} = -g_{ij} = -s \)

**Examples**

```python
>>> from sympy import pi, rot_givens
```

A counterclockwise rotation of \( \pi/3 \) (60 degrees) around the third axis (z-axis):

```python
>>> rot_givens(1, 0, pi/3)
Matrix([[1/2, -sqrt(3)/2, 0],
        [sqrt(3)/2, 1/2, 0],
        [0, 0, 1]])
```

If we rotate by \( \pi/2 \) (90 degrees):

```python
>>> rot_givens(1, 0, pi/2)
Matrix([[0, -1, 0],
        [1, 0, 0],
        [0, 0, 1]])
```

This can be generalized to any number of dimensions:

```python
>>> rot_givens(1, 0, pi/2, dim=4)
Matrix([[0, -1, 0, 0],
        [1, 0, 0, 0],
        [0, 0, 1, 0],
        [0, 0, 0, 1]])
```

SymPy Documentation, Release 1.12.1

rot_ccw_axis3 (page 1370)
Returns a rotation matrix for a rotation of theta (in radians) about the 3-axis (counterclockwise around the z axis)

References

[R616]
sympy.matrices.dense.rot_axis1(theta)
Returns a rotation matrix for a rotation of theta (in radians) about the 1-axis.

Explanation

For a right-handed coordinate system, this corresponds to a clockwise rotation around the x-axis, given by:

\[
R = \begin{bmatrix}
1 & 0 & 0 \\
0 & \cos(\theta) & \sin(\theta) \\
0 & -\sin(\theta) & \cos(\theta)
\end{bmatrix}
\]

Examples

>>> from sympy import pi, rot_axis1
A rotation of pi/3 (60 degrees):

>>> theta = pi/3
>>> rot_axis1(theta)
Matrix([ [1, 0, 0],
[0, 1/2, sqrt(3)/2],
[0, -sqrt(3)/2, 1/2]])
If we rotate by pi/2 (90 degrees):

>>> rot_axis1(pi/2)
Matrix([ [1, 0, 0],
[0, 0, 1],
[0, -1, 0]])

See also:

rot_givens (page 1364)
Returns a Givens rotation matrix (generalized rotation for any number of dimensions)

rot_ccw_axis1 (page 1369)
Returns a rotation matrix for a rotation of theta (in radians) about the 1-axis (counterclockwise around the x axis)
rot_axis2 (page 1367)
Returns a rotation matrix for a rotation of theta (in radians) about the 2-axis (clockwise around the y axis)

rot_axis3 (page 1368)
Returns a rotation matrix for a rotation of theta (in radians) about the 3-axis (clockwise around the z axis)

sympy.matrices.dense.rot_axis2(theta)
Returns a rotation matrix for a rotation of theta (in radians) about the 2-axis.

Explanation
For a right-handed coordinate system, this corresponds to a clockwise rotation around the y-axis, given by:

\[
R = \begin{bmatrix}
\cos(\theta) & 0 & -\sin(\theta) \\
0 & 1 & 0 \\
\sin(\theta) & 0 & \cos(\theta)
\end{bmatrix}
\]

Examples

```python
>>> from sympy import pi, rot_axis2

A rotation of \(\pi/3\) (60 degrees):

```python
>>> theta = pi/3
>>> rot_axis2(theta)
Matrix([[\frac{1}{2}, 0, -\frac{\sqrt{3}}{2}],
        [0, 1, 0],
        [\frac{\sqrt{3}}{2}, 0, \frac{1}{2}]])
```

If we rotate by \(\pi/2\) (90 degrees):

```python
>>> rot_axis2(pi/2)
Matrix([[0, 0, -1],
        [0, 1, 0],
        [1, 0, 0]])
```

See also:
rot_givens (page 1364)
Returns a Givens rotation matrix (generalized rotation for any number of dimensions)

rot_ccw_axis2 (page 1369)
Returns a rotation matrix for a rotation of theta (in radians) about the 2-axis (clockwise around the y axis)

rot_axis1 (page 1366)
Returns a rotation matrix for a rotation of theta (in radians) about the 1-axis (counterclockwise around the x axis)
**rot_axis3** *(page 1368)*

Returns a rotation matrix for a rotation of theta (in radians) about the 3-axis (counterclockwise around the z axis)

```
sympy.matrices.dense.rot_axis3(theta)
```

This function returns a rotation matrix for a rotation of theta (in radians) about the 3-axis.

### Explanation

For a right-handed coordinate system, this corresponds to a clockwise rotation around the z-axis, given by:

\[
R = \begin{bmatrix}
\cos(\theta) & \sin(\theta) & 0 \\
-\sin(\theta) & \cos(\theta) & 0 \\
0 & 0 & 1 \\
\end{bmatrix}
\]

### Examples

```python
>>> from sympy import pi, rot_axis3

A rotation of pi/3 (60 degrees):

```python
>>> theta = pi/3
>>> rot_axis3(theta)
Matrix([ [1/2, sqrt(3)/2, 0], [-sqrt(3)/2, 1/2, 0], [0, 0, 1]])
```

If we rotate by pi/2 (90 degrees):

```python
>>> rot_axis3(pi/2)
Matrix([ [0, 1, 0], [-1, 0, 0], [0, 0, 1]])
```

### See also:

- **rot_givens** *(page 1364)*
  - Returns a Givens rotation matrix (generalized rotation for any number of dimensions)

  - Returns a rotation matrix for a rotation of theta (in radians) about the 3-axis (counterclockwise around the z axis)

- **rot_axis1** *(page 1366)*
  - Returns a rotation matrix for a rotation of theta (in radians) about the 1-axis (clockwise around the x axis)

- **rot_axis2** *(page 1367)*
  - Returns a rotation matrix for a rotation of theta (in radians) about the 2-axis (clockwise around the y axis)
sympy.matrices.dense.rot_ccw_axis1(θ)

Returns a rotation matrix for a rotation of θ (in radians) about the 1-axis.

**Explanation**

For a right-handed coordinate system, this corresponds to a counterclockwise rotation around the x-axis, given by:

\[
R = \begin{bmatrix}
1 & 0 & 0 \\
0 & \cos(θ) & -\sin(θ) \\
0 & \sin(θ) & \cos(θ)
\end{bmatrix}
\]

**Examples**

```python
>>> from sympy import pi, rot_ccw_axis1

A rotation of pi/3 (60 degrees):
>>> theta = pi/3
>>> rot_ccw_axis1(theta)
Matrix([[1, 0, 0],
[0, 1/2, -sqrt(3)/2],
[0, sqrt(3)/2, 1/2]])
```

If we rotate by pi/2 (90 degrees):

```python
>>> rot_ccw_axis1(pi/2)
Matrix([[1, 0, 0],
[0, 0, -1],
[0, 1, 0]])
```

**See also:**

- `rot_givens` ([page 1364](#))
  Returns a Givens rotation matrix (generalized rotation for any number of dimensions)

- `rot_axis1` ([page 1366](#))
  Returns a rotation matrix for a rotation of θ (in radians) about the 1-axis (clockwise around the x axis)

- `rot_ccw_axis2` ([page 1369](#))
  Returns a rotation matrix for a rotation of θ (in radians) about the 2-axis (counterclockwise around the y axis)

- `rot_ccw_axis3` ([page 1370](#))
  Returns a rotation matrix for a rotation of θ (in radians) about the 3-axis (counterclockwise around the z axis)

- sympy.matrices.dense.rot_ccw_axis2(θ)
  Returns a rotation matrix for a rotation of θ (in radians) about the 2-axis.
**Explanation**

For a right-handed coordinate system, this corresponds to a counterclockwise rotation around the $y$-axis, given by:

$$
R = \begin{bmatrix}
\cos(\theta) & 0 & \sin(\theta) \\
0 & 1 & 0 \\
-\sin(\theta) & 0 & \cos(\theta)
\end{bmatrix}
$$

**Examples**

```python
>>> from sympy import pi, rot_ccw_axis2

A rotation of $\pi/3$ (60 degrees):

```python
>>> theta = pi/3
>>> rot_ccw_axis2(theta)
Matrix([[1/2, 0, sqrt(3)/2],
[0, 1, 0],
[-sqrt(3)/2, 0, 1/2]])
```

If we rotate by $\pi/2$ (90 degrees):

```python
>>> rot_ccw_axis2(pi/2)
Matrix([[0, 0, 1],
[0, 1, 0],
[-1, 0, 0]])
```

**See also:**

* **`rot_givens` (page 1364)**
  Returns a Givens rotation matrix (generalized rotation for any number of dimensions)

  Returns a rotation matrix for a rotation of $\theta$ (in radians) about the 2-axis (clockwise around the $y$ axis)

* **`rot_ccw_axis1` (page 1369)**
  Returns a rotation matrix for a rotation of $\theta$ (in radians) about the 1-axis (counterclockwise around the $x$ axis)

* **`rot_ccw_axis3` (page 1370)**
  Returns a rotation matrix for a rotation of $\theta$ (in radians) about the 3-axis (counterclockwise around the $z$ axis)

* `sympy.matrices.dense.rot_ccw_axis3(theta)`
  Returns a rotation matrix for a rotation of $\theta$ (in radians) about the 3-axis.
Explanation

For a right-handed coordinate system, this corresponds to a counterclockwise rotation around the $z$-axis, given by:

$$R = \begin{bmatrix}
\cos(\theta) & -\sin(\theta) & 0 \\
\sin(\theta) & \cos(\theta) & 0 \\
0 & 0 & 1
\end{bmatrix}$$

Examples

```python
>>> from sympy import pi, rot_ccw_axis3

A rotation of $\pi/3$ (60 degrees):

```python
def rot_ccw_axis3(theta):
    return Matrix([[1/2, -sqrt(3)/2, 0],
                    [sqrt(3)/2, 1/2, 0],
                    [0, 0, 1]])
```  

If we rotate by $\pi/2$ (90 degrees):

```python
def rot_ccw_axis3(\pi/2):
    return Matrix([[0, -1, 0],
                   [1, 0, 0],
                   [0, 0, 1]])
```

Numpy Utility Functions

.. currentmodule:: sympy.matrices.dense

.. function:: list2numpy(l, dtype=<class 'object'>)

   Converts Python list of SymPy expressions to a NumPy array.

   See also:
   `matrix2numpy` (page 1372)

.. function:: matrix2numpy(m, dtype=<class 'object'>)

   Converts SymPy's matrix to a NumPy array.

   See also:
   `list2numpy` (page 1372)

.. function:: symarray(prefix, shape, **kwargs)

   Create a numpy ndarray of symbols (as an object array).
   The created symbols are named `prefix_i1_i2_` ... You should thus provide a non-empty
   prefix if you want your symbols to be unique for different output arrays, as SymPy symbols
   with identical names are the same object.

   **Parameters**
   
   - `prefix` : string
     A prefix prepended to the name of every symbol.
   
   - `shape` : int or tuple
     Shape of the created array. If an int, the array is one-dimensional; for
     more than one dimension the shape must be a tuple.
   
   - `**kwargs` : dict
     keyword arguments passed on to `Symbol`

   **Examples**

   These doctests require `numpy`.

   >>> from sympy import symarray
   >>> symarray('', 3)
   [_0 _1 _2]

   If you want multiple symarrays to contain distinct symbols, you must provide unique
   prefixes:

   >>> a = symarray('', 3)
   >>> b = symarray('', 3)
   >>> a[0] == b[0]
   True
   >>> a = symarray('a', 3)
   >>> b = symarray('b', 3)
   >>> a[0] == b[0]
   False

   Creating symarrays with a prefix:
>>> symarray('a', 3)
[a_0  a_1  a_2]

For more than one dimension, the shape must be given as a tuple:

>>> symarray('a', (2, 3))
[[a_0_0  a_0_1  a_0_2]
 [a_1_0  a_1_1  a_1_2]]

>>> symarray('a', (2, 3, 2))
[[[a_0_0 a_0_1]
  [a_1_0 a_1_1]
  [a_2_0 a_2_1]]

[[a_0_0 a_1_0]
 [a_1_0 a_1_1]
 [a_2_0 a_2_1]]]

For setting assumptions of the underlying Symbols:

>>> [s.is_real for s in symarray('a', 2, real=True)]
[True, True]

sympy.matrices.matrices.a2idx(j, n=None)
Return integer after making positive and validating against n.

Common Matrices

class sympy.matrices.common.MatrixCommon
All common matrix operations including basic arithmetic, shaping, and special matrices like zeros, and eye.

property C
By-element conjugation

property H
Return Hermite conjugate.

Examples

>>> from sympy import Matrix, I
>>> m = Matrix(((0, 1 + I, 2, 3))
>>> m
Matrix([[0],
 [1 + I],
 [2],
 [3]])

>>> m.H
Matrix([[0, 1 - I, 2, 3]])

See also:
**conjugate** *(page 1377)*
By-element conjugation

**sym.py.matrices.matrices.MatrixBase.D** *(page 1321)*
Dirac conjugation

**property T**
Matrix transposition

__abs__()  
Returns a new matrix with entry-wise absolute values.

__add__(other)  
Return self + other, raising ShapeError if shapes do not match.

__getitem__(key)  
Implementations of __getitem__ should accept ints, in which case the matrix is indexed as a flat list,
tuples (i,j) in which case the (i,j) entry is returned, slices, or mixed tuples (a,b) where a and b are any combination of slices and integers.

__len__()  
The total number of entries in the matrix.

__mul__(other)  
Return self*other where other is either a scalar or a matrix of compatible dimensions.

**Examples**

```python
>>> from sympy import Matrix
>>> A = Matrix([[1, 2, 3], [4, 5, 6]])
>>> 2*A == A*2 == Matrix([[2, 4, 6], [8, 10, 12]])
True
>>> B = Matrix([[1, 2, 3], [4, 5, 6], [7, 8, 9]])
>>> A*B
Matrix([[
    30, 36, 42],
   [66, 81, 96]])
>>> B*A
Traceback (most recent call last):
...
ShapeError: Matrices size mismatch.
```

See also:  
**matrix_multiply_elementwise** *(page 1359)*

__pow__(exp)  
Return self**exp a scalar or symbol.

__weakref__  
list of weak references to the object (if defined)
adjoint()
Conjugate transpose or Hermitian conjugation.

applyfunc(f)
Apply a function to each element of the matrix.

Examples

```python
>>> from sympy import Matrix
>>> m = Matrix(2, 2, lambda i, j: i*2+j)
>>> m
Matrix([[0, 4], [1, 6]])
>>> m.applyfunc(lambda i: 2*i)
Matrix([[0, 8], [2, 12]])
```

as_real_imag(deep=True, **hints)
Returns a tuple containing the (real, imaginary) part of matrix.

atoms(*types)
Returns the atoms that form the current object.

Examples

```python
>>> from sympy.abc import x, y
>>> from sympy import Matrix
>>> Matrix([[x]])
Matrix([[x]])
>>> _.atoms()
{x}
>>> Matrix([[x, y], [y, x]])
Matrix([[x, y], [y, x]])
>>> _.atoms()
{x, y}
```

col(j)
Elementary column selector.
Examples

```python
>>> from sympy import eye
def eye(2).col(0)
Matrix([1, 0])
```

See also:

* row (page 1397), col_del (page 1376), col_join (page 1376), col_insert (page 1376)

**col_del**(*col*)
Delete the specified column.

**col_insert**(*pos, other*)
Insert one or more columns at the given column position.

Examples

```python
>>> from sympy import zeros, ones
def M = zeros(3)
def V = ones(3, 1)
def M.col_insert(1, V)
Matrix([0, 1, 0, 0], [0, 1, 0, 0], [0, 1, 0, 0])
```

See also:

col (page 1375), row_insert (page 1397)

**col_join**(*other*)
Concatenates two matrices along self’s last and other’s first row.

Examples

```python
>>> from sympy import zeros, ones
def M = zeros(3)
def V = ones(1, 3)
def M.col_join(V)
Matrix([0, 0, 0], [0, 0, 0], [0, 0, 0], [1, 1, 1])
```

See also:

col (page 1375), row_join (page 1398)
classmethod companion(poly)
Returns a companion matrix of a polynomial.

Examples

```
>>> from sympy import Matrix, Poly, Symbol, symbols
>>> x = Symbol('x')
>>> c0, c1, c2, c3, c4 = symbols('c0:5')
>>> p = Poly(c0 + c1*x + c2*x**2 + c3*x**3 + c4*x**4 + x**5, x)
>>> Matrix.companion(p)
Matrix([[0, 0, 0, 0, -c0],
       [1, 0, 0, 0, -c1],
       [0, 1, 0, 0, -c2],
       [0, 0, 1, 0, -c3],
       [0, 0, 0, 1, -c4]])
```

conjugate()
Return the by-element conjugation.

Examples

```
>>> from sympy import SparseMatrix, I
>>> a = SparseMatrix(((1, 2 + I), (3, 4), (I, -I)))
>>> a
Matrix([[1, 2 + I],
       [3, 4],
       [I, -I]])
>>> a.C
Matrix([[1, 2 - I],
       [3, 4],
       [-I, I]])
```

See also:

transpose (page 1400)
Matrix transposition

H (page 1373)
Hermite conjugation

Dirac conjugation

classmethod diag(*args, strict=False, unpack=True, rows=None, cols=None, **kwargs)
Returns a matrix with the specified diagonal. If matrices are passed, a block-diagonal matrix is created (i.e. the “direct sum” of the matrices).
**Kwargs**

**rows**
[rows of the resulting matrix; computed if] not given.

**cols**
[columns of the resulting matrix; computed if] not given.

cls : class for the resulting matrix
unpack : bool which, when True (default), unpacks a single sequence rather than interpreting it as a Matrix.
strict : bool which, when False (default), allows Matrices to have variable-length rows.

**Examples**

```python
>>> from sympy import Matrix

```  
```python
>>> Matrix.diag(1, 2, 3)
Matrix([[1, 0, 0], [0, 2, 0], [0, 0, 3]])
```  
The current default is to unpack a single sequence. If this is not desired, set `unpack = False` and it will be interpreted as a matrix.

```python
>>> Matrix.diag([1, 2, 3]) == Matrix.diag(1, 2, 3)
True
```  
When more than one element is passed, each is interpreted as something to put on the diagonal. Lists are converted to matrices. Filling of the diagonal always continues from the bottom right hand corner of the previous item: this will create a block-diagonal matrix whether the matrices are square or not.

```python
>>> col = [1, 2, 3]
>>> row = [[4, 5]]
>>> Matrix.diag(col, row)
Matrix([[1, 0, 0], [2, 0, 0], [3, 0, 0], [0, 4, 5]])
```  
When `unpack` is False, elements within a list need not all be of the same length. Setting `strict` to True would raise a ValueError for the following:

```python
>>> Matrix.diag([1, 2, 3], [4, 5], [6], unpack=False)
Matrix([[1, 2, 3], [4, 5, 0], [6, 0, 0]])
```  
The type of the returned matrix can be set with the `cls` keyword.
A zero dimension matrix can be used to position the start of the filling at the start of an arbitrary row or column:

```
>>> from sympy import ones
g2 = ones(0, 2)
>>> Matrix.diag(g2, 1, 2)
Matrix([[0, 0, 1, 0], [0, 0, 0, 2]])
```

See also:

- `eye` (page 1381), `diagonal` (page 1379), `dense.diag` (page 1360), `expressions.blockmatrix.BlockMatrix` (page 1424), `sparsetools.banded` (page 1410)

`diagonal(k=0)`

Returns the kth diagonal of self. The main diagonal corresponds to \( k = 0 \); diagonals above and below correspond to \( k > 0 \) and \( k < 0 \), respectively. The values of self[i,j] for which \( j - i = k \), are returned in order of increasing \( i + j \), starting with \( i + j = |k| \).

Examples

```
>>> from sympy import Matrix

>>> m = Matrix(3, 3, lambda i, j: j - i); m
Matrix([[0, 1, 2], [-1, 0, 1], [-2, -1, 0]])
>>> m.diagonal()
Matrix([[0, 0, 0]])
>>> m.diagonal(1)
Matrix([[1, 1]])
>>> m.diagonal(-2)
Matrix([[[-2]])
```

Even though the diagonal is returned as a Matrix, the element retrieval can be done with a single index:

```
>>> Matrix.diag(1, 2, 3).diagonal()[1]    # instead of [0, 1]
2
```

See also:

- `diag` (page 1377)
- `evalf` (\(n=15, \)subs=None, \(maxn=100, \)chop=False, strict=False, quad=None, verbose=False)

Apply `evalf()` to each element of self.
expand\((deep=True, modulus=None, power_base=True, power_exp=True, mul=True, log=True, multinomial=True, basic=True, **hints)\)

Apply core.function.expand to each entry of the matrix.

Examples

```python
>>> from sympy import x
>>> from sympy import Matrix
>>> Matrix(1, 1, [x*(x + 1)])
Matrix([[x**2 + x]])
```

extract\((rowsList, colsList)\)

Return a submatrix by specifying a list of rows and columns. Negative indices can be given. All indices must be in the range \(-n \leq i < n\) where \(n\) is the number of rows or columns.

Examples

```python
>>> from sympy import Matrix
>>> m = Matrix(4, 3, range(12))
>>> m.extract([0, 1, 3], [0, 1])
Matrix([[0, 1], [3, 4], [9, 10]])
```

Rows or columns can be repeated:

```python
>>> m.extract([0, 0, 1], [-1])
Matrix([[2], [2], [5]])
```

Every other row can be taken by using range to provide the indices:

```python
>>> m.extract(range(0, m.rows, 2), [-1])
Matrix([[2], [8]])
```

RowsList or colsList can also be a list of booleans, in which case the rows or columns corresponding to the True values will be selected:
>>> m.extract([0, 1, 2, 3], [True, False, True])
Matrix(
[0, 2],
[3, 5],
[6, 8],
[9, 11])

classmethod eye(rows, cols=None, **kwargs)
Returns an identity matrix.

Parameters
rows : rows of the matrix
cols : cols of the matrix (if None, cols=rows)

Kwargs
cls : class of the returned matrix

property free_symbols
Returns the free symbols within the matrix.

Examples

>>> from sympy import x
>>> from sympy import Matrix
>>> Matrix([[x], [1]]).free_symbols
{x}

get_diag_blocks()
Obtains the square sub-matrices on the main diagonal of a square matrix.
Useful for inverting symbolic matrices or solving systems of linear equations which
may be decoupled by having a block diagonal structure.

Examples

>>> from sympy import Matrix
>>> from sympy import x, y, z
>>> A = Matrix([[1, 3, 0, 0], [y, z, 0, 0], [0, 0, x, 0], [0, 0, 0, w]])
>>> a1, a2, a3 = A.get_diag_blocks()
>>> a1
Matrix([[1, 3],
[y, z**2]])
>>> a2
Matrix([[x]])
>>> a3
Matrix([[0]])
**has(
*patterns
)**

Test whether any subexpression matches any of the patterns.

**Examples**

```python
>>> from sympy import Matrix, SparseMatrix, Float
>>> from sympy.abc import x, y
>>> A = Matrix(((1, x), (0.2, 3)))
>>> B = SparseMatrix(((1, x), (0.2, 3)))
>>> A.has(x)
True
>>> A.has(y)
False
>>> A.has(Float)
True
>>> B.has(x)
True
>>> B.has(y)
False
>>> B.has(Float)
True
```

**classmethod hstack(*args)**

Return a matrix formed by joining args horizontally (i.e. by repeated application of row_join).

**Examples**

```python
>>> from sympy import Matrix, eye
>>> Matrix.hstack(eye(2), 2*eye(2))
Matrix([[1, 0, 2, 0],
[0, 1, 0, 2]])
```

**is_anti_symmetric(simplify=True)**

Check if matrix M is an antisymmetric matrix, that is, M is a square matrix with all 
M[i, j] == -M[j, i].

When simplify=True (default), the sum M[i, j] + M[j, i] is simplified before testing to see if it is zero. By default, the SymPy simplify function is used. To use a custom function set simplify to a function that accepts a single argument which returns a simplified expression. To skip simplification, set simplify to False but note that although this will be faster, it may induce false negatives.
Examples

>>> from sympy import Matrix, symbols
>>> m = Matrix(2, 2, [0, 1, -1, 0])
>>> m
Matrix([[0, 1], [-1, 0]])
>>> m.isAntiSymmetric()
True
>>> x, y = symbols('x y')
>>> m = Matrix(2, 3, [0, 0, x, -y, 0, 0])
>>> m
Matrix([[0, 0, x], [-y, 0, 0]])
>>> m.isAntiSymmetric()
False

Simplification of matrix elements is done by default so even though two elements which should be equal and opposite would not pass an equality test, the matrix is still reported as anti-symmetric:

>>> m[0, 1] == -m[1, 0]
False
>>> m.isAntiSymmetric()
True

If simplify=False is used for the case when a Matrix is already simplified, this will speed things up. Here, we see that without simplification the matrix does not appear anti-symmetric:

>>> m.isAntiSymmetric(simplify=False)
False

But if the matrix were already expanded, then it would appear anti-symmetric and simplification in the isAntiSymmetric routine is not needed:

>>> m = m.expand()
>>> m.isAntiSymmetric(simplify=False)
True

is_diagonal()
Check if matrix is diagonal, that is matrix in which the entries outside the main diagonal are all zero.
Examples

```python
>>> from sympy import Matrix, diag
>>> m = Matrix(2, 2, [1, 0, 0, 2])
>>> m
Matrix([[1, 0], [0, 2]])
>>> m.is_diagonal()
True

>>> m = Matrix(2, 2, [1, 1, 0, 2])
>>> m
Matrix([[1, 1], [0, 2]])
>>> m.is_diagonal()
False

>>> m = diag(1, 2, 3)
>>> m
Matrix([[1, 0, 0], [0, 2, 0], [0, 0, 3]])
>>> m.is_diagonal()
True
```

See also:

- `is_lower` (page 1385), `is_upper` (page 1388), `sympy.matrices.matrices.MatrixEigen.is_diagonalizable` (page 1284), `diagonalize` (page 1280)

**property is_hermitian**

Checks if the matrix is Hermitian.

In a Hermitian matrix element \(i,j\) is the complex conjugate of element \(j,i\).

Examples

```python
>>> from sympy import Matrix
>>> from sympy import I
>>> from sympy.abc import x
>>> a = Matrix([[1, I], [-I, 1]])
>>> a
Matrix([[1, I], [-I, 1]])
>>> a.is_hermitian
True
>>> a[0, 0] = 2*I
>>> a.is_hermitian
(continues on next page)
```
```python
>>> a[0, 0] = x
>>> a.is_hermitian
False
>>> a[0, 1] = a[1, 0]*I
>>> a.is_hermitian
False
```

**property is_lower**

Check if matrix is a lower triangular matrix. True can be returned even if the matrix is not square.

**Examples**

```python
>>> from sympy import Matrix
>>> m = Matrix(2, 2, [1, 0, 0, 1])
>>> m
Matrix([[1, 0],
        [0, 1]])
>>> m.is_lower
True

>>> m = Matrix(4, 3, [0, 0, 0, 2, 0, 0, 1, 4, 0, 6, 6, 5])
>>> m
Matrix([[0, 0, 0],
        [2, 0, 0],
        [1, 4, 0],
        [6, 6, 5]])
>>> m.is_lower
False
```

**See also:**

`is_upper` (page 1388), `is_diagonal` (page 1383), `is_lower_hessenberg` (page 1385)

**property is_lower_hessenberg**

Checks if the matrix is in the lower-Hessenberg form.

The lower hessenberg matrix has zero entries above the first superdiagonal.
Examples

```python
>>> from sympy import Matrix
>>> a = Matrix([[1, 2, 0, 0], [5, 2, 3, 0], [3, 4, 3, 7], [5, 6, 1, 1]])
>>> a
Matrix([[1, 2, 0, 0], [5, 2, 3, 0], [3, 4, 3, 7], [5, 6, 1, 1]])
>>> a.is_lower_hessenberg
True
```

See also: 
* `is_upper_hessenberg` (page 1389), `is_lower` (page 1385)

property `is_square`
Checks if a matrix is square.

A matrix is square if the number of rows equals the number of columns. The empty matrix is square by definition, since the number of rows and the number of columns are both zero.

Examples

```python
>>> from sympy import Matrix
>>> a = Matrix([[1, 2, 3], [4, 5, 6]])
>>> b = Matrix([[1, 2, 3], [4, 5, 6], [7, 8, 9]])
>>> c = Matrix([])
>>> a.is_square
False
>>> b.is_square
True
>>> c.is_square
True
```

property `is_strongly_diagonally_dominant`
Tests if the matrix is row strongly diagonally dominant.

Explanation

A \( n \times n \) matrix \( A \) is row strongly diagonally dominant if

\[
|A_{i,i}| > \sum_{j=0, j\neq i}^{n-1} |A_{i,j}| \quad \text{for all } i \in \{0, ..., n-1\}
\]
Examples

```python
>>> from sympy import Matrix
>>> A = Matrix([[3, -2, 1], [1, -3, 2], [-1, 2, 4]])
>>> A.is_strongly_diagonally_dominant
False

>>> A = Matrix([[-2, 2, 1], [1, 3, 2], [1, -2, 0]])
>>> A.is_strongly_diagonally_dominant
False

>>> A = Matrix([[-4, 2, 1], [1, 6, 2], [1, -2, 5]])
>>> A.is_strongly_diagonally_dominant
True
```

Notes

If you want to test whether a matrix is column diagonally dominant, you can apply the test after transposing the matrix.

is_symbolic()
Checks if any elements contain Symbols.

Examples

```python
>>> from sympy import Matrix
>>> from sympy.abc import x, y
>>> M = Matrix([[x, y], [1, 0]])
>>> M.is_symbolic()
True
```

is_symmetric(simplify=True)
Check if matrix is symmetric matrix, that is square matrix and is equal to its transpose.

By default, simplifications occur before testing symmetry. They can be skipped using 'simplify=False'; while speeding things a bit, this may however induce false negatives.

Examples

```python
>>> from sympy import Matrix
>>> m = Matrix(2, 2, [0, 1, 1, 2])
>>> m
Matrix([[0, 1], [1, 2]])
>>> m.is_symmetric()
True
```
>>> m = Matrix(2, 2, [0, 1, 2, 0])
>>> m
Matrix([0, 1],
[2, 0])
>>> m.is_symmetric()
False

>>> m = Matrix(2, 3, [0, 0, 0, 0, 0, 0])
>>> m
Matrix([0, 0, 0],
[0, 0, 0])
>>> m.is_symmetric()
False

>>> from sympy.abc import x, y
>>> m = Matrix(3, 3, [1, x**2 + 2*x + 1, y, (x + 1)**2, 2, 0, y, 0, 3])
>>> m
Matrix([1, x**2 + 2*x + 1, y],
[(x + 1)**2, 2, 0],
[y, 0, 3])
>>> m.is_symmetric()
True

If the matrix is already simplified, you may speed-up is_symmetric() test by using ‘simplify=False’.

>>> bool(m.is_symmetric(simplify=False))
False
>>> m1 = m.expand()
>>> m1.is_symmetric(simplify=False)
True

property is_upper
Check if matrix is an upper triangular matrix. True can be returned even if the matrix is not square.

Examples

>>> from sympy import Matrix
>>> m = Matrix(2, 2, [1, 0, 0, 1])
>>> m
Matrix([[1, 0],
[0, 1]])
>>> m.is_upper
True
>>> m = Matrix(4, 3, [5, 1, 9, 0, 4, 6, 0, 0, 5, 0, 0, 0])
>>> m
Matrix([  
[5, 1, 9],  
[0, 4, 6],  
[0, 0, 5],  
[0, 0, 0]])
>>> m.is_upper
True

>>> m = Matrix(2, 3, [4, 2, 5, 6, 1, 1])
>>> m
Matrix([  
[4, 2, 5],  
[6, 1, 1]])
>>> m.is_upper
False

See also:

is_lower (page 1385), is_diagonal (page 1383), is_upper_hessenberg (page 1389)

property is_upper_hessenberg
Checks if the matrix is the upper-Hessenberg form.
The upper hessenberg matrix has zero entries below the first subdiagonal.

Examples

>>> from sympy import Matrix
>>> a = Matrix([[1, 4, 2, 3], [3, 4, 1, 7], [0, 2, 3, 4], [0, 0, 1, 3]])
>>> a
Matrix([  
[1, 4, 2, 3],  
[3, 4, 1, 7],  
[0, 2, 3, 4],  
[0, 0, 1, 3]])
>>> a.is_upper_hessenberg
True

See also:

is_lower_hessenberg (page 1385), is_upper (page 1388)

property is_weakly_diagonally_dominant
Tests if the matrix is row weakly diagonally dominant.
A $n,n$ matrix $A$ is row weakly diagonally dominant if

$$\left| A_{i,i} \right| \geq \sum_{j=0, j\neq i}^{n-1} \left| A_{i,j} \right| \quad \text{for all } i \in \{0, \ldots, n-1\}$$

Examples

```python
>>> from sympy import Matrix
>>> A = Matrix([[3, -2, 1], [1, -3, 2], [-1, 2, 4]])
>>> A.is_weakly_diagonally_dominant
True
```

```python
>>> A = Matrix([[-2, 2, 1], [1, 3, 2], [1, -2, 0]])
>>> A.is_weakly_diagonally_dominant
False
```

```python
>>> A = Matrix([[-4, 2, 1], [1, 6, 2], [1, -2, 5]])
>>> A.is_weakly_diagonally_dominant
True
```

Notes

If you want to test whether a matrix is column diagonally dominant, you can apply the test after transposing the matrix.

**property is_zero_matrix**

Checks if a matrix is a zero matrix.

A matrix is zero if every element is zero. A matrix need not be square to be considered zero. The empty matrix is zero by the principle of vacuous truth. For a matrix that may or may not be zero (e.g. contains a symbol), this will be None

Examples

```python
>>> from sympy import Matrix, zeros
>>> from sympy.abc import x
>>> a = Matrix([[0, 0], [0, 0]])
>>> b = zeros(3, 4)
>>> c = Matrix([[0, 1], [0, 0]])
>>> d = Matrix([[]])
>>> e = Matrix([[x, 0], [0, 0]])
>>> a.is_zero_matrix
True
>>> b.is_zero_matrix
True
>>> c.is_zero_matrix
```

(continues on next page)
False
>>> d.is_zero_matrix
True
>>> e.is_zero_matrix

```python
classmethod jordan_block__(size=None, eigenvalue=None, *, band='upper', **kwargs)
```

Returns a Jordan block

**Parameters**

- **size**: Integer, optional
  Specifies the shape of the Jordan block matrix.

- **eigenvalue**: Number or Symbol
  Specifies the value for the main diagonal of the matrix.

---

**Note**: The keyword `eigenval` is also specified as an alias of this keyword, but it is not recommended to use.

We may deprecate the alias in later release.

- **band**: ‘upper’ or ‘lower’, optional
  Specifies the position of the off-diagonal to put 1 s on.

- **cls**: Matrix, optional
  Specifies the matrix class of the output form.

  If it is not specified, the class type where the method is being executed on will be returned.

**Returns**

Matrix

A Jordan block matrix.

**Raises**

ValueError

If insufficient arguments are given for matrix size specification, or no `eigenvalue` is given.

**Examples**

Creating a default Jordan block:

```python
>>> from sympy import Matrix
>>> from sympy.abc import x
>>> Matrix.jordan_block(4, x)
Matrix([[x, 1, 0, 0],
        [0, x, 1, 0],
        [0, 0, x, 1],
        [0, 0, 0, x]])
```
Creating an alternative Jordan block matrix where 1 is on lower off-diagonal:

```python
>>> Matrix.jordan_block(4, x, band='lower')
Matrix([[/i],[x, 0, 0, 0],
[1, x, 0, 0],
[0, 1, x, 0],
[0, 0, 1, x]])
```

Creating a Jordan block with keyword arguments

```python
>>> Matrix.jordan_block(size=4, eigenvalue=x)
Matrix([[/i],[x, 1, 0, 0],
[0, x, 1, 0],
[0, 0, x, 1],
[0, 0, 0, x]])
```

**References**

[R580]  
`lower_triangular(k=0)`  
Return the elements on and below the kth diagonal of a matrix. If k is not specified then simply returns lower-triangular portion of a matrix

**Examples**

```python
>>> from sympy import ones
>>> A = ones(4)
>>> A.lower_triangular()
Matrix([[/i],[1, 0, 0, 0],
[1, 1, 0, 0],
[1, 1, 1, 0],
[1, 1, 1, 1]])
```

```python
>>> A.lower_triangular(-2)
Matrix([[/i],[0, 0, 0, 0],
[0, 0, 0, 0],
[1, 0, 0, 0],
[1, 1, 0, 0]])
```

```python
>>> A.lower_triangular(1)
Matrix([[/i],[1, 1, 0, 0],
[1, 1, 1, 0],
[1, 1, 1, 1],
[1, 1, 1, 1]])
```
**multiply**(other, dotprodsimp=None)

Same as __mul__() but with optional simplification.

**Parameters**

- **dotprodsimp**: bool, optional

  Specifies whether intermediate term algebraic simplification is used during matrix multiplications to control expression blowup and thus speed up calculation. Default is off.

**multiply_elementwise**(other)

Return the Hadamard product (elementwise product) of A and B

**Examples**

```python
>>> from sympy import Matrix
>>> A = Matrix([[0, 1, 2], [3, 4, 5]])
>>> B = Matrix([[1, 10, 100], [100, 10, 1]])
>>> A.multiply_elementwise(B)
Matrix([[0, 10, 200],
       [300, 40, 5]])
```

See also:

**n**(*args, **kwargs)

Apply evalf() to each element of self.

**classmethod ones**(rows, cols=None, **kwargs)

Returns a matrix of ones.

**Parameters**

- **rows**: rows of the matrix
- **cols**: cols of the matrix (if None, cols=rows)

**Kwargs**

- **cls**: class of the returned matrix

**permute**(perm, orientation='rows', direction='forward')

Permutes the rows or columns of a matrix by the given list of swaps.

**Parameters**

- **perm**: Permutation, list, or list of lists

  A representation for the permutation.

  If it is Permutation, it is used directly with some resizing with respect to the matrix size.

  If it is specified as list of lists, (e.g., [[0, 1], [0, 2]]), then the permutation is formed from applying the product of cycles. The direction how the cyclic product is applied is described in below.
If it is specified as a list, the list should represent an array form of a permutation. (e.g., [1, 2, 0]) which would form the swapping function 0 \mapsto 1, 1 \mapsto 2, 2 \mapsto 0.

**orientation**: `rows`, `cols`

A flag to control whether to permute the rows or the columns

**direction**: `forward`, `backward`

A flag to control whether to apply the permutations from the start of the list first, or from the back of the list first.

For example, if the permutation specification is [[0, 1], [0, 2]],
If the flag is set to `forward`, the cycle would be formed as 0 \mapsto 2, 2 \mapsto 1, 1 \mapsto 0.
If the flag is set to `backward`, the cycle would be formed as 0 \mapsto 1, 1 \mapsto 2, 2 \mapsto 0.
If the argument `perm` is not in a form of list of lists, this flag takes no effect.

**Examples**

```python
>>> from sympy import eye
>>> M = eye(3)
>>> M.permute([[0, 1], [0, 2]], orientation='rows', direction='forward')
Matrix([[0, 0, 1],
        [1, 0, 0],
        [0, 1, 0]])
```

```python
>>> from sympy import eye
>>> M = eye(3)
>>> M.permute([[0, 1], [0, 2]], orientation='rows', direction='backward')
Matrix([[0, 1, 0],
        [0, 0, 1],
        [1, 0, 0]])
```

**Notes**

If a bijective function \( \sigma : \mathbb{N}_0 \to \mathbb{N}_0 \) denotes the permutation.

If the matrix \( A \) is the matrix to permute, represented as a horizontal or a vertical stack of vectors:

\[
A = \begin{bmatrix}
    a_0 \\
    a_1 \\
    \vdots \\
    a_{n-1}
\end{bmatrix} = [a_0 \ a_1 \ \cdots \ a_{n-1}]
\]
If the matrix $B$ is the result, the permutation of matrix rows is defined as:

$$B := \begin{bmatrix}
    a_{\sigma(0)} \\
    a_{\sigma(1)} \\
    \vdots \\
    a_{\sigma(n-1)}
\end{bmatrix}$$

And the permutation of matrix columns is defined as:

$$B := [a_{\sigma(0)} \ a_{\sigma(1)} \ \cdots \ a_{\sigma(n-1)}]$$

`permute_cols` *(swaps, direction='forward')*

Alias for `self.permute(swaps, orientation='cols', direction=direction)`

**See also:**

`permute` (page 1393)

`permute_rows` *(swaps, direction='forward')*

Alias for `self.permute(swaps, orientation='rows', direction=direction)`

**See also:**

`permute` (page 1393)

`pow` *(exp, method=None)*

Return `self**exp` a scalar or symbol.

**Parameters**

`method` : multiply, mulsimp, jordan, cayley

If multiply then it returns exponentiation using recursion. If jordan then Jordan form exponentiation will be used. If cayley then the exponentiation is done using Cayley-Hamilton theorem. If mulsimp then the exponentiation is done using recursion with dotprodsimp. This specifies whether intermediate term algebraic simplification is used during naive matrix power to control expression blowup and thus speed up calculation. If None, then it heuristically decides which method to use.

`refine` *(assumptions=True)*

Apply `refine` to each element of the matrix.

**Examples**

```python
>>> from sympy import Symbol, Matrix, Abs, sqrt, Q
>>> x = Symbol('x')
>>> Matrix([[Abs(x)**2, sqrt(x**2)],[sqrt(x**2), Abs(x)**2]])
Matrix([[Abs(x)**2, sqrt(x**2)],
        [sqrt(x**2), Abs(x)**2]])
>>> _.refine(Q.real(x))
Matrix([[x**2, Abs(x)],
        [Abs(x), x**2]])
```
replace($F, G$, map=False, simultaneous=True, exact=None)
Replaces Function $F$ in Matrix entries with Function $G$.

**Examples**

```python
>>> from sympy import symbols, Function, Matrix
>>> F, G = symbols('F, G', cls=Function)
>>> M = Matrix([ [F(0), F(1)], [F(1), F(2)] ]); M
Matrix([[F(0), F(1)], [F(1), F(2)]])
>>> N = M.replace(F,G)
>>> N
Matrix([[G(0), G(1)], [G(1), G(2)]])
```

reshape(rows, cols)
Reshape the matrix. Total number of elements must remain the same.

**Examples**

```python
>>> from sympy import Matrix
>>> m = Matrix([ [1, 1, 1], [1, 1, 1] ]); m
Matrix([[1, 1, 1], [1, 1, 1]])
>>> m.reshape(1, 6)
Matrix([[1, 1, 1, 1, 1, 1]])
>>> m.reshape(3, 2)
Matrix([[1, 1], [1, 1], [1, 1]])
```

rmultiply(other, dotprodsimp=None)
Same as __rmul__() but with optional simplification.

**Parameters**

- **dotprodsimp** : bool, optional
  Specifies whether intermediate term algebraic simplification is used during matrix multiplications to control expression blowup and thus speed up calculation. Default is off.

rot90($k=1$)
Rotates Matrix by 90 degrees

**Parameters**

- **k** : int
Specifies how many times the matrix is rotated by 90 degrees (clockwise when positive, counter-clockwise when negative).

**Examples**

```python
>>> from sympy import Matrix, symbols
>>> A = Matrix(2, 2, symbols('a:d'))
>>> A
Matrix([[a, b],
        [c, d]])
```

Rotating the matrix clockwise one time:

```python
>>> A.rot90(1)
Matrix([[c, a],
        [d, b]])
```

Rotating the matrix anticlockwise two times:

```python
>>> A.rot90(-2)
Matrix([[d, c],
        [b, a]])
```

**row(i)**

Elementary row selector.

**Examples**

```python
>>> from sympy import eye
>>> eye(2).row(0)
Matrix([[[1, 0]]])
```

**See also:**

`col` (page 1375), `row_del` (page 1397), `row_join` (page 1398), `row_insert` (page 1397)

**row_del(row)**

Delete the specified row.

**row_insert(pos, other)**

Insert one or more rows at the given row position.
Examples

```python
>>> from sympy import zeros, ones
>>> M = zeros(3)
>>> V = ones(1, 3)
>>> M.row_insert(1, V)
Matrix([[0, 0, 0], [1, 1, 1], [0, 0, 0], [0, 0, 0]])
```

See also:
- `row` (page 1397), `col_insert` (page 1376)

```
row_join(other)
```

Concatenates two matrices along self’s last and rhs’s first column.

Examples

```python
>>> from sympy import zeros, ones
>>> M = zeros(3)
>>> V = ones(3, 1)
>>> M.row_join(V)
Matrix([[0, 0, 0, 1], [0, 0, 0, 1], [0, 0, 0, 1]])
```

See also:
- `row` (page 1397), `col_join` (page 1376)

property shape

The shape (dimensions) of the matrix as the 2-tuple (rows, cols).

Examples

```python
>>> from sympy import zeros
>>> M = zeros(2, 3)
>>> M.shape
(2, 3)
>>> M.rows
2
>>> M.cols
3
```

`simplify(**kwargs)`

Apply `simplify` to each element of the matrix.
Examples

```python
>>> from sympy.abc import x, y
>>> from sympy import SparseMatrix, sin, cos
>>> SparseMatrix(1, 1, [x*sin(y)**2 + x*cos(y)**2])
Matrix([[x*sin(y)**2 + x*cos(y)**2]])
>>> _.simplify()
Matrix([[x]])
```

**subs(*args, **kwargs)**

Return a new matrix with subs applied to each entry.

Examples

```python
>>> from sympy.abc import x, y
>>> from sympy import SparseMatrix, Matrix
>>> SparseMatrix(1, 1, [x])
Matrix([[x]])
>>> _.subs(x, y)
Matrix([[y]])
>>> Matrix(_).subs(y, x)
Matrix([[x]])
```

**todod()**

Returns matrix as dict of dicts containing non-zero elements of the Matrix

Examples

```python
>>> from sympy import Matrix
>>> A = Matrix([[0, 1],[0, 3]])
>>> A.todod()
{0: {1: 1}, 1: {1: 3}}
```

**todok()**

Return the matrix as dictionary of keys.
Examples

```python
>>> from sympy import Matrix
>>> M = Matrix.eye(3)
>>> M.todok()
{(0, 0): 1, (1, 1): 1, (2, 2): 1}
```

tolist()
Return the Matrix as a nested Python list.

Examples

```python
>>> from sympy import Matrix, ones
>>> m = Matrix(3, 3, range(9))
>>> m
t Matrix([[0, 1, 2], [3, 4, 5], [6, 7, 8]])
>>> m.tolist()
[[0, 1, 2], [3, 4, 5], [6, 7, 8]]
>>> ones(3, 0).tolist()
[[], [], []]
```

When there are no rows then it will not be possible to tell how many columns were in the original matrix:

```python
>>> ones(0, 3).tolist()
[]
```

trace()
Returns the trace of a square matrix i.e. the sum of the diagonal elements.

Examples

```python
>>> from sympy import Matrix
>>> A = Matrix(2, 2, [1, 2, 3, 4])
>>> A.trace()
5
```

transpose()
Returns the transpose of the matrix.
Examples

```python
>>> from sympy import Matrix
>>> A = Matrix(2, 2, [1, 2, 3, 4])
>>> A.transpose()
Matrix([[1, 3],
        [2, 4]])
```

```python
>>> from sympy import Matrix, I
>>> m = Matrix(((1, 2+I), (3, 4)))
>>> m
Matrix([[1, 2 + I],
        [3, 4]])
>>> m.transpose()
Matrix([[1, 3],
        [2 + I, 4]])
>>> m.T == m.transpose()
True
```

See also:

- `conjugate` (page 1377)
  - By-element conjugation

- `upper_triangular(k=0)`
  - Return the elements on and above the kth diagonal of a matrix. If k is not specified then simply returns upper-triangular portion of a matrix.

Examples

```python
>>> from sympy import ones
>>> A = ones(4)
>>> A.upper_triangular()
Matrix([[1, 1, 1, 1],
        [0, 1, 1, 1],
        [0, 0, 1, 1],
        [0, 0, 0, 1]])
```

```python
>>> A.upper_triangular(2)
Matrix([[0, 0, 1, 1],
        [0, 0, 0, 1],
        [0, 0, 0, 0],
        [0, 0, 0, 0]])
```
```
>>> A.upper_triangular(-1)
Matrix(
    [1, 1, 1, 1],
    [1, 1, 1, 1],
    [0, 1, 1, 1],
    [0, 0, 1, 1])
```

**values()**
Return non-zero values of self.

**vec()**
Return the Matrix converted into a one column matrix by stacking columns.

**Examples**
```
>>> from sympy import Matrix
>>> m=Matrix([[1, 3], [2, 4]])
>>> m
Matrix([[1, 3],
    [2, 4]])
>>> m.vec()
Matrix([1,
    2,
    3,
    4])
```

**See also:**

vec (page 1402)

vec(diagonal=True, check_symmetry=True)
Reshapes the matrix into a column vector by stacking the elements in the lower triangle.

**Parameters**
- **diagonal**: bool, optional
  - If True, it includes the diagonal elements.
- **check_symmetry**: bool, optional
  - If True, it checks whether the matrix is symmetric.
Examples

```python
>>> from sympy import Matrix
>>> m=Matrix([[1, 2], [2, 3]])
>>> m
Matrix([[1, 2],
        [2, 3]])
>>> m.vech()
Matrix([[1],
        [2],
        [3]])
>>> m.vech(diagonal=False)
Matrix([[2]])
```

Notes

This should work for symmetric matrices and vech can represent symmetric matrices in vector form with less size than vec.

See also:

vec (page 1402)

classmethod vstack(*args)

Return a matrix formed by joining args vertically (i.e. by repeated application of col_join).

Examples

```python
>>> from sympy import Matrix, eye
>>> Matrix.vstack(eye(2), 2*eye(2))
Matrix([[1, 0],
        [0, 1],
        [2, 0],
        [0, 2]])
```

classmethod wilkinson(n, **kwargs)

Returns two square Wilkinson Matrix of size $2n + 1$ $W_{2n+1}^-, W_{2n+1}^+ = Wilkinson(n)$

5.8. Topics
Examples

```python
>>> from sympy import Matrix
>>> wminus, wplus = Matrix.wilkinson(3)
>>> wminus
Matrix([[ -3,  1,  0,  0,  0,  0,  0],
        [  1, -2,  1,  0,  0,  0,  0],
        [  0,  1, -1,  1,  0,  0,  0],
        [  0,  0,  1,  0,  1,  0,  0],
        [  0,  0,  0,  1,  1,  1,  0],
        [  0,  0,  0,  0,  1,  2,  1],
        [  0,  0,  0,  0,  0,  1,  3]])
```

```python
>>> wplus
Matrix([[  3,  1,  0,  0,  0,  0,  0],
        [  1,  2,  1,  0,  0,  0,  0],
        [  0,  1,  1,  0,  0,  0,  0],
        [  0,  0,  1,  0,  1,  0,  0],
        [  0,  0,  0,  1,  1,  1,  0],
        [  0,  0,  0,  0,  1,  2,  1],
        [  0,  0,  0,  0,  0,  1,  3]])
```

References

[R581], [R582]

xreplace(rule)
Return a new matrix with xreplace applied to each entry.

Examples

```python
>>> from sympy import x, y
>>> from sympy import SparseMatrix, Matrix
>>> SparseMatrix(1, 1, [x])
Matrix([[x]])
>>> _.xreplace({x: y})
Matrix([[y]])
>>> Matrix(_.xreplace({y: x})
Matrix([[x]])
```

classmethod zeros(rows, cols=None, **kwargs)
Returns a matrix of zeros.

Parameters

- **rows**: rows of the matrix
- **cols**: cols of the matrix (if None, cols=rows)
Kwargs

cls : class of the returned matrix

class sympy.matrices.common.MatrixKind(element_kind=NumberKind)
Kind for all matrices in SymPy.
Basic class for this kind is MatrixBase and MatrixExpr, but any expression representing
the matrix can have this.

Parameters

- element_kind : Kind
  Kind of the element. Default is sympy.core.kind.NumberKind
  (page 1118), which means that the matrix contains only numbers.

Examples

Any instance of matrix class has MatrixKind:

```python
>>> from sympy import MatrixSymbol
>>> A = MatrixSymbol('A', 2, 2)
>>> A.kind
MatrixKind(NumberKind)
```

Although expression representing a matrix may be not instance of matrix class, it will
have MatrixKind as well:

```python
>>> from sympy import MatrixExpr, Integral
>>> from sympy.abc import x
>>> intM = Integral(A, x)
>>> isinstance(intM, MatrixExpr)
False
>>> intM.kind
MatrixKind(NumberKind)
```

Use isinstance() to check for MatrixKind without specifying the element kind. Use is
with specifying the element kind:

```python
>>> from sympy import Matrix
>>> from sympy.core import NumberKind
>>> from sympy.matrices import MatrixKind
>>> M = Matrix([1, 2])
>>> isinstance(M.kind, MatrixKind)
True
>>> M.kind is MatrixKind(NumberKind)
True
```

See also:

sympy.core.kind.NumberKind (page 1118), sympy.core.kind.UndefinedKind
(page 1118), sympy.core.containers.TupleKind (page 1115), sympy.sets.sets.
SetKind (page 1259)
Dense Matrices

sympy.matrices.dense.Matrix
    alias of MutableDenseMatrix (page 1408)

class sympy.matrices.dense.DenseMatrix
    Matrix implementation based on DomainMatrix as the internal representation

LDLdecomposition(hermitian=True)
    Returns the LDL Decomposition (L, D) of matrix A, such that L * D * L.H == A
    if hermitian flag is True, or L * D * L.T == A if hermitian is False. This method
    eliminates the use of square root. Further this ensures that all the diagonal entries
    of L are 1. A must be a Hermitian positive-definite matrix if hermitian is True, or a
    symmetric matrix otherwise.

Examples

```python
>>> from sympy import Matrix, eye
>>> A = Matrix(((25, 15, -5), (15, 18, 0), (-5, 0, 11)))
>>> L, D = A.LDLdecomposition()
>>> L
Matrix([ [ 1, 0, 0],
         [ 3/5, 1, 0],
         [-1/5, 1/3, 1]])
>>> D
Matrix([ [25, 0, 0],
         [ 0, 9, 0],
         [ 0, 0, 9]])
>>> L * D * L.T * A.inv() == eye(A.rows)
True
```

The matrix can have complex entries:

```python
>>> from sympy import I
>>> A = Matrix(((9, 3*I), (-3*I, 5)))
>>> L, D = A.LDLdecomposition()
>>> L
Matrix([ [ 1, 0],
         [-I/3, 1]])
>>> D
Matrix([ [9, 0],
         [0, 4]])
>>> L*D*L.H == A
True
```

See also:

sympy.matrices.dense.DenseMatrix.cholesky (page 1407), sympy.matrices.
matrices.MatrixBase.LUdecomposition (page 1323), QRdecomposition
(page 1328)
**as_immutable()**

Returns an Immutable version of this Matrix

**as_mutable()**

Returns a mutable version of this matrix

**Examples**

```python
>>> from sympy import ImmutableMatrix
>>> X = ImmutableMatrix([[1, 2], [3, 4]])
>>> Y = X.as_mutable()
>>> Y[1, 1] = 5  # Can set values in Y
>>> Y
Matrix([[1, 2],
        [3, 5]])
```

**cholesky(hermitian=True)**

Returns the Cholesky-type decomposition $L$ of a matrix $A$ such that $L \cdot L.H == A$ if hermitian flag is True, or $L \cdot L.T == A$ if hermitian is False.

$A$ must be a Hermitian positive-definite matrix if hermitian is True, or a symmetric matrix if it is False.

**Examples**

```python
>>> from sympy import Matrix
>>> A = Matrix(((25, 15, -5), (15, 18, 0), (-5, 0, 11)))
>>> A.cholesky()
Matrix([[
          5 , 0 , 0 ],
          [ 3 , 3 , 0 ],
          [-1, 1, 3]])
>>> A.cholesky() * A.cholesky().T
Matrix([[
          25, 15, -5],
          [15, 18, 0],
          [-5, 0, 11]])
```

The matrix can have complex entries:

```python
>>> from sympy import I
>>> A = Matrix(((9, 3*I), (-3*I, 5)))
>>> A.cholesky()
Matrix([[
          3, 0 ],
          [-I, 2]])
>>> A.cholesky() * A.cholesky().H
Matrix([[
          9, 3*I ],
          [-3*I, 5]])
```
Non-hermitian Cholesky-type decomposition may be useful when the matrix is not positive-definite.

```python
>>> A = Matrix([[1, 2], [2, 1]])
>>> L = A.cholesky(hermitian=False)
>>> L
Matrix([[1, 0],
        [2, sqrt(3)*I]])
>>> L*L.T == A
True
```

`applyfunc(applyfunc(applyfunc(lambda x: simplify(x, ratio, measure)))

See also:

* `sympy.simplify.simplify.simplify` (page 719)

class `sympy.matrices.immutable.ImmutableDenseMatrix(*args, **kwargs)`

Create an immutable version of a matrix.
Examples

```python
>>> from sympy import eye, ImmutableMatrix
>>> ImmutableMatrix(eye(3))
Matrix([
[1, 0, 0],
[0, 1, 0],
[0, 0, 1]])
>>> [0, 0] = 42
Traceback (most recent call last):
...
TypeError: Cannot set values of ImmutableDenseMatrix
```

Sparse Matrices

**SparseMatrix Class Reference**

sympy.matrices.sparse.SparseMatrix
alias of MutableSparseMatrix (page 1409)

class sympy.matrices.sparse.MutableSparseMatrix(*args, **kwargs)

**ImmutableSparseMatrix Class Reference**

class sympy.matrices.immutable.ImmutableSparseMatrix(*args, **kwargs)

Create an immutable version of a sparse matrix.

Examples

```python
>>> from sympy import eye, ImmutableSparseMatrix
>>> ImmutableSparseMatrix(eye(3))
Matrix([[1, 0, 0],
[0, 1, 0],
[0, 0, 1]])
>>> [0, 0] = 42
Traceback (most recent call last):
...
TypeError: Cannot set values of ImmutableSparseMatrix
>>> _.shape
(3, 3)
```
Sparse Tools

sympy.matrices.sparsetools._doktocsr()

Converts a sparse matrix to Compressed Sparse Row (CSR) format.

**Parameters**
- **A**: contains non-zero elements sorted by key (row, column)
- **JA**: JA[i] is the column corresponding to A[i]
- **IA**: IA[i] contains the index in A for the first non-zero element of row[i]. Thus IA[i+1] - IA[i] gives number of non-zero elements row[i]. The length of IA is always 1 more than the number of rows in the matrix.

**Examples**

```python
>>> from sympy.matrices.sparsetools import _doktocsr
>>> from sympy import SparseMatrix, diag
>>> m = SparseMatrix(diag(1, 2, 3))
>>> m[2, 0] = -1
>>> _doktocsr(m)
([[1, 2, -1, 3], [0, 1, 0, 2], [0, 1, 2, 4], [3, 3]])
```

sympy.matrices.sparsetools._csrtodok()

Converts a CSR representation to DOK representation.

**Examples**

```python
>>> from sympy.matrices.sparsetools import _csrtodok
>>> _csrtodok([[5, 8, 3, 6], [0, 1, 2, 1], [0, 0, 2, 3, 4], [4, 3]])
Matrix(
[0, 0, 0],
[5, 8, 0],
[0, 0, 3],
[0, 6, 0])
```

sympy.matrices.sparsetools.banded(**kwargs)

Returns a SparseMatrix from the given dictionary describing the diagonals of the matrix. The keys are positive for upper diagonals and negative for those below the main diagonal. The values may be:

- expressions or single-argument functions,
- lists or tuples of values,
- matrices

Unless dimensions are given, the size of the returned matrix will be large enough to contain the largest non-zero value provided.
**Kwargs**

- **rows**
  [rows of the resulting matrix; computed if] not given.

- **cols**
  [columns of the resulting matrix; computed if] not given.

**Examples**

```python
>>> from sympy import banded, ones, Matrix
>>> from sympy.abc import x
```

If explicit values are given in tuples, the matrix will autosize to contain all values, otherwise a single value is filled onto the entire diagonal:

```python
>>> banded({1: (1, 2, 3), -1: (4, 5, 6), 0: x})
```

```
[x, 1, 0, 0],
[4, x, 2, 0],
[0, 5, x, 3],
[0, 0, 6, x]]
```

A function accepting a single argument can be used to fill the diagonal as a function of diagonal index (which starts at 0). The size (or shape) of the matrix must be given to obtain more than a 1x1 matrix:

```python
>>> s = lambda d: (1 + d)**2
>>> banded(5, {0: s, 2: s, -2: 2})
```

```
[1, 0, 1, 0, 0],
[0, 4, 0, 4, 0],
[2, 0, 9, 0, 9],
[0, 2, 0, 16, 0],
[0, 0, 2, 0, 25]]
```

The diagonal of matrices placed on a diagonal will coincide with the indicated diagonal:

```python
>>> vert = Matrix([1, 2, 3])
>>> banded({0: vert}, cols=3)
```

```
[1, 0, 0],
[2, 1, 0],
[3, 2, 1],
[0, 3, 2],
[0, 0, 3]]
```

```python
>>> banded(4, {0: ones(2)})
```

```
[1, 1, 0, 0],
[1, 1, 0, 0],
[0, 0, 1, 1],
[0, 0, 1, 1]]
```
Errors are raised if the designated size will not hold all values an integral number of times. Here, the rows are designated as odd (but an even number is required to hold the off-diagonal 2x2 ones):

```python
>>> banded({0: 2, 1: ones(2)}, rows=5)
Traceback (most recent call last):
... ValueError:
sequence does not fit an integral number of times in the matrix
```

And here, an even number of rows is given...but the square matrix has an even number of columns, too. As we saw in the previous example, an odd number is required:

```python
>>> banded(4, {0: 2, 1: ones(2)})  # trying to make 4x4 and cols must be odd
Traceback (most recent call last):
... ValueError:
sequence does not fit an integral number of times in the matrix
```

A way around having to count rows is to enclosing matrix elements in a tuple and indicate the desired number of them to the right:

```python
>>> banded({0: 2, 2: (ones(2),)*3})
Matrix([2, 0, 1, 1, 0, 0, 0, 0],
[0, 2, 1, 1, 0, 0, 0, 0],
[0, 0, 2, 0, 1, 1, 0, 0],
[0, 0, 0, 2, 1, 1, 0, 0],
[0, 0, 0, 0, 2, 0, 1, 1],
[0, 0, 0, 0, 0, 2, 1, 1])
```

An error will be raised if more than one value is written to a given entry. Here, the ones overlap with the main diagonal if they are placed on the first diagonal:

```python
>>> banded({0: (2,)*5, 1: (ones(2),)*3})
Traceback (most recent call last):
... ValueError: collision at (1, 1)
```

By placing a 0 at the bottom left of the 2x2 matrix of ones, the collision is avoided:

```python
>>> u2 = Matrix([... [1, 1],
... [0, 1]])
>>> banded({0: [2]*5, 1: [u2]*3})
Matrix([2, 1, 1, 0, 0, 0, 0],
[0, 2, 1, 0, 0, 0, 0],
[0, 0, 2, 1, 1, 0, 0],
[0, 0, 0, 2, 1, 0, 0],
[0, 0, 0, 0, 2, 1, 1],
[0, 0, 0, 0, 0, 0, 1])
```
Immutable Matrices

The standard *Matrix* (page 1406) class in SymPy is mutable. This is important for performance reasons but means that standard matrices cannot interact well with the rest of SymPy. This is because the *Basic* (page 979) object, from which most SymPy classes inherit, is mutable.

The mission of the *ImmutableDenseMatrix* (page 1413) class, which is aliased as *ImmutableMatrix* (page 1413) for short, is to bridge the tension between performance/mutability and safety/immutability. Immutable matrices can do almost everything that normal matrices can do but they inherit from *Basic* (page 979) and can thus interact more naturally with the rest of SymPy. *ImmutableMatrix* (page 1413) also inherits from *MatrixExpr* (page 1414), allowing it to interact freely with SymPy’s Matrix Expression module.

You can turn any Matrix-like object into an *ImmutableMatrix* (page 1413) by calling the constructor

```python
>>> from sympy import Matrix, ImmutableMatrix
>>> M = Matrix([ [1, 2, 3], [4, 5, 6], [7, 8, 9] ]) #
>>> M[1, 1] = 0
>>> IM = ImmutableMatrix(M)
>>> IM
Matrix([ [1, 2, 3], [4, 0, 6], [7, 8, 9] ])
>>> IM[1, 1] = 5
Traceback (most recent call last):
... TypeError: Can not set values in Immutable Matrix. Use Matrix instead.
```

**ImmutableMatrix Class Reference**

`sympy.matrices.immutable.ImmutableMatrix`

Alias of *ImmutableDenseMatrix* (page 1413)

```python
class sympy.matrices.immutable.ImmutableDenseMatrix(*args, **kwargs)
```

Create an immutable version of a matrix.

**Examples**

```python
>>> from sympy import eye, ImmutableMatrix
>>> ImmutableMatrix(eye(3))
Matrix([ [1, 0, 0], [0, 1, 0], [0, 0, 1] ])
>>> [0, 0] = 42
Traceback (most recent call last):
... TypeError: Cannot set values of ImmutableDenseMatrix
```
Matrix Expressions

The Matrix expression module allows users to write down statements like

```python
>>> from sympy import MatrixSymbol, Matrix
>>> X = MatrixSymbol('X', 3, 3)
>>> Y = MatrixSymbol('Y', 3, 3)
>>> (X.T*X).I*Y
X**(-1)*X.T**(-1)*Y
```

```python
>>> Matrix(X)
Matrix([X[0, 0], X[0, 1], X[0, 2]], [X[1, 0], X[1, 1], X[1, 2]], [X[2, 0], X[2, 1], X[2, 2]])
```

```python
>>> (X*Y)[1, 2]
X[1, 0]*Y[0, 2] + X[1, 1]*Y[1, 2] + X[1, 2]*Y[2, 2]
```

where X and Y are `MatrixSymbol` (page 1417)'s rather than scalar symbols.

Matrix expression derivatives are supported. The derivative of a matrix by another matrix is generally a 4-dimensional array, but if some dimensions are trivial or diagonal, the derivation algorithm will try to express the result as a matrix expression:

```python
>>> a = MatrixSymbol("a", 3, 1)
>>> b = MatrixSymbol("b", 3, 1)
>>> (a.T*X**2*b).diff(X)
a*b.T*X.T + X.T*a*b.T
```

```python
>>> X.diff(X)
PermuteDims(ArrayTensorProduct(I, I), (3)(1 2))
```

The last output is an array expression, as the returned symbol is 4-dimensional.

Matrix Expressions Core Reference

```python
class sympy.matrices.expressions.MatrixExpr(*args, **kwargs)
    Superclass for Matrix Expressions
```

MatrixExprs represent abstract matrices, linear transformations represented within a particular basis.
Examples

```python
>>> from sympy import MatrixSymbol
>>> A = MatrixSymbol('A', 3, 3)
>>> y = MatrixSymbol('y', 3, 1)
>>> x = (A.T*A).I * A * y
```

See also:

`MatrixSymbol` (page 1417), `MatAdd` (page 1417), `MatMul` (page 1417), `Transpose` (page 1419), `Inverse` (page 1419)

property T

Matrix transposition

`as_coeff_Mul`(rational=False)

Efficiently extract the coefficient of a product.

`as_explicit`()

Returns a dense Matrix with elements represented explicitly

Returns an object of type `ImmutableDenseMatrix`.

Examples

```python
>>> from sympy import Identity
>>> I = Identity(3)
>>> I
I
>>> I.as_explicit()
Matrix([[-
    [1, 0, 0],
    [0, 1, 0],
    [0, 0, 1]])
```

See also:

`as_mutable` (page 1415)

returns mutable Matrix type

`as_mutable`()

Returns a dense, mutable matrix with elements represented explicitly

Examples

```python
>>> from sympy import Identity
>>> I = Identity(3)
>>> I
I
>>> I.shape
(3, 3)
```
```python
>>> I.as_mutable()
Matrix([
[1, 0, 0],
[0, 1, 0],
[0, 0, 1]])
```

See also:

**as_explicit** (page 1415)

returns ImmutableDenseMatrix

**equals**(*other*)

Test elementwise equality between matrices, potentially of different types

```python
>>> from sympy import Identity, eye
>>> Identity(3).equals(eye(3))
True
```

**static from_index_summation**(*expr, first_index=None, last_index=None, dimensions=None*)

Parse expression of matrices with explicitly summed indices into a matrix expression without indices, if possible.

This transformation expressed in mathematical notation:

\[
\sum_{j=0}^{N-1} A_{i,j} B_{j,k} \rightarrow A \cdot B
\]

Optional parameter first_index: specify which free index to use as the index starting the expression.

Examples

```python
>>> from sympy import MatrixSymbol, MatrixExpr, Sum
>>> from sympy.abc import i, j, k, l, N
>>> A = MatrixSymbol("A", N, N)
>>> B = MatrixSymbol("B", N, N)
>>> expr = Sum(A[i, j]*B[j, k], (j, 0, N-1))
>>> MatrixExpr.from_index_summation(expr)
A*B
```

Transposition is detected:

```python
>>> expr = Sum(A[j, i]*B[j, k], (j, 0, N-1))
>>> MatrixExpr.from_index_summation(expr)
A.T*B
```

Detect the trace:

```python
>>> expr = Sum(A[i, i], (i, 0, N-1))
>>> MatrixExpr.from_index_summation(expr)
Trace(A)
```

More complicated expressions:
```python
>>> expr = Sum(A[i, j]*B[k, j]*A[l, k], (j, 0, N-1), (k, 0, N-1))
>>> MatrixExpr.from_index_summation(expr)
A*B.T*A.T
```

class sympy.matrices.expressions.MatrixSymbol(name, n, m)
Symbolic representation of a Matrix object

Creates a SymPy Symbol to represent a Matrix. This matrix has a shape and can be included in Matrix Expressions

**Examples**

```python
>>> from sympy import MatrixSymbol, Identity
>>> A = MatrixSymbol('A', 3, 4) # A 3 by 4 Matrix
>>> B = MatrixSymbol('B', 4, 3) # A 4 by 3 Matrix
>>> A.shape
(3, 4)
>>> 2*A*B + Identity(3)
I + 2*A*B
```

class sympy.matrices.expressions.MatAdd(*args, evaluate=False, check=None, _sympify=True)
A Sum of Matrix Expressions

MatAdd inherits from and operates like SymPy Add

**Examples**

```python
>>> from sympy import MatAdd, MatrixSymbol
>>> A = MatrixSymbol('A', 5, 4)
>>> B = MatrixSymbol('B', 4, 3)
>>> C = MatrixSymbol('C', 3, 6)
>>> MatAdd(A, B, C)
A + B + C
```

class sympy.matrices.expressions.MatMul(*args, evaluate=False, check=None, _sympify=True)
A product of matrix expressions

**Examples**

```python
>>> from sympy import MatMul, MatrixSymbol
>>> A = MatrixSymbol('A', 5, 4)
>>> B = MatrixSymbol('B', 4, 3)
>>> C = MatrixSymbol('C', 3, 6)
>>> MatMul(A, B, C)
A*B*C
```

class sympy.matrices.expressions.MatPow(base, exp, evaluate=False, **options)
sympy.matrices.expressions.hadamard_product(*matrices)

Return the elementwise (aka Hadamard) product of matrices.

Examples

```python
>>> from sympy import hadamard_product, MatrixSymbol
>>> A = MatrixSymbol('A', 2, 3)
>>> B = MatrixSymbol('B', 2, 3)
>>> hadamard_product(A)
A
>>> hadamard_product(A, B)
HadamardProduct(A, B)
>>> hadamard_product(A, B)[0, 1]
A[0, 1]*B[0, 1]
```

class sympy.matrices.expressions.HadamardProduct(*args, evaluate=False, check=None)

Elementwise product of matrix expressions

Examples

Hadamard product for matrix symbols:

```python
>>> from sympy import hadamard_product, HadamardProduct, MatrixSymbol
>>> A = MatrixSymbol('A', 5, 5)
>>> B = MatrixSymbol('B', 5, 5)
>>> isinstance(hadamard_product(A, B), HadamardProduct)
True
```

Notes

This is a symbolic object that simply stores its argument without evaluating it. To actually compute the product, use the function hadamard_product() or HadamardProduct.doit

class sympy.matrices.expressions.HadamardPower(base, exp)

Elementwise power of matrix expressions

Parameters

- `base` : scalar or matrix
- `exp` : scalar or matrix
Notes

There are four definitions for the hadamard power which can be used. Let’s consider $A, B$ as $(m, n)$ matrices, and $a, b$ as scalars.

Matrix raised to a scalar exponent:

$$A^b = \begin{bmatrix}
A^b_{0,0} & A^b_{0,1} & \cdots & A^b_{0,n-1} \\
A^b_{1,0} & A^b_{1,1} & \cdots & A^b_{1,n-1} \\
& \vdots & \ddots & \vdots \\
A^b_{m-1,0} & A^b_{m-1,1} & \cdots & A^b_{m-1,n-1}
\end{bmatrix}$$

Scalar raised to a matrix exponent:

$$a^B = \begin{bmatrix}
a^{B_{0,0}} & a^{B_{0,1}} & \cdots & a^{B_{0,n-1}} \\
a^{B_{1,0}} & a^{B_{1,1}} & \cdots & a^{B_{1,n-1}} \\
& \vdots & \ddots & \vdots \\
a^{B_{m-1,0}} & a^{B_{m-1,1}} & \cdots & a^{B_{m-1,n-1}}
\end{bmatrix}$$

Matrix raised to a matrix exponent:

$$A^B = \begin{bmatrix}
A_{0,0}^B & A_{0,1}^B & \cdots & A_{0,n-1}^B \\
A_{1,0}^B & A_{1,1}^B & \cdots & A_{1,n-1}^B \\
& \vdots & \ddots & \vdots \\
A_{m-1,0}^B & A_{m-1,1}^B & \cdots & A_{m-1,n-1}^B
\end{bmatrix}$$

Scalar raised to a scalar exponent:

$$a^b = a^b$$

**class** `sympy.matrices.expressions.Inverse(mat, exp=-1)`

The multiplicative inverse of a matrix expression.

This is a symbolic object that simply stores its argument without evaluating it. To actually compute the inverse, use the `.inverse()` method of matrices.

**Examples**

```python
from sympy import MatrixSymbol, Inverse

A = MatrixSymbol('A', 3, 3)
B = MatrixSymbol('B', 3, 3)

Inverse(A)
A**(-1)
A.inverse() == Inverse(A)
True

(A*B).inverse()
B**(-1)*A**(-1)
Inverse(A*B)
(A*B)**(-1)
```

**class** `sympy.matrices.expressions.Transpose(*args, **kwargs)`

The transpose of a matrix expression.

This is a symbolic object that simply stores its argument without evaluating it. To actually compute the transpose, use the `transpose()` function, or the `.T` attribute of matrices.
Examples

```python
>>> from sympy import MatrixSymbol, Transpose, transpose
>>> A = MatrixSymbol('A', 3, 5)
>>> B = MatrixSymbol('B', 5, 3)
>>> Transpose(A)
A.T
>>> A.T == transpose(A) == Transpose(A)
True
>>> Transpose(A*B)
(A*B).T
>>> transpose(A*B)
B.T*A.T
```

class sympy.matrices.expressions.Trace(mat)
Matrix Trace
Represents the trace of a matrix expression.

Examples

```python
>>> from sympy import MatrixSymbol, Trace, eye
>>> A = MatrixSymbol('A', 3, 3)
>>> Trace(A)
Trace(A)
>>> Trace(eye(3))
Trace(Matrix([1, 0, 0], [0, 1, 0], [0, 0, 1]))
>>> Trace(eye(3)).simplify()
3
```

class sympy.matrices.expressions.FunctionMatrix(rows, cols, lamda)
Represents a matrix using a function (Lambda) which gives outputs according to the coordinates of each matrix entries.

Parameters
- **rows**: nonnegative integer. Can be symbolic.
- **cols**: nonnegative integer. Can be symbolic.
- **lamda**: Function, Lambda or str
  
  If it is a SymPy Function or Lambda instance, it should be able to accept two arguments which represents the matrix coordinates.

  If it is a pure string containing Python lambda semantics, it is interpreted by the SymPy parser and casted into a SymPy Lambda instance.
Examples

Creating a FunctionMatrix from Lambda:

```python
>>> from sympy import FunctionMatrix, symbols, Lambda, MatPow
>>> i, j, n, m = symbols('i,j,n,m')
>>> FunctionMatrix(n, m, Lambda((i, j), i + j))
FunctionMatrix(n, m, Lambda((i, j), i + j))
```

Creating a FunctionMatrix from a SymPy function:

```python
>>> from sympy import KroneckerDelta
>>> X = FunctionMatrix(3, 3, KroneckerDelta)
>>> X.as_explicit()
Matrix([[1, 0, 0],
        [0, 1, 0],
        [0, 0, 1]])
```

Creating a FunctionMatrix from a SymPy undefined function:

```python
>>> from sympy import Function
>>> f = Function('f')
>>> X = FunctionMatrix(3, 3, f)
>>> X.as_explicit()
Matrix([[f(0, 0), f(0, 1), f(0, 2)],
        [f(1, 0), f(1, 1), f(1, 2)],
        [f(2, 0), f(2, 1), f(2, 2)]])
```

Creating a FunctionMatrix from Python lambda:

```python
>>> FunctionMatrix(n, m, 'lambda i, j: i + j')
FunctionMatrix(n, m, Lambda((i, j), i + j))
```

Example of lazy evaluation of matrix product:

```python
>>> Y = FunctionMatrix(1000, 1000, Lambda((i, j), i + j))
>>> isinstance(Y*Y, MatPow) # this is an expression object
True
>>> (Y**2)[10,10] # So this is evaluated lazily
342923500
```

Notes

This class provides an alternative way to represent an extremely dense matrix with entries in some form of a sequence, in a most sparse way.

```python
class sympy.matrices.expressions.PermutationMatrix(perm)
    A Permutation Matrix
    Parameters
    perm : Permutation
```
The permutation the matrix uses.

The size of the permutation determines the matrix size.

See the documentation of `sympy.combinatorics.permutations.Permutation` (page 312) for the further information of how to create a permutation object.

**Examples**

```python
>>> from sympy import Matrix, PermutationMatrix
>>> from sympy.combinatorics import Permutation

Creating a permutation matrix:

```python
>>> p = Permutation(1, 2, 0)
>>> P = PermutationMatrix(p)
>>> P
Matrix([[0, 1, 0],
        [0, 0, 1],
        [1, 0, 0]])
```

Permuting a matrix row and column:

```python
>>> M = Matrix([[0, 1, 2]])
>>> Matrix(P*M)
Matrix([[1],
        [2],
        [0]])
```

```python
>>> Matrix(M.T*P)
Matrix([[2, 0, 1]])
```

See also:

`sympy.combinatorics.permutations.Permutation` (page 312)

class sympy.matrices.expressions.MatrixPermute(mat, perm, axis=0)

Symbolic representation for permuting matrix rows or columns.

**Parameters**

- `perm`: Permutation, PermutationMatrix
  
  The permutation to use for permuting the matrix. The permutation can be resized to the suitable one,

- `axis`: 0 or 1
  
  The axis to permute alongside. If 0, it will permute the matrix rows. If 1, it will permute the matrix columns.
Notes

This follows the same notation used in `sympy.matrices.common.MatrixCommon.permute()` (page 1393).

Examples

```python
>>> from sympy import Matrix, MatrixPermute
>>> from sympy.combinatorics import Permutation

Permuting the matrix rows:

```python
>>> p = Permutation(1, 2, 0)
>>> A = Matrix([[1, 2, 3], [4, 5, 6], [7, 8, 9]])
>>> B = MatrixPermute(A, p, axis=0)
>>> B.as_explicit()
Matrix(
    [4, 5, 6],
    [7, 8, 9],
    [1, 2, 3])
```

Permuting the matrix columns:

```python
>>> B = MatrixPermute(A, p, axis=1)
>>> B.as_explicit()
Matrix(
    [2, 3, 1],
    [5, 6, 4],
    [8, 9, 7])
```

See also:
`sympy.matrices.common.MatrixCommon.permute` (page 1393)

class `sympy.matrices.expressions.Identity(n)`
The Matrix Identity I - multiplicative identity

Examples

```python
>>> from sympy import Identity, MatrixSymbol
>>> A = MatrixSymbol('A', 3, 5)
>>> I = Identity(3)
>>> I*A
A
```

class `sympy.matrices.expressions.ZeroMatrix(m, n)`
The Matrix Zero 0 - additive identity
Examples

```python
>>> from sympy import MatrixSymbol, ZeroMatrix
>>> A = MatrixSymbol('A', 3, 5)
>>> Z = ZeroMatrix(3, 5)
>>> A + Z
A
>>> Z*A.T
0
```

class sympy.matrices.expressions.CompanionMatrix(poly)

A symbolic companion matrix of a polynomial.

Examples

```python
>>> from sympy import Poly, Symbol, symbols
>>> from sympy.matrices.expressions import CompanionMatrix
>>> x = Symbol('x')
>>> c0, c1, c2, c3, c4 = symbols('c0:5')
>>> p = Poly(c0 + c1*x + c2*x**2 + c3*x**3 + c4*x**4 + x**5, x)
>>> CompanionMatrix(p)
CompanionMatrix(Poly(x**5 + c4*x**4 + c3*x**3 + c2*x**2 + c1*x + c0, 
x, domain='ZZ[c0,c1,c2,c3,c4]'))
```

class sympy.matrices.expressions.MatrixSet(n, m, set)

MatrixSet represents the set of matrices with shape = (n, m) over the given set.

Examples

```python
>>> from sympy.matrices import MatrixSet
>>> from sympy import S, I, Matrix
>>> M = MatrixSet(2, 2, set=S.Reals)
>>> X = Matrix([[1, 2], [3, 4]])
>>> X in M
True
>>> X = Matrix([[1, 2], [I, 4]])
>>> X in M
False
```

Block Matrices

Block matrices allow you to construct larger matrices out of smaller sub-blocks. They can work with `MatrixExpr` (page 1414) or `ImmutableMatrix` (page 1413) objects.

class sympy.matrices.expressions.blockmatrix.BlockMatrix(*args, **kwargs)

A BlockMatrix is a Matrix comprised of other matrices.

The submatrices are stored in a SymPy Matrix object but accessed as part of a Matrix Expression
```python
>>> from sympy import (MatrixSymbol, BlockMatrix, symbols, ...
    Identity, ZeroMatrix, block_collapse)
>>> n, m, l = symbols('n m l')
>>> X = MatrixSymbol('X', n, n)
>>> Y = MatrixSymbol('Y', m, m)
>>> Z = MatrixSymbol('Z', n, m)
>>> B = BlockMatrix([[X, Z], [ZeroMatrix(m, n), Y]])
>>> print(B)
Matrix([[X, Z], [0, Y]])
```
L : Lower Diagonal Matrix  D : Diagonal Matrix  U : Upper Diagonal Matrix

Raises

ShapeError
  If the block matrix is not a 2x2 matrix

NonInvertibleMatrixError
  If the matrix “A” is non-invertible

Examples

```python
>>> from sympy import symbols, MatrixSymbol, BlockMatrix, block_collapse

>>> m, n = symbols('m n')
    A = MatrixSymbol('A', n, n)
    B = MatrixSymbol('B', n, m)
    C = MatrixSymbol('C', m, n)
    D = MatrixSymbol('D', m, m)
    X = BlockMatrix([[A, B], [C, D]])
    L, D, U = X.LDUdecomposition()
    block_collapse(L*D*U)
    Matrix([[A, B], [C, D]])
```

See also:

sympy.matrices.expressions.blockmatrix.BlockMatrix.UDLdecomposition
(page 1427),  sympy.matrices.expressions.blockmatrix.BlockMatrix.LUdecomposition
(page 1426)

LUdecomposition()

Returns the Block LU decomposition of a 2x2 Block Matrix

Returns

(L, U) : Matrices
  L : Lower Diagonal Matrix  U : Upper Diagonal Matrix

Raises

ShapeError
  If the block matrix is not a 2x2 matrix

NonInvertibleMatrixError
  If the matrix “A” is non-invertible
Examples

```python
from sympy import symbols, MatrixSymbol, BlockMatrix, block_collapse
m, n = symbols('m n')
A = MatrixSymbol('A', n, n)
B = MatrixSymbol('B', n, m)
C = MatrixSymbol('C', m, n)
D = MatrixSymbol('D', m, m)
X = BlockMatrix([[A, B], [C, D]])
L, U = X.LUdecomposition()
block_collapse(L*U)
```

See also:

sympy.matrices.expressions.blockmatrix.BlockMatrix.UDLdecomposition (page 1427), sympy.matrices.expressions.blockmatrix.BlockMatrix.LDUdecomposition (page 1425)

UDLdecomposition()

Returns the Block UDL decomposition of a 2x2 Block Matrix

Returns

(U, D, L) : Matrices

U : Upper Diagonal Matrix
D : Diagonal Matrix
L : Lower Diagonal Matrix

Raises

ShapeError

If the block matrix is not a 2x2 matrix

NonInvertibleMatrixError

If the matrix "D" is non-invertible

Examples

```python
from sympy import symbols, MatrixSymbol, BlockMatrix, block_collapse
m, n = symbols('m n')
A = MatrixSymbol('A', n, n)
B = MatrixSymbol('B', n, m)
C = MatrixSymbol('C', m, n)
D = MatrixSymbol('D', m, m)
X = BlockMatrix([[A, B], [C, D]])
U, D, L = X.LUdecomposition()
block_collapse(U*D*L)
```
See also:

- `sympy.matrices.expressions.blockmatrix.BlockMatrix.LDUdecomposition`
- `sympy.matrices.expressions.blockmatrix.BlockMatrix.LUdecomposition`

`schur(mat='A', generalized=False)`

Return the Schur Complement of the 2x2 BlockMatrix

**Parameters**

- `mat` : String, optional
  
  The matrix with respect to which the Schur Complement is calculated. ‘A’ is used by default

- `generalized` : bool, optional
  
  If True, returns the generalized Schur Component which uses Moore-Penrose Inverse

**Returns**

- `M` : Matrix
  
  The Schur Complement Matrix

**Raises**

- `ShapeError`
  
  If the block matrix is not a 2x2 matrix

- `NonInvertibleMatrixError`
  
  If given matrix is non-invertible

**Examples**

```python
>>> from sympy import symbols, MatrixSymbol, BlockMatrix
>>> m, n = symbols('m n')
>>> A = MatrixSymbol('A', n, n)
>>> B = MatrixSymbol('B', n, m)
>>> C = MatrixSymbol('C', m, n)
>>> D = MatrixSymbol('D', m, m)
>>> X = BlockMatrix([[A, B], [C, D]])
```

The default Schur Complement is evaluated with ‘A’

```python
>>> X.schur()
-C*A**(-1)*B + D
```

```python
>>> X.schur('D')
A - B*D**(-1)*C
```

Schur complement with non-invertible matrices is not defined. Instead, the generalized Schur complement can be calculated which uses the Moore-Penrose Inverse. To achieve this, `generalized` must be set to `True`

```python
>>> X.schur('B', generalized=True)
C - D*(B.T*B)**(-1)*B.T*A
```

(continues on next page)
```python
>>> X.schur('C', generalized=True)
-A*(C.T*C)**(-1)*C.T*D + B
```

See also:

`sympy.matrices.matrices.MatrixBase.pinv` (page 1346)

References

[R583]

transpose()

Return transpose of matrix.

Examples

```python
>>> from sympy import MatrixSymbol, BlockMatrix, ZeroMatrix
>>> from sympy.abc import m, n
>>> X = MatrixSymbol('X', n, n)
>>> Y = MatrixSymbol('Y', m, m)
>>> Z = MatrixSymbol('Z', n, m)
>>> B = BlockMatrix([[X, Z], [ZeroMatrix(m,n), Y]])
>>> B.transpose()
Matrix([[X.T, 0], [Z.T, Y.T]])
```

```python
>>> B.transpose()
Matrix([[X, Z], [0, Y]])
```

```python
class sympy.matrices.expressions.blockmatrix.BlockDiagMatrix(*mats)
A sparse matrix with block matrices along its diagonals
```

Examples

```python
>>> from sympy import MatrixSymbol, BlockDiagMatrix, symbols
>>> n, m, l = symbols('n m l')
>>> X = MatrixSymbol('X', n, n)
>>> Y = MatrixSymbol('Y', m, m)
>>> BlockDiagMatrix(X, Y)
Matrix([[X, 0], [0, Y]])
```

Notes

If you want to get the individual diagonal blocks, use `get_diag_blocks()` (page 1430).

See also:

* sympy.matrices.dense.diag (page 1360)

**get_diag_blocks()**

Return the list of diagonal blocks of the matrix.

Examples

```python
>>> from sympy import BlockDiagMatrix, Matrix

>>> A = Matrix([[1, 2], [3, 4]])
>>> B = Matrix([[5, 6], [7, 8]])
>>> M = BlockDiagMatrix(A, B)

How to get diagonal blocks from the block diagonal matrix:

```python
>>> diag_blocks = M.get_diag_blocks()
>>> diag_blocks[0]
Matrix([[1, 2],
       [3, 4]])
>>> diag_blocks[1]
Matrix([[5, 6],
       [7, 8]])
```

```
sympy.matrices.expressions.blockmatrix.block Collapse(expr)
```

Evaluates a block matrix expression

```python
>>> from sympy import MatrixSymbol, BlockMatrix, symbols, Identity,
    ZeroMatrix, block Collapse

>>> n,m,l = symbols('n m l')
>>> X = MatrixSymbol('X', n, n)
>>> Y = MatrixSymbol('Y', m, m)
>>> Z = MatrixSymbol('Z', n, m)
>>> B = BlockMatrix([[X, Z], [ZeroMatrix(m, n), Y]])
```

```python
>>> print(B)
Matrix([[X, Z],
        [0, Y]])
```

```python
>>> C = BlockMatrix([[Identity(n), Z]])
```

```python
>>> print(C)
Matrix([[I, Z]])
```

```python
>>> print(block Collapse(C*B))
Matrix([[X, Z + Z*Y]])
```
Matrix Normal Forms

```python
sympy.matrices.normalforms.smith_normal_form(m, domain=None)
```
Return the Smith Normal Form of a matrix $m$ over the ring $domain$. This will only work if the ring is a principal ideal domain.

Examples

```python
>>> from sympy import Matrix, ZZ
>>> from sympy.matrices.normalforms import smith_normal_form
>>> m = Matrix([[12, 6, 4], [3, 9, 6], [2, 16, 14]])
>>> print(smith_normal_form(m, domain=ZZ))
Matrix([[1, 0, 0], [0, 10, 0], [0, 0, -30]])
```

```python
sympy.matrices.normalforms.hermite_normal_form(A, *, D=None, check_rank=False)
```
Compute the Hermite Normal Form of a Matrix $A$ of integers.

Parameters

- $A$: $m \times n$ Matrix of integers.
- $D$: int, optional
  Let $W$ be the HNF of $A$. If known in advance, a positive integer $D$ being any multiple of $\det(W)$ may be provided. In this case, if $A$ also has rank $m$, then we may use an alternative algorithm that works mod $D$ in order to prevent coefficient explosion.
- $check\_rank$: boolean, optional (default=False)
  The basic assumption is that, if you pass a value for $D$, then you already believe that $A$ has rank $m$, so we do not waste time checking it for you. If you do want this to be checked (and the ordinary, non-modulo $D$ algorithm to be used if the check fails), then set $check\_rank$ to True.

Returns

- Matrix
  The HNF of matrix $A$.

Raises

- DMDomainError
  If the domain of the matrix is not $ZZ$ (page 2605).
- DMShapeError
  If the mod $D$ algorithm is used but the matrix has more rows than columns.
Examples

```python
>>> from sympy import Matrix
>>> from sympy.matrices.normalforms import hermite_normal_form
>>> m = Matrix([[12, 6, 4], [3, 9, 6], [2, 16, 14]])
>>> print(hermite_normal_form(m))
Matrix([[10, 0, 2], [0, 15, 3], [0, 0, 2]])
```

References

[R617]

Tensor

A module to manipulate symbolic objects with indices including tensors

Contents

N-dim array

N-dim array module for SymPy.

Four classes are provided to handle N-dim arrays, given by the combinations dense/sparse (i.e. whether to store all elements or only the non-zero ones in memory) and mutable/immutable (immutable classes are SymPy objects, but cannot change after they have been created).

Examples

The following examples show the usage of Array. This is an abbreviation for ImmutableDenseNDimArray, that is an immutable and dense N-dim array, the other classes are analogous. For mutable classes it is also possible to change element values after the object has been constructed.

Array construction can detect the shape of nested lists and tuples:

```python
>>> from sympy import Array
>>> a1 = Array([[1, 2], [3, 4], [5, 6]])
>>> a1
[[1, 2], [3, 4], [5, 6]]
>>> a1.shape
(3, 2)
>>> a1.rank()
2
>>> from sympy import x, y, z
>>> a2 = Array([[x, y], [z, x*z]], [[1, x*y], [1/x, x/y]])
>>> a2
[[[x, y], [z, x*z]], [[1, x*y], [1/x, x/y]]]
```
>>> a2.shape
(2, 2, 2)
>>> a2.rank()
3

Otherwise one could pass a 1-dim array followed by a shape tuple:

```python
>>> m1 = Array(range(12), (3, 4))
>>> m1
[[0, 1, 2, 3], [4, 5, 6, 7], [8, 9, 10, 11]]
>>> m2 = Array(range(12), (3, 2, 2))
>>> m2
[[[0, 1], [2, 3]], [[4, 5], [6, 7]], [[8, 9], [10, 11]]]
>>> m2[1,1,1]
7
>>> m2.reshape(4, 3)
[[0, 1, 2], [3, 4, 5], [6, 7, 8], [9, 10, 11]]
```

Slice support:

```python
>>> m2[::, 1, 1]
[3, 7, 11]
```

Elementwise derivative:

```python
>>> from sympy.abc import x, y, z
>>> m3 = Array([x**3, x*y, z])
>>> m3.diff(x)
[3*x**2, y, 0]
>>> m3.diff(z)
[0, 0, 1]
```

Multiplication with other SymPy expressions is applied elementwisely:

```python
>>> (1+x)*m3
[x**3*(x + 1), x*y*(x + 1), z*(x + 1)]
```

To apply a function to each element of the N-dim array, use applyfunc:

```python
>>> m3.applyfunc(lambda x: x/2)
[x**3/2, x*y/2, z/2]
```

N-dim arrays can be converted to nested lists by the tolist() method:

```python
>>> m2.tolist()
[[[0, 1], [2, 3]], [[4, 5], [6, 7]], [[8, 9], [10, 11]]]
>>> isinstance(m2.tolist(), list)
True
```

If the rank is 2, it is possible to convert them to matrices with tomatrix():

```python
>>> m1.tomatrix()
Matrix([...
```
Products and contractions

Tensor product between arrays $A_{i_1,...,i_n}$ and $B_{j_1,...,j_m}$ creates the combined array $P = A \otimes B$ defined as

$$P_{i_1,...,i_n,j_1,...,j_m} := A_{i_1,...,i_n} \cdot B_{j_1,...,j_m}.$$  

It is available through `tensorproduct(...):

```python
>>> from sympy import Array, tensorproduct
>>> A = Array([x, y, z, t])
>>> B = Array([1, 2, 3, 4])
>>> tensorproduct(A, B)
[[x, 2*x, 3*x, 4*x], [y, 2*y, 3*y, 4*y], [z, 2*z, 3*z, 4*z], [t, 2*t, 3*t, 4*t]]
```

In case you don’t want to evaluate the tensor product immediately, you can use `ArrayTensorProduct`, which creates an unevaluated tensor product expression:

```python
>>> from sympy.tensor.array.expressions import ArrayTensorProduct
>>> ArrayTensorProduct(A, B)
ArrayTensorProduct([x, y, z, t], [1, 2, 3, 4])
```

Calling `.as_explicit()` on `ArrayTensorProduct` is equivalent to just calling `tensorproduct(...):

```python
>>> ArrayTensorProduct(A, B).as_explicit()
[[x, 2*x, 3*x, 4*x], [y, 2*y, 3*y, 4*y], [z, 2*z, 3*z, 4*z], [t, 2*t, 3*t, 4*t]]
```

Tensor product between a rank-1 array and a matrix creates a rank-3 array:

```python
>>> from sympy import eye
>>> p1 = tensorproduct(A, eye(4))
>>> p1
[[[x, 0, 0, 0], [0, x, 0, 0], [0, 0, x, 0], [0, 0, 0, x]], [[y, 0, 0, 0], [0, y, 0, 0], [0, 0, y, 0], [0, 0, 0, y]], [[z, 0, 0, 0], [0, z, 0, 0], [0, 0, z, 0], [0, 0, 0, z]], [[t, 0, 0, 0], [0, t, 0, 0], [0, 0, t, 0], [0, 0, 0, t]]]
```

Now, to get back $A_0 \otimes 1$ one can access $p_0,m,n$ by slicing:

```python
>>> p1[0,:,:]
[[x, 0, 0, 0], [0, x, 0, 0], [0, 0, x, 0], [0, 0, 0, x]]
```

Tensor contraction sums over the specified axes, for example contracting positions $a$ and $b$ means:

$$A_{i_1,...,i_a,...,i_b,...,i_n} \Rightarrow \sum_k A_{i_1,...,k,...,i_n}$$
Remember that Python indexing is zero starting, to contract the a-th and b-th axes it is therefore necessary to specify \( a - 1 \) and \( b - 1 \)

```python
>>> from sympy import tensorcontraction
>>> C = Array([[x, y], [z, t]])
```

The matrix trace is equivalent to the contraction of a rank-2 array:

\[
A_{m,n} \Rightarrow \sum_k A_{k,k}
\]

```python
>>> tensorcontraction(C, (0, 1))
t + x
```

To create an expression representing a tensor contraction that does not get evaluated immediately, use `ArrayContraction`, which is equivalent to `tensorcontraction(...)` if it is followed by `.as_explicit()`:

```python
>>> from sympy.tensor.array.expressions import ArrayContraction
>>> ArrayContraction(C, (0, 1))
ArrayContraction([[x, y], [z, t]], (0, 1))
>>> ArrayContraction(C, (0, 1)).as_explicit()
t + x
```

Matrix product is equivalent to a tensor product of two rank-2 arrays, followed by a contraction of the 2nd and 3rd axes (in Python indexing axes number 1, 2).

\[
A_{m,n} \cdot B_{i,j} \Rightarrow \sum_k A_{m,k} \cdot B_{k,j}
\]

```python
>>> D = Array([[2, 1], [0, -1]])
>>> tensorcontraction(tensorproduct(C, D), (1, 2))
[[2*x, x - y], [2*z, -t + z]]
```

One may verify that the matrix product is equivalent:

```python
>>> from sympy import Matrix
>>> Matrix([[x, y], [z, t]])*Matrix([[2, 1], [0, -1]])
Matrix([[2*x, x - y], [2*z, -t + z]])
```

or equivalently

```python
>>> C.tomatrix()*D.tomatrix()
Matrix([[2*x, x - y], [2*z, -t + z]])
```
Diagonal operator

The `tensordiagonal` function acts in a similar manner as `tensorcontraction`, but the joined indices are not summed over; for example diagonalizing positions \(a\) and \(b\) means

\[ A_{i_1, \ldots, i_a, \ldots, i_b, \ldots, i_n} \rightarrow \tilde{A}_{i_1, \ldots, i_a-1, i_a+1, \ldots, i_b-1, i_b+1, \ldots, i_n, k} \]

where \(\tilde{A}\) is the array equivalent to the diagonal of \(A\) at positions \(a\) and \(b\) moved to the last index slot.

Compare the difference between contraction and diagonal operators:

```python
>>> from sympy import tensordiagonal
>>> from sympy import Matrix
>>> m = Matrix([[a, b], [c, d]])
>>> tensorcontraction(m, [0, 1])
a + d
>>> tensordiagonal(m, [0, 1])
[a, d]
```

In short, no summation occurs with `tensordiagonal`.

Derivatives by array

The usual derivative operation may be extended to support derivation with respect to arrays, provided that all elements in the that array are symbols or expressions suitable for derivations.

The definition of a derivative by an array is as follows: given the array \(A_{i_1, \ldots, i_N}\) and the array \(X_{j_1, \ldots, j_M}\) the derivative of arrays will return a new array \(B\) defined by

\[ B_{j_1, \ldots, j_M, i_1, \ldots, i_N} := \frac{\partial A_{i_1, \ldots, i_N}}{\partial X_{j_1, \ldots, j_M}} \]

The function `derive_by_array` performs such an operation:

```python
>>> from sympy import derive_by_array
>>> from sympy import sin, exp

With scalars, it behaves exactly as the ordinary derivative:

```python
>>> derive_by_array(sin(x*y), x)
y*cos(x*y)
```

Scalar derived by an array basis:

```python
>>> derive_by_array(sin(x*y), [x, y, z])
[y*cos(x*y), x*cos(x*y), 0]
```

Deriving array by an array basis: \(B^n_m := \frac{\partial A^n}{\partial x^m}\)

```python
>>> basis = [x, y, z]
>>> ax = derive_by_array([exp(x), sin(y*z), t], basis)
>>> ax
[[exp(x), 0, 0], [0, z*cos(y*z), 0], [0, y*cos(y*z), 0]]
```

Contraction of the resulting array: \(\sum_m \frac{\partial A^n}{\partial x^m}\)
>>> tensorcontraction(ax, ([0, 1]))

\[z\cos(yz) + \exp(x)\]

**Classes**

```python
class sympy.tensor.array.ImmutableDenseNDimArray(iterable, shape=None, **kwargs)
class sympy.tensor.array.ImmutableSparseNDimArray(iterable=None, shape=None, **kwargs)
class sympy.tensor.array.MutableDenseNDimArray(iterable=None, shape=None, **kwargs)
class sympy.tensor.array.MutableSparseNDimArray(iterable=None, shape=None, **kwargs)
```

**Functions**

sympy.tensor.array.derive_by_array(expr, dx)

Derivative by arrays. Supports both arrays and scalars.

The equivalent operator for array expressions is `array_derive`.

**Explanation**

Given the array \( A_{i_1,...,i_N} \) and the array \( X_{j_1,...,j_M} \) this function will return a new array \( B \) defined by

\[
B_{j_1,...,j_M,i_1,...,i_N} = \frac{\partial A_{i_1,...,i_N}}{\partial X_{j_1,...,j_M}}
\]

**Examples**

```python
>>> from sympy import derive_by_array
>>> from sympy import x, y, z, t
>>> derive_by_array(cos(x*t), x)
-t*sin(t*x)

>>> derive_by_array(cos(x*t), [x, y, z, t])
[-t*sin(t*x), 0, 0, -x*sin(t*x)]

>>> derive_by_array([[x, y**2*z], [[x, y], [z, t]]]
[[[1, 0], [0, 2*y*z]], [[0, y**2], [0, 0]]]
```

sympy.tensor.array.permutedims(expr, perm=None, index_order_old=None, index_order_new=None)

Permutes the indices of an array.

Parameter specifies the permutation of the indices.

The equivalent operator for array expressions is `PermuteDims`, which can be used to keep the expression unevaluated.
Examples

```python
>>> from sympy.abc import x, y, z, t
>>> from sympy import sin
>>> from sympy import Array, permutedims

>>> a = Array([[x, y, z], [t, sin(x), 0]])
>>> a
[[x, y, z], [t, sin(x), 0]]
>>> permutedims(a, (1, 0))
[[x, t], [y, sin(x)], [z, 0]]
```

If the array is of second order, transpose can be used:

```python
>>> from sympy import transpose

>>> transpose(a)
[[x, t], [y, sin(x)], [z, 0]]
```

Examples on higher dimensions:

```python
>>> b = Array([[[1, 2], [3, 4]], [[5, 6], [7, 8]]])
>>> permutedims(b, (2, 1, 0))
[[[1, 5], [3, 7]], [[2, 6], [4, 8]]]
>>> permutedims(b, (1, 2, 0))
[[[1, 5], [2, 6]], [[3, 7], [4, 8]]]
```

An alternative way to specify the same permutations as in the previous lines involves passing the old and new indices, either as a list or as a string:

```python
>>> permutedims(b, index_order_old="cba", index_order_new="abc")
[[[1, 5], [3, 7]], [[2, 6], [4, 8]]]
>>> permutedims(b, index_order_old="cab", index_order_new="abc")
[[[1, 5], [2, 6]], [[3, 7], [4, 8]]]
```

Permutation objects are also allowed:

```python
>>> from sympy.combinatorics import Permutation

>>> permutedims(b, Permutation([1, 2, 0]))
[[[1, 5], [2, 6]], [[3, 7], [4, 8]]]
```

See also:

- `sympy.tensor.array.expressions.array_expressions.PermuteDims` (page 1444)
- `sympy.tensor.array.tensorcontraction(array, *contraction_axes)`
  Contraction of an array-like object on the specified axes.

The equivalent operator for array expressions is ArrayContraction, which can be used to keep the expression unevaluated.
Examples

```python
>>> from sympy import Array, tensorcontraction
>>> from sympy import Matrix, eye

>>> tensorcontraction(eye(3), (0, 1))
3

>>> A = Array(range(18), (3, 2, 3))
>>> A
[[[0, 1, 2], [3, 4, 5]], [[6, 7, 8], [9, 10, 11]], [[12, 13, 14], [15, 16, 17]]]

>>> tensorcontraction(A, (0, 2))
[21, 30]
```

Matrix multiplication may be emulated with a proper combination of tensorcontraction and tensorproduct

```python
>>> from sympy import tensorproduct

>>> from sympy.abc import a, b, c, d, e, f, g, h

>>> m1 = Matrix([[a, b], [c, d]])
>>> m2 = Matrix([[e, f], [g, h]])

>>> p = tensorproduct(m1, m2)

>>> p
[[[a*e, a*f], [a*g, a*h]], [[b*e, b*f], [b*g, b*h]]]`  

>>> tensorcontraction(p, (1, 2))
```

See also:

- `sympy.tensor.array.expressions.array_expressions.ArrayContraction` (page 1444)

`sympy.tensor.array.tensorproduct(*args)`

Tensor product among scalars or array-like objects.

The equivalent operator for array expressions is `ArrayTensorProduct`, which can be used to keep the expression unevaluated.

Examples

```python
>>> from sympy.tensor.array import tensorproduct, Array

>>> from sympy.abc import x, y, z, t

>>> A = Array([[1, 2], [3, 4]])
>>> B = Array([x, y])

>>> tensorproduct(A, B)
```

(continues on next page)
Applying this function on two matrices will result in a rank 4 array.

\[
\begin{bmatrix}
[[[x^2, x*y], [x*y, y^2]], [[2*x^2, 2*x*y], [2*x*y, 2*y^2]]], \\
[[[3*x^2, 3*x*y], [3*x*y, 3*y^2]], [[4*x^2, 4*x*y], [4*x*y, 4*y^2]]]
\end{bmatrix}
\]

See also:

sympy.tensor.array.array_expressions.ArrayTensorProduct

Diagonalization of an array-like object on the specified axes.
This is equivalent to multiplying the expression by Kronecker deltas unifying the axes.
The diagonal indices are put at the end of the axes.
The equivalent operator for array expressions is ArrayDiagonal, which can be used to keep the expression unevaluated.

Examples

tensordiagonal acting on a 2-dimensional array by axes 0 and 1 is equivalent to the diagonal of the matrix:

```python
>>> from sympy import Array, tensordiagonal
>>> from sympy import Matrix, eye
>>> tensordiagonal(eye(3), (0, 1))
[1, 1, 1]
```

```python
>>> from sympy import a, b, c, d
>>> m1 = Matrix([[a, b], [c, d]])
>>> tensordiagonal(m1, [0, 1])
[a, d]
```

In case of higher dimensional arrays, the diagonalized out dimensions are appended removed and appended as a single dimension at the end:

```python
>>> A = Array(range(18), (3, 2, 3))
>>> A
[[[0, 1, 2], [3, 4, 5]], [[6, 7, 8], [9, 10, 11]], [[12, 13, 14], [15, 16, 17]]]
>>> tensordiagonal(A, (0, 2))
[[0, 7, 14], [3, 10, 17]]
```
See also:

`sympy.tensor.array.expressions.array_expressions.ArrayDiagonal` (page 1444)

**N-dim array expressions**

Array expressions are expressions representing N-dimensional arrays, without evaluating them. These expressions represent in a certain way abstract syntax trees of operations on N-dimensional arrays.

Every N-dimensional array operator has a corresponding array expression object.

Table of correspondences:

<table>
<thead>
<tr>
<th>Array operator</th>
<th>Array expression operator</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>tensorproduct</code></td>
<td><code>ArrayTensorProduct</code></td>
</tr>
<tr>
<td><code>tensorcontraction</code></td>
<td><code>ArrayContraction</code></td>
</tr>
<tr>
<td><code>tensordiagonal</code></td>
<td><code>ArrayDiagonal</code></td>
</tr>
<tr>
<td><code>permutedims</code></td>
<td><code>PermuteDims</code></td>
</tr>
</tbody>
</table>

**Examples**

ArraySymbol objects are the N-dimensional equivalent of MatrixSymbol objects in the matrix module:

```python
>>> from sympy.tensor.array.expressions import ArraySymbol
>>> from sympy import i, j, k
>>> A = ArraySymbol("A", (3, 2, 4))
>>> A.shape
(3, 2, 4)
>>> A[i, j, k]
A[i, j, k]
```

Component-explicit arrays can be added inside array expressions:

```python
>>> from sympy import Array
>>> from sympy import tensorproduct
>>> from sympy.tensor.array.expressions import ArrayTensorProduct
```

(continues on next page)
Constructing array expressions from index-explicit forms

Array expressions are index-implicit. This means they do not use any indices to represent array operations. The function `convert_indexed_to_array( ... )` may be used to convert index-explicit expressions to array expressions. It takes as input two parameters: the index-explicit expression and the order of the indices:

```
>>> from sympy.tensor.array.expressions import convert_indexed_to_array
>>> from sympy import Sum
>>> A = ArraySymbol("A", (3, 3))
>>> B = ArraySymbol("B", (3, 3))
>>> convert_indexed_to_array(A[i, j], [i, j])
A
>>> convert_indexed_to_array(A[i, j], [j, i])
PermuteDims(A, (0 1))
>>> convert_indexed_to_array(A[i, j] + B[j, i], [i, j])
ArrayAdd(A, PermuteDims(B, (0 1)))
>>> convert_indexed_to_array(Sum(A[i, j]*B[j, k], (j, 0, 2)), [i, k])
ArrayContraction(ArrayTensorProduct(A, B), (1, 2))
```

The diagonal of a matrix in the array expression form:

```
>>> convert_indexed_to_array(A[i, i], [i])
ArrayDiagonal(A, (0, 1))
```

The trace of a matrix in the array expression form:

```
>>> convert_indexed_to_array(Sum(A[i, i], (i, 0, 2)), [i])
ArrayContraction(A, (0, 1))
```

Compatibility with matrices

Array expressions can be mixed with objects from the matrix module:

```
>>> from sympy import MatrixSymbol
>>> M = MatrixSymbol("M", 3, 3)
>>> N = MatrixSymbol("N", 3, 3)
```

Express the matrix product in the array expression form:
The expression can be converted back to matrix form:

```python
from sympy.tensor.array.expressions import convert_matrix_to_array
>>> convert_matrix_to_array(expr)
M*N
```

Add a second contraction on the remaining axes in order to get the trace of $M \cdot N$:

```python
>>> expr_tr = ArrayContraction(expr, (0, 1))
>>> expr_tr
ArrayContraction(ArrayContraction(ArrayTensorProduct(M, N), (1, 2)), (0, 1))
```

Flatten the expression by calling `.doit()` and remove the nested array contraction operations:

```python
>>> expr_tr.doit()
ArrayContraction(ArrayTensorProduct(M, N), (0, 3), (1, 2))
```

Get the explicit form of the array expression:

```python
>>> expr.as_explicit()
[[M[0, 0]*N[0, 0] + M[0, 1]*N[1, 0] + M[0, 2]*N[2, 0], M[0, 0]*N[0, 1] + M[0, 1]*N[1, 1] + M[0, 2]*N[2, 1], M[0, 0]*N[0, 2] + M[0, 1]*N[1, 2] + M[0, 2]*N[2, 2]],
 [M[1, 0]*N[0, 0] + M[1, 1]*N[1, 0] + M[1, 2]*N[2, 0], M[1, 0]*N[0, 1] + M[1, 1]*N[1, 1] + M[1, 2]*N[2, 1], M[1, 0]*N[0, 2] + M[1, 1]*N[1, 2] + M[1, 2]*N[2, 2]],
```

Express the trace of a matrix:

```python
from sympy import Trace
>>> convert_matrix_to_array(Trace(M))
ArrayContraction(M, (0, 1))
>>> convert_matrix_to_array(Trace(M*N))
ArrayContraction(ArrayTensorProduct(M, N), (0, 3), (1, 2))
```

Express the transposition of a matrix (will be expressed as a permutation of the axes):

```python
>>> convert_matrix_to_array(M.T)
PermuteDims(M, (0 1))
```

Compute the derivative array expressions:

```python
from sympy.tensor.array.expressions import array_derive
>>> d = array_derive(M, M)
>>> d
PermuteDims(ArrayTensorProduct(I, I), (3)(1 2))
```
Verify that the derivative corresponds to the form computed with explicit matrices:

```python
>>> d.as_explicit()

\[
\begin{bmatrix}
[1, 0, 0], [0, 0, 0], [0, 0, 0],
[0, 1, 0], [0, 0, 0], [0, 0, 0],
[0, 0, 0], [1, 0, 0], [0, 0, 0]
\end{bmatrix}
\]
```

```python
>>> M = M.as_explicit()
```

```python
>>> Me = M.diff(Me)
```

```python
[[[1, 0, 0], [0, 0, 0], [0, 0, 0]], [[0, 1, 0], [0, 0, 0], [0, 0, 0]], [[0, 0, 0], [1, 0, 0], [0, 0, 0]], [[0, 0, 0], [0, 0, 0], [0, 1, 0]], [[0, 0, 0], [0, 0, 0], [0, 0, 1]], [[0, 0, 0], [0, 1, 0]]]
```

**class** sympy.tensor.array.expressions.ArrayTensorProduct(*args, **kwargs)**

Class to represent the tensor product of array-like objects.

**class** sympy.tensor.array.expressions.ArrayContraction(expr, *contraction_indices, **kwargs)**

This class is meant to represent contractions of arrays in a form easily processable by the code printers.

**class** sympy.tensor.array.expressions.ArrayDiagonal(expr, *diagonal_indices, **kwargs)**

Class to represent the diagonal operator.

**Explanation**

In a 2-dimensional array it returns the diagonal, this looks like the operation:

\[ A_{ij} \rightarrow A_{ii} \]

The diagonal over axes 1 and 2 (the second and third) of the tensor product of two 2-dimensional arrays \( A \otimes B \) is

\[ [A_{ab} B_{cd}]_{abcd} \rightarrow [A_{ai} B_{id}]_{adi} \]

In this last example the array expression has been reduced from 4-dimensional to 3-dimensional. Notice that no contraction has occurred, rather there is a new index \( i \) for the diagonal, contraction would have reduced the array to 2 dimensions.

Notice that the diagonalized out dimensions are added as new dimensions at the end of the indices.

**class** sympy.tensor.array.expressions.PermuteDims(expr, permutation=None, index_order_old=None, index_order_new=None, **kwargs)**

Class to represent permutation of axes of arrays.
Examples

```python
>>> from sympy.tensor.array import permutedims
>>> from sympy import MatrixSymbol

>>> M = MatrixSymbol("M", 3, 3)
>>> cg = permutedims(M, [1, 0])
```

The object `cg` represents the transposition of `M`, as the permutation `[1, 0]` will act on its indices by switching them:

\[ M_{ij} \Rightarrow M_{ji} \]

This is evident when transforming back to matrix form:

```python
>>> from sympy.tensor.array.expressions.from_array_to_matrix import convert_array_to_matrix

>>> convert_array_to_matrix(cg)
M.T
```

```python
>>> N = MatrixSymbol("N", 3, 2)
>>> cg = permutedims(N, [1, 0])
```

```python
>>> cg.shape
(2, 3)
```

There are optional parameters that can be used as alternative to the permutation:

```python
>>> from sympy.tensor.array.expressions import ArraySymbol, PermuteDims

>>> M = ArraySymbol("M", (1, 2, 3, 4, 5))
>>> expr = PermuteDims(M, index_order_old="ijklm", index_order_new="kijml")
```

```python
>>> expr.shape
(3, 1, 2, 5, 4)
```

Permutations of tensor products are simplified in order to achieve a standard form:

```python
>>> from sympy.tensor.array import tensorproduct

>>> M = MatrixSymbol("M", 4, 5)
>>> tp = tensorproduct(M, N)
```

```python
>>> tp.shape
(4, 5, 3, 2)
```

```python
>>> perm1 = permutedims(tp, [2, 3, 1, 0])
```

The args \((M, N)\) have been sorted and the permutation has been simplified, the expression is equivalent:

```python
>>> perm1.args
(N, M)
>>> perm1.shape
(3, 2, 5, 4)
>>> perm1.permutation
(2 3)
```
The permutation in its array form has been simplified from [2, 3, 1, 0] to [0, 1, 3, 2], as the arguments of the tensor product \( M \) and \( N \) have been switched:

```python
>>> perm1.permutation.array_form
[0, 1, 3, 2]
```

We can nest a second permutation:

```python
>>> perm2 = permutedims(perm1, [1, 0, 2, 3])
>>> perm2.shape
(2, 3, 5, 4)
>>> perm2.permutation.array_form
[1, 0, 3, 2]
```

### Indexed Objects

Module that defines indexed objects.

The classes `IndexedBase`, `Indexed`, and `Idx` represent a matrix element \( M[i, j] \) as in the following diagram:

1) The `Indexed` class represents the entire indexed object.

```
            ,__|__,
            M[i, j]
            /   \__\____
```

2) The `Idx` class represents indices; each `Idx` can optionally contain information about its range.

```
            |
            2) The `Idx` class represents indices; each `Idx` can optionally contain information about its range.
```

3) `IndexedBase` represents the 'stem' of an indexed object, here `M`.

The stem used by itself is usually taken to represent the entire array.

There can be any number of indices on an Indexed object. No transformation properties are implemented in these Base objects, but implicit contraction of repeated indices is supported.

Note that the support for complicated (i.e. non-atomic) integer expressions as indices is limited. (This should be improved in future releases.)

### Examples

To express the above matrix element example you would write:

```python
>>> from sympy import symbols, IndexedBase, Idx
>>> M = IndexedBase('M')
>>> i, j = symbols('i j', cls=Idx)
>>> M[i, j]
M[i, j]
```
Repeated indices in a product implies a summation, so to express a matrix-vector product in terms of Indexed objects:

```python
tax = IndexedBase('x')
M[i, j]*x[j]
```

If the indexed objects will be converted to component based arrays, e.g. with the code printers or the autowrap framework, you also need to provide (symbolic or numerical) dimensions. This can be done by passing an optional shape parameter to IndexedBase upon construction:

```python
dim1, dim2 = symbols('dim1 dim2', integer=True)
A = IndexedBase('A', shape=(dim1, 2*dim1, dim2))
A[i, j, 3].shape
(dim1, 2*dim1, dim2)
```

If an IndexedBase object has no shape information, it is assumed that the array is as large as the ranges of its indices:

```python
n, m = symbols('n m', integer=True)
i = Idx('i', m)
j = Idx('j', n)
M[i, j].shape
(m, n)
M[i, j].ranges
[(0, m - 1), (0, n - 1)]
```

The above can be compared with the following:

```python
A[i, 2, j].shape
(dim1, 2*dim1, dim2)
A[i, 2, j].ranges
[(0, 2 - 1), None, (0, n - 1)]
```

To analyze the structure of indexed expressions, you can use the methods `get_indices()` and `get_contraction_structure()`:

```python
from sympy.tensor import get_indices, get_contraction_structure
get_indices(A[i, j, j])
({i}, {})
get_contraction_structure(A[i, j, j])
{(j,): {A[i, j, j]}}
```

See the appropriate docstrings for a detailed explanation of the output.

```python
class sympy.tensor.indexed.Idx(label, range=None, **kw_args)
```
Represents an integer index as an Integer or integer expression.

There are a number of ways to create an Idx object. The constructor takes two arguments:

```python
label
An integer or a symbol that labels the index.
```
range

Optionally you can specify a range as either

- **Symbol or integer**: This is interpreted as a dimension. Lower and upper bounds are set to 0 and \( \text{range} - 1 \), respectively.
- **tuple**: The two elements are interpreted as the lower and upper bounds of the range, respectively.

Note: bounds of the range are assumed to be either integer or infinite (oo and -oo are allowed to specify an unbounded range). If \( n \) is given as a bound, then \( n \text{.is_integer} \) must not return false.

For convenience, if the label is given as a string it is automatically converted to an integer symbol. (Note: this conversion is not done for range or dimension arguments.)

**Examples**

```python
>>> from sympy import Idx, symbols, oo
>>> n, i, L, U = symbols('n i L U', integer=True)
```

If a string is given for the label an integer Symbol is created and the bounds are both None:

```python
>>> idx = Idx('qwerty'); idx
qwerty
>>> idx.lower, idx.upper
(None, None)
```

Both upper and lower bounds can be specified:

```python
>>> idx = Idx(i, (L, U)); idx
i
>>> idx.lower, idx.upper
(L, U)
```

When only a single bound is given it is interpreted as the dimension and the lower bound defaults to 0:

```python
>>> idx = Idx(i, n); idx.lower, idx.upper
(0, n - 1)
>>> idx = Idx(i, 4); idx.lower, idx.upper
(0, 3)
>>> idx = Idx(i, oo); idx.lower, idx.upper
(0, oo)
```

**property label**

Returns the label (Integer or integer expression) of the Idx object.
Examples

```python
>>> from sympy import Idx, Symbol
>>> x = Symbol('x', integer=True)
>>> Idx(x).label
x
>>> j = Symbol('j', integer=True)
>>> Idx(j).label
j
>>> Idx(j + 1).label
j + 1
```

property `lower`
Returns the lower bound of the `Idx`.

Examples

```python
>>> from sympy import Idx
>>> Idx('j', 2).lower
0
>>> Idx('j', 5).lower
0
>>> Idx('j').lower is None
True
```

property `upper`
Returns the upper bound of the `Idx`.

Examples

```python
>>> from sympy import Idx
>>> Idx('j', 2).upper
1
>>> Idx('j', 5).upper
4
>>> Idx('j').upper is None
True
```

class `sympy.tensor.indexed.Indexed`(base, *args, **kw_args)
Represents a mathematical object with indices.

```python
>>> from sympy import Indexed, IndexedBase, Idx, symbols
>>> i, j = symbols('i j', cls=Idx)
>>> Indexed('A', i, j)
A[i, j]
```

It is recommended that `Indexed` objects be created by indexing `IndexedBase`: `IndexedBase('A')[i, j]` instead of `Indexed(IndexedBase('A'), i, j)`.
```python
>>> A = IndexedBase('A')
>>> a_ij = A[i, j]  # Prefer this,
>>> b_ij = Indexed(A, i, j)  # over this.
>>> a_ij == b_ij
True
```

**property base**

Returns the IndexedBase of the Indexed object.

**Examples**

```python
>>> from sympy import Indexed, IndexedBase, Idx, symbols
>>> i, j = symbols('i j', cls=Idx)
>>> Indexed('A', i, j).base
A
>>> B = IndexedBase('B')
>>> B == B[i, j].base
True
```

**property indices**

Returns the indices of the Indexed object.

**Examples**

```python
>>> from sympy import Indexed, Idx, symbols
>>> i, j = symbols('i j', cls=Idx)
>>> Indexed('A', i, j).indices
(i, j)
```

**property ranges**

Returns a list of tuples with lower and upper range of each index.

If an index does not define the data members upper and lower, the corresponding slot in the list contains None instead of a tuple.

**Examples**

```python
>>> from sympy import Indexed, Idx, symbols
>>> Indexed('A', Idx('i', 2), Idx('j', 4), Idx('k', 8)).ranges
[(0, 1), (0, 3), (0, 7)]
>>> Indexed('A', Idx('i', 3), Idx('j', 3), Idx('k', 3)).ranges
[(0, 2), (0, 2), (0, 2)]
>>> x, y, z = symbols('x y z', integer=True)
>>> Indexed('A', x, y, z).ranges
[None, None, None]
```

**property rank**

Returns the rank of the Indexed object.
Examples

```python
>>> from sympy import Indexed, Idx, symbols
>>> i, j, k, l, m = symbols('i:m', cls=Idx)
>>> Indexed('A', i, j).rank
2
>>> q = Indexed('A', i, j, k, l, m)
>>> q.rank
5
>>> q.rank == len(q.indices)
True
```

**property shape**

Returns a list with dimensions of each index.

Dimensions is a property of the array, not of the indices. Still, if the IndexedBase does not define a shape attribute, it is assumed that the ranges of the indices correspond to the shape of the array.

```python
>>> from sympy import IndexedBase, Idx, symbols
>>> n, m = symbols('n m', integer=True)
>>> i = Idx('i', m)
>>> j = Idx('j', m)
>>> A = IndexedBase('A', shape=(n, n))
>>> B = IndexedBase('B')
>>> A[i, j].shape
(n, n)
>>> B[i, j].shape
(m, m)
```

**class sympy.tensor.indexed.IndexedBase(label, shape=None, *, offset=0, strides=None, **kw_args)**

Represent the base or stem of an indexed object

The IndexedBase class represent an array that contains elements. The main purpose of this class is to allow the convenient creation of objects of the Indexed class. The `__getitem__` method of IndexedBase returns an instance of Indexed. Alone, without indices, the IndexedBase class can be used as a notation for e.g. matrix equations, resembling what you could do with the Symbol class. But, the IndexedBase class adds functionality that is not available for Symbol instances:

- An IndexedBase object can optionally store shape information. This can be used in to check array conformance and conditions for numpy broadcasting. (TODO)
- An IndexedBase object implements syntactic sugar that allows easy symbolic representation of array operations, using implicit summation of repeated indices.
- The IndexedBase object symbolizes a mathematical structure equivalent to arrays, and is recognized as such for code generation and automatic compilation and wrapping.

```python
>>> from sympy.tensor import IndexedBase, Idx
>>> from sympy import symbols
>>> A = IndexedBase('A'); A
A
```

(continues on next page)
When an IndexedBase object receives indices, it returns an array with named axes, represented by an Indexed object:

```python
>>> i, j = symbols('i j', integer=True)
>>> A[i, j, 2]
A[i, j, 2]
>>> type(A[i, j, 2])
<class 'sympy.tensor.indexed.Indexed'>
```

The IndexedBase constructor takes an optional shape argument. If given, it overrides any shape information in the indices. (But not the index ranges!)

```python
>>> m, n, o, p = symbols('m n o p', integer=True)
>>> i = Idx('i', m)
>>> j = Idx('j', n)
>>> A[i, j].shape
(m, n)
>>> B = IndexedBase('B', shape=(o, p))
>>> B[i, j].shape
(o, p)
```

Assumptions can be specified with keyword arguments the same way as for Symbol:

```python
>>> A_real = IndexedBase('A', real=True)
>>> A_real.is_real
True
>>> A != A_real
True
```

Assumptions can also be inherited if a Symbol is used to initialize the IndexedBase:

```python
>>> I = symbols('I', integer=True)
>>> C_inherit = IndexedBase(I)
>>> C_explicit = IndexedBase('I', integer=True)
>>> C_inherit == C_explicit
True
```

property `label`

    Returns the label of the IndexedBase object.
Examples

```python
>>> from sympy import IndexedBase
>>> from sympy.abc import x, y
>>> IndexedBase('A', shape=(x, y)).label
A
```

**property offset**

Returns the offset for the IndexedBase object.

This is the value added to the resulting index when the 2D Indexed object is unrolled to a 1D form. Used in code generation.

Examples

```python
>>> from sympy.printing import ccode
>>> from sympy.tensor import IndexedBase, Idx
>>> from sympy import symbols
>>> l, m, n, o = symbols('l m n o', integer=True)
>>> A = IndexedBase('A', strides=(l, m, n), offset=o)
>>> i, j, k = map(Idx, 'ijk')
>>> ccode(A[i, j, k])
'A[l*i + m*j + n*k + o]'
```

**property shape**

Returns the shape of the IndexedBase object.

Examples

```python
>>> from sympy import IndexedBase, Idx
>>> from sympy.abc import x, y
>>> IndexedBase('A', shape=(x, y)).shape
(x, y)
```

Note: If the shape of the IndexedBase is specified, it will override any shape information given by the indices.

```python
>>> A = IndexedBase('A', shape=(x, y))
>>> B = IndexedBase('B')
>>> i = Idx('i', 2)
>>> j = Idx('j', 1)
>>> A[i, j].shape
(x, y)
>>> B[i, j].shape
(2, 1)
```

**property strides**

Returns the strided scheme for the IndexedBase object.

Normally this is a tuple denoting the number of steps to take in the respective dimension when traversing an array. For code generation purposes strides='C' and strides='F' can also be used.
strides='C' would mean that code printer would unroll in row-major order and 'F' means unroll in column major order.

Methods

Module with functions operating on IndexedBase, Indexed and Idx objects

• Check shape conformance
• Determine indices in resulting expression

etc.

Methods in this module could be implemented by calling methods on Expr objects instead. When things stabilize this could be a useful refactoring.

sympy.tensor.index_methods.get_contraction_structure(expr)

Determine dummy indices of expr and describe its structure

By dummy we mean indices that are summation indices.

The structure of the expression is determined and described as follows:

1) A conforming summation of Indexed objects is described with a dict where the keys are summation indices and the corresponding values are sets containing all terms for which the summation applies. All Add objects in the SymPy expression tree are described like this.

2) For all nodes in the SymPy expression tree that are not of type Add, the following applies:

If a node discovers contractions in one of its arguments, the node itself will be stored as a key in the dict. For that key, the corresponding value is a list of dicts, each of which is the result of a recursive call to get_contraction_structure(). The list contains only dicts for the non-trivial deeper contractions, omitting dicts with None as the one and only key.

Note: The presence of expressions among the dictionary keys indicates multiple levels of index contractions. A nested dict displays nested contractions and may itself contain dicts from a deeper level. In practical calculations the summation in the deepest nested level must be calculated first so that the outer expression can access the resulting indexed object.

Examples

```python
default_sort_key
def IndexedBase, Idx
d = map(Idx, ['i', 'j', 'k', 'l'])
get_contraction_structure(x[i]*y[i] + A[j, j])
{(i,): {x[i]*y[i]}, (j,): {A[j, j]}}
get_contraction_structure(x[i]*y[j])
{None: {x[i]*y[j]}}
```
A multiplication of contracted factors results in nested dicts representing the internal contractions.

```python
>>> d = get_contraction_structure(x[i, i]*y[j, j])
>>> sorted(d.keys(), key=default_sort_key)
[None, x[i, i]*y[j, j]]
```

In this case, the product has no contractions:

```python
>>> d[None]
{x[i, i]*y[j, j]}
```

Factors are contracted “first”:

```python
>>> sorted(d[x[i, i]*y[j, j]], key=default_sort_key)
[None, {x[i, i], y[j, j]}]
```

A parenthesized Add object is also returned as a nested dictionary. The term containing the parenthesis is a Mul with a contraction among the arguments, so it will be found as a key in the result. It stores the dictionary resulting from a recursive call on the Add expression.

```python
>>> d = get_contraction_structure(x[i]*(y[i] + A[i, j]*x[j]))
>>> sorted(d.keys(), key=default_sort_key)
[None: {y[i]}, (j,): {A[j, j]*x[j]}, (i,): {x[i]}]
```

Powers with contractions in either base or exponent will also be found as keys in the dictionary, mapping to a list of results from recursive calls:

```python
>>> d = get_contraction_structure(A[j, j]**A[i, i])
>>> d[None]
{A[j, j]**A[i, i]}
>>> nested_contractions = d[A[j, j]**A[i, i]]
>>> nested_contractions[0]
{(i,): {A[j, j]}}
>>> nested_contractions[1]
{(j,): {A[i, i]}}
```

The description of the contraction structure may appear complicated when represented with a string in the above examples, but it is easy to iterate over:

```python
>>> from sympy import Expr
>>> for key in d:
...     if isinstance(key, Expr):
...         continue
...     for term in d[key]:
...         if term in d:
...             # treat deepest contraction first
...             pass
...         # treat outermost contactions here
```
sympy.tensor.index_methods.get_indices(expr)

Determine the outer indices of expression expr

By outer we mean indices that are not summation indices. Returns a set and a dict. The set contains outer indices and the dict contains information about index symmetries.

Examples

```python
>>> from sympy.tensor.index_methods import get_indices
>>> from sympy import symbols
>>> from sympy.tensor import IndexedBase

>>> x, y, A = map(IndexedBase, ['x', 'y', 'A'])
>>> i, j, a, z = symbols('i j a z', integer=True)

The indices of the total expression is determined, Repeated indices imply a summation, for instance the trace of a matrix A:

```python
>>> get_indices(A[i, i])
(set(), {})
```

In the case of many terms, the terms are required to have identical outer indices. Else an IndexConformanceException is raised.

```python
>>> get_indices(x[i] + A[i, j]*y[j])
({i}, {})
```

Exceptions

An IndexConformanceException means that the terms ar not compatible, e.g.

```python
>>> get_indices(x[i] + y[j])
(...)
IndexConformanceException: Indices are not consistent: x(i) + y(j)
```

Warning: The concept of outer indices applies recursively, starting on the deepest level. This implies that dummies inside parenthesis are assumed to be summed first, so that the following expression is handled gracefully:

```python
>>> get_indices((x[i] + A[i, j]*y[j])*x[j])
({i, j}, {})
```

This is correct and may appear convenient, but you need to be careful with this as SymPy will happily .expand() the product, if requested. The resulting expression would mix the outer j with the dummies inside the parenthesis, which makes it a different expression. To be on the safe side, it is best to avoid such ambiguities by using unique indices for all contractions that should be held separate.
class sympy.tensor.tensor.TensorIndexType(name, dummy_name=None, dim=None, eps_dim=None, metric_symmetry=1, metric_name='metric', **kwargs)

A TensorIndexType is characterized by its name and its metric.

Parameters

name : name of the tensor type
dummy_name : name of the head of dummy indices
dim : dimension, it can be a symbol or an integer or None
eps_dim : dimension of the epsilon tensor
metric_symmetry : integer that denotes metric symmetry or None for no metric
metric_name : string with the name of the metric tensor

Notes

The possible values of the metric_symmetry parameter are:

1 : metric tensor is fully symmetric
0 : metric tensor possesses no index symmetry
-1 : metric tensor is fully antisymmetric
None : there is no metric tensor (metric equals to None)

The metric is assumed to be symmetric by default. It can also be set to a custom tensor
by the .set_metric() method.

If there is a metric the metric is used to raise and lower indices.

In the case of non-symmetric metric, the following raising and lowering conventions will
be adopted:

\[
\psi(a) = g(a, b)\psi(-b); \quad \chi(-a) = \chi(b)g(-b, -a)
\]

From these it is easy to find:

\[
g(-a, b) = \delta(-a, b)
\]

where \(\delta(-a, b) = \delta(b, -a)\) is the Kronecker delta (see TensorIndex for the
conventions on indices). For antisymmetric metrics there is also the following equality:

\[
g(a, -b) = -\delta(a, -b)
\]

If there is no metric it is not possible to raise or lower indices; e.g. the index of the
defining representation of SU(N) is ‘covariant’ and the conjugate representation is ‘con-
travariant’; for \(N > 2\) they are linearly independent.

eps_dim is by default equal to dim, if the latter is an integer; else it can be assigned (for
use in naive dimensional regularization); if eps_dim is not an integer epsilon is None.
Examples

```python
>>> from sympy.tensor.tensor import TensorIndexType
>>> Lorentz = TensorIndexType('Lorentz', dummy_name='L')
>>> Lorentz.metric
metric(Lorentz, Lorentz)
```

```
class sympy.tensor.tensor.TensorIndex(name, tensor_index_type, is_up=True)
```

Represents a tensor index

**Parameters**

- **name**: name of the index, or True if you want it to be automatically assigned
- **tensor_index_type**: TensorIndexType of the index
- **is_up**: flag for contravariant index (is_up=True by default)

**Notes**

Tensor indices are contracted with the Einstein summation convention.

An index can be in contravariant or in covariant form; in the latter case it is represented prepending a - to the index name. Adding - to a covariant (is_up=False) index makes it contravariant.

Dummy indices have a name with head given by `tensor_inde_type.dummy_name` with underscore and a number.

Similar to symbols multiple contravariant indices can be created at once using `tensor_indices(s, typ)`, where `s` is a string of names.

Examples

```python
>>> from sympy.tensor.tensor import TensorIndexType, TensorIndex, TensorHead, tensor_indices
>>> Lorentz = TensorIndexType('Lorentz', dummy_name='L')
>>> mu = TensorIndex('mu', Lorentz, is_up=False)
>>> nu, rho = tensor_indices('nu, rho', Lorentz)
>>> A = TensorHead('A', [Lorentz, Lorentz])
>>> A(mu, nu)
A(-mu, nu)
>>> A(-mu, -rho)
```

(continues on next page)
Attributes

```
name
tensor_index_type
is_up
```

class sympy.tensor.tensor.TensorHead(name, index_types, symmetry=None, comm=0)

Tensor head of the tensor.

**Parameters**

- **name**: name of the tensor
- **index_types**: list of TensorIndexType
- **symmetry**: TensorSymmetry of the tensor
- **comm**: commutation group number

**Notes**

Similar to symbols multiple TensorHeads can be created using tensorhead(s, typ, sym=None, comm=0) function, where s is the string of names and sym is the monoterm tensor symmetry (see tensorsymmetry).

A TensorHead belongs to a commutation group, defined by a symbol on number comm (see _TensorManager.set_comm); tensors in a commutation group have the same commutation properties; by default comm is 0, the group of the commuting tensors.

**Examples**

Define a fully antisymmetric tensor of rank 2:

```
>>> from sympy.tensor.tensor import TensorIndexType, TensorHead,
>>> TensorSymmetry
>>> Lorentz = TensorIndexType('Lorentz', dummy_name='L')
>>> asym2 = TensorSymmetry.fully_symmetric(-2)
>>> A = TensorHead('A', [Lorentz, Lorentz], asym2)
```

Examples with ndarray values, the components data assigned to the TensorHead object are assumed to be in a fully-contravariant representation. In case it is necessary to assign components data which represents the values of a non-fully covariant tensor, see the other examples.
>>> from sympy.tensor.tensor import tensor_indices
>>> from sympy import diag

>>> Lorentz = TensorIndexType('Lorentz', dummy_name='L')

>>> i0, i1 = tensor_indices('i0:2', Lorentz)

Specify a replacement dictionary to keep track of the arrays to use for replacements in the tensorial expression. The TensorIndexType is associated to the metric used for contractions (in fully covariant form):

>>> repl = {Lorentz: diag(1, -1, -1, -1)}

Let's see some examples of working with components with the electromagnetic tensor:

>>> from sympy import symbols

>>> Ex, Ey, Ez, Bx, By, Bz = symbols('E_x E_y E_z B_x B_y B_z')

>>> c = symbols('c', positive=True)

Let's define $F$, an antisymmetric tensor:

>>> F = TensorHead('F', [Lorentz, Lorentz], asym2)

Let's update the dictionary to contain the matrix to use in the replacements:

```python
>>> repl.update({F(-i0, -i1): [
... [0, Ex/c, Ey/c, Ez/c],
... [-Ex/c, 0, -Bz, By],
... [-Ey/c, Bz, 0, -Bx],
... [-Ez/c, -By, Bx, 0]]})
```

Now it is possible to retrieve the contravariant form of the Electromagnetic tensor:

```python
>>> F(i0, i1).replace_with_arrays(repl, [i0, i1])
[[0, Ex/c, Ey/c, Ez/c], [E_x/c, 0, -B_z, B_y], [E_y/c, B_z, 0, -B_x], [E_z/c, -B_y, B_x, 0]]
```

and the mixed contravariant-covariant form:

```python
>>> F(i0, -i1).replace_with_arrays(repl, [i0, -i1])
[[0, Ex/c, Ey/c, Ez/c], [E_x/c, 0, B_z, -B_y], [E_y/c, -B_z, 0, B_x], [E_z/c, B_y, -B_x, 0]]
```

Energy-momentum of a particle may be represented as:

```python
>>> from sympy import symbols

>>> P = TensorHead('P', [Lorentz], TensorSymmetry.no_symmetry(1))

>>> E, px, py, pz = symbols('E p_x p_y p_z', positive=True)

>>> repl.update({P(i0): [E, px, py, pz]})
```

The contravariant and covariant components are, respectively:

```python
>>> P(i0).replace_with_arrays(repl, [i0])
[E, p_x, p_y, p_z]

>>> P(-i0).replace_with_arrays(repl, [-i0])
[E, -p_x, -p_y, -p_z]
```
The contraction of a 1-index tensor by itself:

```python
>>> expr = P(i0)*P(-i0)
>>> expr.replace_with_arrays(repl, [])
E**2 - p_x**2 - p_y**2 - p_z**2
```

**Attributes**

<table>
<thead>
<tr>
<th>name</th>
<th>index_types</th>
<th>rank</th>
<th>symmetry</th>
<th>comm</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td>(total number of indices)</td>
<td></td>
<td>(commutation group)</td>
</tr>
</tbody>
</table>

**commutes_with(other)**

Returns 0 if self and other commute, 1 if they anticommute.

Returns None if self and other neither commute nor anticommute.

**sympy.tensor.tensor.tensor_heads(s, index_types, symmetry=None, comm=0)**

Returns a sequence of TensorHeads from a string `s`

**class sympy.tensor.tensor.TensExpr(*args)**

Abstract base class for tensor expressions

**Notes**

A tensor expression is an expression formed by tensors; currently the sums of tensors are distributed.

A TensExpr can be a TensAdd or a TensMul.

TensMul objects are formed by products of component tensors, and include a coefficient, which is a SymPy expression.

In the internal representation contracted indices are represented by `(ipos1, ipos2, icomp1, icomp2)`, where `icomp1` is the position of the component tensor with contravariant index, `ipos1` is the slot which the index occupies in that component tensor.

Contracted indices are therefore nameless in the internal representation.

**get_matrix()**

DEPRECATED: do not use.

Returns ndarray components data as a matrix, if components data are available and ndarray dimension does not exceed 2.

**replace_with_arrays(replacement_dict, indices=None)**

Replace the tensorial expressions with arrays. The final array will correspond to the N-dimensional array with indices arranged according to `indices`.

**Parameters**

- `replacement_dict`
  - dictionary containing the replacement rules for tensors.
indices

the index order with respect to which the array is read. The original index order will be used if no value is passed.

Examples

```python
>>> from sympy.tensor.tensor import TensorIndexType, tensor_indices
>>> from sympy.tensor.tensor import TensorHead
>>> from sympy import symbols, diag

>>> L = TensorIndexType("L")
>>> i, j = tensor_indices("i j", L)
>>> A = TensorHead("A", [L])
>>> A(i).replace_with_arrays({A(i): [1, 2]}, [i])
[1, 2]
```

Since ‘indices’ is optional, we can also call replace_with_arrays by this way if no specific index order is needed:

```python
>>> A(i).replace_with_arrays({A(i): [1, 2]})
[1, 2]
```

For contractions, specify the metric of the TensorIndexType, which in this case is L, in its covariant form:

```python
>>> expr = A(i)*A(-i)
>>> expr.replace_with_arrays({A(i): [1, 2]}, L: diag(1, -1))
-3
```

Symmetrization of an array:

```python
>>> H = TensorHead("H", [L, L])
>>> a, b, c, d = symbols("a b c d")
>>> expr = H(i, j)/2 + H(j, i)/2
>>> expr.replace_with_arrays({H(i, j): [[a, b], [c, d]]})
[[a, b/2 + c/2], [b/2 + c/2, d]]
```

Anti-symmetrization of an array:

```python
>>> expr = H(i, j)/2 - H(j, i)/2
>>> repl = {H(i, j): [[a, b], [c, d]]}
>>> expr.replace_with_arrays(repl)
[[0, b/2 - c/2], [-b/2 + c/2, 0]]
```

The same expression can be read as the transpose by inverting i and j:

```python
>>> expr.replace_with_arrays(repl, [j, i])
[[0, -b/2 + c/2], [b/2 - c/2, 0]]
```
class sympy.tensor.tensor.TensAdd(*args, **kw_args)

Sum of tensors.

Parameters

**free_args**: list of the free indices

Examples

```python
>>> from sympy.tensor.tensor import TensorIndexType, tensor_heads, tensor_indices
>>> Lorentz = TensorIndexType('Lorentz', dummy_name='L')
>>> a, b = tensor_indices('a,b', Lorentz)
>>> p, q = tensor_heads('p,q', [Lorentz])
>>> t = p(a) + q(a); t
p(a) + q(a)
```

Examples with components data added to the tensor expression:

```python
>>> from sympy import symbols, diag
>>> x, y, z, t = symbols("x y z t")
>>> repl = {}
>>> repl[Lorentz] = diag(1, -1, -1, -1)
>>> repl[p(a)] = [1, 2, 3, 4]
>>> repl[q(a)] = [x, y, z, t]
```

```python
>>> expr = p(a) + q(a)
>>> expr.replace_with_arrays(repl, [a])
[x + 1, y + 2, z + 3, t + 4]
```

</tbody>
</table>

`canon_bp()`

Canonicalize using the Butler-Portugal algorithm for canonicalization under monoterms symmetries.

`contract_metric(g)`

Raise or lower indices with the metric g.

Parameters

**g**: metric

**contract_all**: if True, eliminate all g which are contracted
Notes

see the TensorIndexType docstring for the contraction conventions

```python
class sympy.tensor.tensor.TensMul(*args, **kw_args)
```
Product of tensors.

Parameters

- `coeff`: SymPy coefficient of the tensor
- `args`

Notes

args[0] list of TensorHead of the component tensors.

args[1] list of (ind, ipos, icomp) where ind is a free index, ipos is the slot position of ind in the icomp-th component tensor.

args[2] list of tuples representing dummy indices. (ipos1, ipos2, icomp1, icomp2) indicates that the contravariant dummy index is the ipos1-th slot position in the icomp1-th component tensor; the corresponding covariant index is in the ipos2 slot position in the icomp2-th component tensor.

Attributes

- `components` (list of TensorHead of the component tensors)
- `types` (list of nonrepeated TensorIndexType)
- `free` (list of (ind, ipos, icomp), see Notes)
- `dum` (list of (ipos1, ipos2, icomp1, icomp2), see Notes)
- `ext_rank` (rank of the tensor counting the dummy indices)
- `rank` (rank of the tensor)
- `coeff` (SymPy coefficient of the tensor)
- `free_args` (list of the free indices in sorted order)
- `is_canon_bp` (True if the tensor in in canonical form)

```python
canon_bp()
```
Canonicalize using the Butler-Portugal algorithm for canonicalization under monoterms symmetries.

Examples

```python
>>> from sympy.tensor.tensor import TensorIndexType, tensor_indices,
... TensorHead, TensorSymmetry
>>> Lorentz = TensorIndexType('Lorentz', dummy_name='L')
>>> m0, m1, m2 = tensor_indices('m0,m1,m2', Lorentz)
>>> A = TensorHead('A', [Lorentz]*2, TensorSymmetry.fully_symmetric(-2))
>>> t = A(m0,-m1)*A(m1,-m0)
>>> t.cannon_bp()
```
-A(L_0, L_1)*A(-L_0, -L_1)

```python
>>> t = A(m0,-m1)*A(m1,-m2)*A(m2,-m0)
>>> t.canon_bp()
0
```

**contract_metric(g)**

Raise or lower indices with the metric g.

**Parameters**

- `g`: metric

**Notes**

See the `TensorIndexType` docstring for the contraction conventions.

**Examples**

```python
>>> from sympy.tensor.tensor import TensorIndexType, tensor_indices, tensor_heads
>>> Lorentz = TensorIndexType('Lorentz', dummy_name='L')
>>> m0, m1, m2 = tensor_indices('m0,m1,m2', Lorentz)
>>> g = Lorentz.metric
>>> p, q = tensor_heads('p,q', [Lorentz])
>>> t = p(m0)*q(m1)*g(-m0, -m1)
>>> t.canon_bp()
metric(L_0, L_1)*p(-L_0)*q(-L_1)
```

**get_free_indices()** → list[TensorIndex](page 1458)

Returns the list of free indices of the tensor.

**Explanation**

The indices are listed in the order in which they appear in the component tensors.

**Examples**

```python
>>> from sympy.tensor.tensor import TensorIndexType, tensor_indices, tensor_heads
>>> Lorentz = TensorIndexType('Lorentz', dummy_name='L')
>>> m0, m1, m2 = tensor_indices('m0,m1,m2', Lorentz)
>>> g = Lorentz.metric
>>> p, q = tensor_heads('p,q', [Lorentz])
>>> t = p(m1)*g(m0,m2)
>>> t.get_free_indices()
[m1, m0, m2]
```
get_indices()
Returns the list of indices of the tensor.

Explanation
The indices are listed in the order in which they appear in the component tensors. The dummy indices are given a name which does not collide with the names of the free indices.

Examples

```
>>> from sympy.tensor.tensor import TensorIndexType, tensor_indices,
    tensor_heads
>>> Lorentz = TensorIndexType('Lorentz', dummy_name='L')
>>> m0, m1, m2 = tensor_indices('m0,m1,m2', Lorentz)
>>> g = Lorentz.metric
>>> p, q = tensor_heads('p,q', [Lorentz])
>>> t = p(m1)*g(m0,m2)
>>> t.get_indices()
[m1, m0, m2]
>>> t2 = p(m1)*g(-m1, m2)
>>> t2.get_indices()
[L_0, -L_0, m2]
```

perm2tensor(g, is_canon_bp=False)
Returns the tensor corresponding to the permutation g
For further details, see the method in TIDS with the same name.

sorted_components()
Returns a tensor product with sorted components.

split()
Returns a list of tensors, whose product is self.

Explanation
Dummy indices contracted among different tensor components become free indices with the same name as the one used to represent the dummy indices.
Examples

```python
>>> from sympy.tensor.tensor import TensorIndexType, tensor_indices,
    tensor_heads, TensorSymmetry
>>> Lorentz = TensorIndexType('Lorentz', dummy_name='L')
>>> a, b, c, d = tensor_indices('a,b,c,d', Lorentz)
>>> A, B = tensor_heads('A,B', [Lorentz]*2, TensorSymmetry.fully_symmetric(2))
>>> t = A(a, b)*B(-b, c)
>>> t
A(a, L_0)*B(-L_0, c)
>>> t.split()
[A(a, L_0), B(-L_0, c)]
```

`sympy.tensor.tensor.canon_bp(p)`
Butler-Portugal canonicalization. See `tensor_can.py` from the combinatorics module for the details.

`sympy.tensor.tensor.riemann_cyclic_replace(t_r)`
replace Riemann tensor with an equivalent expression

\[ R(m,n,p,q) \rightarrow 2/3*R(m,n,p,q) - 1/3*R(m,q,n,p) + 1/3*R(m,p,n,q) \]

`sympy.tensor.tensor.riemann_cyclic(t2)`
Replace each Riemann tensor with an equivalent expression satisfying the cyclic identity. This trick is discussed in the reference guide to Cadabra.

Examples

```python
>>> from sympy.tensor.tensor import TensorIndexType, tensor_indices,
    TensorHead, riemann_cyclic, TensorSymmetry
>>> Lorentz = TensorIndexType('Lorentz', dummy_name='L')
>>> i, j, k, l = tensor_indices('i,j,k,l', Lorentz)
>>> R = TensorHead('R', [Lorentz]*4, TensorSymmetry.riemann())
>>> t = R(i,j,k,l)*R(-i,-j,-k,-l) - 2*R(-i,-k,-j,-l)
>>> riemann_cyclic(t)
0
```

`class sympy.tensor.tensor.TensorSymmetry(*args, **kw_args)`
Monoterm symmetry of a tensor (i.e. any symmetric or anti-symmetric index permutation). For the relevant terminology see `tensor_can.py` section of the combinatorics module.

**Parameters**

- `bsgs`: tuple `(base, sgs)` BSGS of the symmetry of the tensor
Notes

A tensor can have an arbitrary monoterm symmetry provided by its BSGS. Multiterm symmetries, like the cyclic symmetry of the Riemann tensor (i.e., Bianchi identity), are not covered. See combinatorics module for information on how to generate BSGS for a general index permutation group. Simple symmetries can be generated using built-in methods.

Examples

Define a symmetric tensor of rank 2

```python
>>> from sympy.tensor.tensor import TensorIndexType, TensorSymmetry, get_symmetric_group_sgs, TensorHead
>>> Lorentz = TensorIndexType('Lorentz', dummy_name='L')
>>> sym = TensorSymmetry(get_symmetric_group_sgs(2))
>>> T = TensorHead('T', [Lorentz]*2, sym)
```

Note, that the same can also be done using built-in TensorSymmetry methods

```python
>>> sym2 = TensorSymmetry.fully_symmetric(2)
>>> sym == sym2
True
```

See also:

* sympy.combinatorics.tensor_can.get_symmetric_group_sgs (page 430)*

Attributes

<table>
<thead>
<tr>
<th>base</th>
<th>(base of the BSGS)</th>
</tr>
</thead>
<tbody>
<tr>
<td>generators</td>
<td>(generators of the BSGS)</td>
</tr>
<tr>
<td>rank</td>
<td>(rank of the tensor)</td>
</tr>
</tbody>
</table>

classmethod direct_product(*args)

Returns a TensorSymmetry object that is being a direct product of fully (anti-)symmetric index permutation groups.

Notes

Some examples for different values of (*args): (1) vector, equivalent to `TensorSymmetry.fully_symmetric(1)` (2) tensor with 2 symmetric indices, equivalent to `fully_symmetric(2)` (2) tensor with 2 antisymmetric indices, equivalent to `fully_symmetric(-2)` (2, -2) tensor with the first 2 indices commuting and the last 2 anticommuting (1, 1, 1) tensor with 3 indices without any symmetry

classmethod fully_symmetric(rank)

Returns a fully symmetric (antisymmetric if rank``<0) TensorSymmetry object for \`\`abs(rank) indices.
classmethod no_symmetry(rank)
    TensorSymmetry object for rank indices with no symmetry

classmethod riemann()
    Returns a monoterm symmetry of the Riemann tensor

sympy.tensor.tensor.tensorSymmetry(*args)
    Returns a TensorSymmetry object. This method is deprecated, use TensorSymmetry.

direct_product() or .riemann() instead.

**Explanation**

One can represent a tensor with any monoterm slot symmetry group using a BSGS.

args can be a BSGS args[0] base args[1] sgs

Usually tensors are in (direct products of) representations of the symmetric group; args can be a list of lists representing the shapes of Young tableaux

**Notes**

For instance: [[1]] vector [[1]*n] symmetric tensor of rank n [[n]] antisymmetric tensor of rank n [[2, 2]] monoterm slot symmetry of the Riemann tensor [[1],[1]] vector*vector [[2],[1],[1]] (antisymmetric tensor)*vector*vector

Notice that with the shape [2, 2] we associate only the monoterm symmetries of the Riemann tensor; this is an abuse of notation, since the shape [2, 2] corresponds usually to the irreducible representation characterized by the monoterm symmetries and by the cyclic symmetry.

class sympy.tensor.tensor.TensorType(*args, **kwargs)
    Class of tensor types. Deprecated, use tensor_heads() instead.

    **Parameters**
    - `index_types`: list of TensorIndexType of the tensor indices
    - `symmetry`: TensorSymmetry of the tensor

    **Attributes**

    | Attribute     |
    |---------------|
    | index_types   |
    | symmetry      |
    | types         |

    (list of TensorIndexType without repetitions)

class sympy.tensor.tensor._TensorManager
    Class to manage tensor properties.
Notes

Tensors belong to tensor commutation groups; each group has a label \( \text{comm} \); there are predefined labels:

0 tensors commuting with any other tensor
1 tensors anticommuting among themselves
2 tensors not commuting, apart with those with \( \text{comm}=0 \)

Other groups can be defined using \text{set}_{\text{comm}}; tensors in those groups commute with those with \( \text{comm}=0 \); by default they do not commute with any other group.

\text{clear}()

Clear the TensorManager.

\text{comm\_i2symbol}(i)

Returns the symbol corresponding to the commutation group number.

\text{comm\_symbols2i}(i)

Get the commutation group number corresponding to \( i \).

\( i \) can be a symbol or a number or a string.

If \( i \) is not already defined its commutation group number is set.

\text{get\_comm}(i, j)

Return the commutation parameter for commutation group numbers \( i, j \)

\text{see \_TensorManager.set\_comm}

\text{set\_comm}(i, j, c)

Set the commutation parameter \( c \) for commutation groups \( i, j \).

Parameters

\( i, j \) : symbols representing commutation groups
\( c \) : group commutation number

Notes

\( i, j \) can be symbols, strings or numbers, apart from 0, 1 and 2 which are reserved respectively for commuting, anticommuting tensors and tensors not commuting with any other group apart with the commuting tensors. For the remaining cases, use this method to set the commutation rules; by default \( c=\text{None} \).

The group commutation number \( c \) is assigned in correspondence to the group commutation symbols; it can be

0 commuting
1 anticommuting
None no commutation property
Examples

G and GH do not commute with themselves and commute with each other; A is commuting.

```python
>>> from sympy.tensor.tensor import TensorIndexType, tensor_indices,
   TensorHead, TensorManager, TensorSymmetry
>>> Lorentz = TensorIndexType('Lorentz')
>>> i0,i1,i2,i3,i4 = tensor_indices('i0:5', Lorentz)
>>> A = TensorHead('A', [Lorentz])
>>> G = TensorHead('G', [Lorentz], TensorSymmetry.no_symmetry(1),
   'Gcomm')
>>> GH = TensorHead('GH', [Lorentz], TensorSymmetry.no_symmetry(1),
   'GHcomm')
>>> TensorManager.set_comm('Gcomm', 'GHcomm', 0)
>>> (GH(i1)*G(i0)).canon_bp()
G(i0)*GH(i1)
>>> (G(i1)*G(i0)).canon_bp()
G(i1)*G(i0)
>>> (G(i1)*A(i0)).canon_bp()
A(i0)*G(i1)
```

`set_comms(*args)`

Set the commutation group numbers c for symbols i, j.

**Parameters**

- `args`: sequence of (i, j, c)

Tensor Operators

```python
class sympy.tensor.toperators.PartialDerivative(expr,*variables)
```

Partial derivative for tensor expressions.

Examples

```python
>>> from sympy.tensor.tensor import TensorIndexType, TensorHead
>>> from sympy.tensor.toperators import PartialDerivative
>>> from sympy import symbols

>>> L = TensorIndexType("L")
>>> A = TensorHead("A", [L])
>>> B = TensorHead("B", [L])
>>> i, j, k = symbols("i j k")

>>> expr = PartialDerivative(A(i), A(j))
>>> expr
PartialDerivative(A(i), A(j))
```

The `PartialDerivative` object behaves like a tensorial expression:

```python
>>> expr.get_indices()
[i, -j]
```
Notice that the deriving variables have opposite valence than the printed one: \(A(j)\) is printed as covariant, but the index of the derivative is actually contravariant, i.e. \(-j\).

Indices can be contracted:

```python
>>> expr = PartialDerivative(A(i), A(i))
>>> expr
PartialDerivative(A(L_0), A(L_0))
>>> expr.get_indices()
[L_0, -L_0]
```

The method .get_indices() always returns all indices (even the contracted ones). If only uncontracted indices are needed, call .get_free_indices():

```python
>>> expr.get_free_indices()
[]
```

Nested partial derivatives are flattened:

```python
>>> expr = PartialDerivative(PartialDerivative(A(i), A(j)), A(k))
>>> expr
PartialDerivative(A(i), A(j), A(k))
>>> expr.get_indices()
[i, -j, -k]
```

Replace a derivative with array values:

```python
>>> from sympy.abc import x, y
>>> from sympy import sin, log
>>> compA = [sin(x), log(x)*y**3]
>>> compB = [x, y]
>>> expr = PartialDerivative(A(i), B(j))
>>> expr.replace_with_arrays({A(i): compA, B(i): compB})
[[cos(x), 0], [y**3/x, 3*y**2*log(x)]]
```

The returned array is indexed by \((i, -j)\).

Be careful that other SymPy modules put the indices of the deriving variables before the indices of the derivand in the derivative result. For example:

```python
>>> expr.get_free_indices()
[i, -j]
```

```python
>>> from sympy import Matrix, Array
>>> Matrix(compA).diff(Matrix(compB)).reshape(2, 2)
[[cos(x), y**3/x], [0, 3*y**2*log(x)]]
>>> Array(compA).diff(Array(compB))
[[cos(x), y**3/x], [0, 3*y**2*log(x)]]
```

These are the transpose of the result of PartialDerivative, as the matrix and the array modules put the index \(-j\) before \(i\) in the derivative result. An array read with index order \((-j, i)\) is indeed the transpose of the same array read with index order \((i, -j)\). By specifying the index order to .replace_with_arrays one can get a compatible expression:

```python
>>> expr.replace_with_arrays({A(i): compA, B(i): compB}, [-j, i])
[[cos(x), y**3/x], [0, 3*y**2*log(x)]]
```
Vector

The vector module provides tools for basic vector math and differential calculus with respect to 3D Cartesian coordinate systems. This documentation provides an overview of all the features offered, and relevant API.

Guide to Vector

Introduction

This page gives a brief conceptual overview of the functionality present in sympy.vector (page 1473).

Vectors and Scalars

In vector math, we deal with two kinds of quantities – scalars and vectors.

A scalar is an entity which only has a magnitude - no direction. Examples of scalar quantities include mass, electric charge, temperature, distance, etc.

A vector, on the other hand, is an entity that is characterized by a magnitude and a direction. Examples of vector quantities are displacement, velocity, magnetic field, etc.

A scalar can be depicted just by a number, for e.g. a temperature of 300 K. On the other hand, vectorial quantities like acceleration are usually denoted by a vector. Given a vector $\mathbf{V}$, the magnitude of the corresponding quantity can be calculated as the magnitude of the vector itself $\|\mathbf{V}\|$, while the direction would be specified by a unit vector in the direction of the original vector, $\hat{\mathbf{V}} = \frac{\mathbf{V}}{\|\mathbf{V}\|}$.

For example, consider a displacement of $(3\hat{i} + 4\hat{j} + 5\hat{k})$ m, where, as per standard convention, $\hat{i}$, $\hat{j}$ and $\hat{k}$ represent unit vectors along the $X$, $Y$ and $Z$ axes respectively. Therefore, it can be concluded that the distance traveled is $\|3\hat{i} + 4\hat{j} + 5\hat{k}\| = 5\sqrt{2}$ m. The direction of travel is given by the unit vector $\frac{3}{5\sqrt{2}}\hat{i} + \frac{4}{5\sqrt{2}}\hat{j} + \frac{5}{5\sqrt{2}}\hat{k}$.

Coordinate Systems

A coordinate system is an abstract mathematical entity used to define the notion of directions and locations in n-dimensional spaces. This module deals with 3-dimensional spaces, with the conventional $X$, $Y$ and $Z$ axes defined with respect to each coordinate system.

Each coordinate system also has a special reference point called the ‘origin’ defined for it. This point is used either while referring to locations in 3D space, or while calculating the coordinates of pre-defined points with respect to the system.

It is a pretty well-known concept that there is no absolute notion of location or orientation in space. Any given coordinate system defines a unique ‘perspective’ of quantifying positions and directions. Therefore, even if we assume that all systems deal with the same units of measurement, the expression of vectorial and scalar quantities differs according to the coordinate system a certain observer deals with.

Consider two points $P$ and $Q$ in space. Assuming units to be common throughout, the distance between these points remains the same regardless of the coordinate system in which the
measurements are being made. However, the 3-D coordinates of each of the two points, as well as the position vector of any of the points with respect to the other, do not. In fact, these two quantities don’t make sense at all, unless they are being measured keeping in mind a certain location and orientation of the measurer (essentially the coordinate system).

Therefore, it is quite clear that the orientation and location (of the origin) of a coordinate system define the way different quantities will be expressed with respect to it. Neither of the two properties can be measured on an absolute scale, but rather with respect to another coordinate system. The orientation of one system with respect to another is measured using the rotation matrix, while the relative position can be quantified via the position vector of one system’s origin with respect to the other.

**Fields**

A **field** is a vector or scalar quantity that can be specified everywhere in space as a function of position (Note that in general a field may also be dependent on time and other custom variables). Since we only deal with 3D spaces in this module, a field is defined as a function of the \( x, y \) and \( z \) coordinates corresponding to a location in the coordinate system. Here, \( x, y \) and \( z \) act as scalar variables defining the position of a general point.

For example, temperature in 3 dimensional space (a temperature field) can be written as \( T(x, y, z) \) – a scalar function of the position. An example of a scalar field in electromagnetism is the electric potential.

In a similar manner, a vector field can be defined as a vectorial function of the location \( (x, y, z) \) of any point in space.

For instance, every point on the earth may be considered to be in the gravitational force field of the earth. We may specify the field by the magnitude and the direction of acceleration due to gravity (i.e. force per unit mass) \( \vec{g}(x, y, z) \) at every point in space.

To give an example from electromagnetism, consider an electric potential of form \( 2x^2y \), a scalar field in 3D space. The corresponding conservative electric field can be computed as the gradient of the electric potential function, and expressed as \( 4xy\hat{i} + 2x^2\hat{j} \). The magnitude of this electric field can in turn be expressed as a scalar field of the form \( \sqrt{4x^4 + 16x^2y^2} \).

**Basic Implementation details**

**Coordinate Systems and Vectors**

Currently, `sympy.vector` (page 1473) is able to deal with the Cartesian (also called rectangular), spherical and other curvilinear coordinate systems.

A 3D Cartesian coordinate system can be initialized in `sympy.vector` (page 1473) as

```python
>>> from sympy.vector import CoordSys3D
>>> N = CoordSys3D('N')
```

The string parameter to the constructor denotes the name assigned to the system, and will primarily be used for printing purposes.

Once a coordinate system (in essence, a `CoordSys3D` instance) has been defined, we can access the orthonormal unit vectors (i.e. the \( \hat{i}, \hat{j} \) and \( \hat{k} \) vectors) and coordinate variables/base scalars (i.e. the \( x, y \) and \( z \) variables) corresponding to it. We will talk about coordinate variables in the later sections.
The basis vectors for the $X$, $Y$ and $Z$ axes can be accessed using the $i$, $j$ and $k$ properties respectively.

```python
>>> N.i
N.i
>>> type(N.i)
<class 'sympy.vector.vector.BaseVector'>
```

As seen above, the basis vectors are all instances of a class called `BaseVector`.

When a `BaseVector` is multiplied by a scalar (essentially any SymPy Expr), we get a `VectorMul` - the product of a base vector and a scalar.

```python
>>> 3*N.i
3*N.i
>>> type(3*N.i)
<class 'sympy.vector.vector.VectorMul'>
```

Addition of `VectorMul` and `BaseVectors` gives rise to formation of `VectorAdd` - except for special cases, of course.

```python
>>> v = 2*N.i + N.j
>>> type(v)
<class 'sympy.vector.vector.VectorAdd'>
>>> v - N.j
2*N.i
>>> type(v - N.j)
<class 'sympy.vector.vector.VectorMul'>
```

What about a zero vector? It can be accessed using the zero attribute assigned to class `Vector`. Since the notion of a zero vector remains the same regardless of the coordinate system in consideration, we use `Vector.zero` wherever such a quantity is required.

```python
>>> from sympy.vector import Vector
>>> Vector.zero
0
>>> type(Vector.zero)
<class 'sympy.vector.vector.VectorZero'>
>>> N.i + Vector.zero
N.i
>>> Vector.zero == 2*Vector.zero
True
```

All the classes shown above - `BaseVector`, `VectorMul`, `VectorAdd` and `VectorZero` are subclasses of `Vector`.

You should never have to instantiate objects of any of the subclasses of `Vector`. Using the `BaseVector` instances assigned to a `CoordSys3D` instance and (if needed) `Vector.zero` as building blocks, any sort of vectorial expression can be constructed with the basic mathematical operators $+$, $-$, $*$, and $/$.

```python
>>> v = N.i - 2*N.j
>>> v/3
1/3*N.i + (-2/3)*N.j
>>> v + N.k
```

(continues on next page)
In addition to the elementary mathematical operations, the vector operations of `dot` and `cross` can also be performed on `Vector`.

```python
>>> v1 = 2*N.i + 3*N.j - N.k
>>> v2 = N.i - 4*N.j + N.k
>>> v1.dot(v2)
-11
>>> v1.cross(v2)
(-1)*N.i + (-3)*N.j + (-11)*N.k
>>> v2.cross(v1)
N.i + 3*N.j + 11*N.k
```

The `&` and `^` operators have been overloaded for the `dot` and `cross` methods respectively.

```python
>>> v1 & v2
-11
>>> v1 ^ v2
(-1)*N.i + (-3)*N.j + (-11)*N.k
```

However, this is not the recommended way of performing these operations. Using the original methods makes the code clearer and easier to follow.

In addition to these operations, it is also possible to compute the outer products of `Vector` instances in `sympy.vector` (page 1473). More on that in a little bit.

### SymPy operations on Vectors

The SymPy operations of `simplify`, `trigsimp`, `diff`, and `factor` work on `Vector` objects, with the standard SymPy API.

In essence, the methods work on the measure numbers (The coefficients of the basis vectors) present in the provided vectorial expression.

```python
>>> from sympy.abc import a, b, c
>>> from sympy import sin, cos, trigsimp, diff
>>> v = (a*b + a*c + b**2 + b*c)*N.i + N.j
>>> v.factor()
((a + b)*(b + c))*N.i + N.j
>>> v = (sin(a)**2 + cos(a)**2)*N.i - (2*cos(b)**2 - 1)*N.k
>>> trigsimp(v)
N.i + (-cos(2*b))*N.k
>>> v.simplify()
N.i + (-cos(2*b))*N.k
>>> diff(v, b)
(4*sin(b)*cos(b))*N.k
>>> from sympy import Derivative
```

(continues on next page)
Integral also works with Vector instances, similar to Derivative.

```python
>>> from sympy import Integral
>>> v1 = a*N.i + sin(a)*N.j - N.k
>>> Integral(v1, a)
(Integral(a, a))*N.i + (Integral(sin(a), a))*N.j + (Integral(-1, a))*N.k
>>> Integral(v1, a).doit()
a**2/2*N.i + (-cos(a))*N.j + (-a)*N.k
```

### Points

As mentioned before, every coordinate system corresponds to a unique origin point. Points, in general, have been implemented in `sympy.vector` (page 1473) in the form of the `Point` class.

To access the origin of system, use the `origin` property of the `CoordSys3D` class.

```python
>>> from sympy.vector import CoordSys3D
>>> N = CoordSys3D('N')
>>> N.origin
N.origin
>>> type(N.origin)
<class 'sympy.vector.point.Point'>
```

You can instantiate new points in space using the `locate_new` method of `Point`. The arguments include the name(string) of the new `Point`, and its position vector with respect to the 'parent' `Point`.

```python
>>> from sympy.abc import a, b, c
>>> P = N.origin.locate_new('P', a*N.i + b*N.j + c*N.k)
>>> Q = P.locate_new('Q', -b*N.j)
```

Like Vector, a user never has to expressly instantiate an object of `Point`. This is because any location in space (albeit relative) can be pointed at by using the `origin` of a `CoordSys3D` as the reference, and then using `locate_new` on it and subsequent `Point` instances.

The position vector of a `Point` with respect to another `Point` can be computed using the `position_wrt` method.

```python
>>> P.position_wrt(Q)
b*N.j
>>> Q.position_wrt(N.origin)
a*N.i + c*N.k
```

Additionally, it is possible to obtain the $X$, $Y$ and $Z$ coordinates of a `Point` with respect to a `CoordSys3D` in the form of a tuple. This is done using the `express_coordinates` method.

```python
>>> Q.express_coordinates(N)
(a, 0, c)
```
Dyadics

A dyadic, or dyadic tensor, is a second-order tensor formed by the juxtaposition of pairs of vectors. Therefore, the outer products of vectors give rise to the formation of dyadics. Dyadic tensors have been implemented in `sympy.vector` (page 1473) in the Dyadic class.

Once again, you never have to instantiate objects of Dyadic. The outer products of vectors can be computed using the outer method of Vector. The \( | \) operator has been overloaded for outer.

```python
>>> from sympy.vector import CoordSys3D
>>> N = CoordSys3D('N')
>>> N.i.outer(N.j)
(N.i|N.j)
```

Similar to Vector, Dyadic also has subsequent subclasses like BaseDyadic, DyadicMul, DyadicAdd. As with Vector, a zero dyadic can be accessed from Dyadic.zero.

All basic mathematical operations work with Dyadic too.

```python
>>> dyad = N.i.outer(N.k)
>>> dyad*3
3*(N.i|N.k)
>>> dyad - dyad
0
>>> dyad + 2*(N.j|N.i)
(N.i|N.k) + 2*(N.j|N.i)
```

dot and cross also work among Dyadic instances as well as between a Dyadic and Vector (and also vice versa) - as per the respective mathematical definitions. As with Vector, & and ^ have been overloaded for dot and cross.

```python
>>> d = N.i.outer(N.j)
>>> d.dot(N.j|N.j)
(N.i|N.j)
>>> d.dot(N.i)
0
>>> d.dot(N.j)
N.i
>>> N.i.dot(d)
N.j
>>> N.k ^ d
(N.j|N.j)
```
More about Coordinate Systems

We will now look at how we can initialize new coordinate systems in sympy.vector (page 1473), transformed in user-defined ways with respect to already-existing systems.

Locating new systems

We already know that the origin property of a CoordSys3D corresponds to the Point instance denoting its origin reference point.

Consider a coordinate system \( N \). Suppose we want to define a new system \( M \), whose origin is located at \( 3\vec{i} + 4\vec{j} + 5\vec{k} \) from \( N \)'s origin. In other words, the coordinates of \( M \)'s origin from \( N \)'s perspective happen to be \((3, 4, 5)\). Moreover, this would also mean that the coordinates of \( N \)'s origin with respect to \( M \) would be \((-3, -4, -5)\).

This can be achieved programmatically as follows -

```python
>>> from sympy.vector import CoordSys3D
>>> N = CoordSys3D('N')
>>> M = N.locate_new('M', 3*N.i + 4*N.j + 5*N.k)
>>> M.position_wrt(N)
3*N.i + 4*N.j + 5*N.k
>>> N.origin.express_coordinates(M)
(-3, -4, -5)
```

It is worth noting that \( M \)'s orientation is the same as that of \( N \). This means that the rotation matrix of \( N \) with respect to \( M \), and also vice versa, is equal to the identity matrix of dimensions 3x3. The `locate_new` method initializes a CoordSys3D that is only translated in space, not re-oriented, relative to the ‘parent’ system.

Orienting new systems

Similar to ‘locating’ new systems, sympy.vector (page 1473) also allows for initialization of new CoordSys3D instances that are oriented in user-defined ways with respect to existing systems.

Suppose you have a coordinate system \( A \).

```python
>>> from sympy.vector import CoordSys3D
>>> A = CoordSys3D('A')
```

You want to initialize a new coordinate system \( B \), that is rotated with respect to \( A \)'s Z-axis by an angle \( \theta \).

```python
>>> from sympy import Symbol
>>> theta = Symbol('theta')
```

The orientation is shown in the diagram below:
There are two ways to achieve this.

**Using a method of CoordSys3D directly**

This is the easiest, cleanest, and hence the recommended way of doing it.

```
>>> B = A.orient_new_axis('B', theta, A.k)
```

This initializes $B$ with the required orientation information with respect to $A$.

CoordSys3D provides the following direct orientation methods in its API-

1. `orient_new_axis`
2. `orient_new_body`
3. `orient_new_space`
4. `orient_new_quaternion`

Please look at the CoordSys3D class API given in the docs of this module, to know their functionality and required arguments in detail.

**Using Orienter(s) and the `orient_new` method**

You would first have to initialize an `AxisOrienter` instance for storing the rotation information.

```
>>> from sympy.vector import AxisOrienter
>>> axis_orienter = AxisOrienter(theta, A.k)
```

And then apply it using the `orient_new` method, to obtain $B$.

```
>>> B = A.orient_new('B', axis_orienter)
```

`orient_new` also lets you orient new systems using multiple Orienter instances, provided in an iterable. The rotations/orientations are applied to the new system in the order the Orienter instances appear in the iterable.
from sympy.vector import BodyOrienter

from sympy.abc import a, b, c

body_orienter = BodyOrienter(a, b, c, 'XYZ')

C = A.orient_new('C', (axis_orienter, body_orienter))

The **sympy.vector** (page 1473) API provides the following four Orienter classes for orientation purposes:

1. AxisOrienter
2. BodyOrienter
3. SpaceOrienter
4. QuaternionOrienter

Please refer to the API of the respective classes in the docs of this module to know more.

In each of the above examples, the origin of the new coordinate system coincides with the origin of the ‘parent’ system.

B = A.orient_new_axis('B', a, A.k)

B.rotation_matrix(A)

Matrix(
    [[ cos(a), sin(a), 0],
    [-sin(a), cos(a), 0],
    [ 0, 0, 1]])

B.rotation_matrix(B)

Matrix(
    [[1, 0, 0],
    [0, 1, 0],
    [0, 0, 1]])

**Orienting AND Locating new systems**

What if you want to initialize a new system that is not only oriented in a pre-defined way, but also translated with respect to the parent?

Each of the orient_new_<method of orientation> methods, as well as the orient_new method, support a location keyword argument.

If a Vector is supplied as the value for this kwarg, the new system’s origin is automatically defined to be located at that position vector with respect to the parent coordinate system.

Thus, the orientation methods also act as methods to support orientation+ location of the new systems.

C = A.orient_new_axis('C', a, A.k, location=2*A.j)

C.position_wrt(A)

2*A.j

(continues on next page)
from sympy.vector import express

express(A.position_wrt(C), C)

(-2*sin(a))*C.i + (-2*cos(a))*C.j

More on the express function in a bit.

Transforming new system

The most general way of creating user-defined system is to use transformation parameter in CoordSys3D. Here we can define any transformation equations. If we are interested in some typical curvilinear coordinate system different that Cartesian, we can also use some predefined ones. It could be also possible to translate or rotate system by setting appropriate transformation equations.

from sympy.vector import CoordSys3D

from sympy import sin, cos

A = CoordSys3D('A', transformation='spherical')
B = CoordSys3D('A', transformation=lambda x,y,z: (x*sin(y), x*cos(y), z))

In CoordSys3D is also dedicated method, create_new which works similarly to methods like locate_new, orient_new_axis etc.

from sympy.vector import CoordSys3D

A = CoordSys3D('A')
B = A.create_new('B', transformation='spherical')

Expression of quantities in different coordinate systems

Vectors and Dyadics

As mentioned earlier, the same vector attains different expressions in different coordinate systems. In general, the same is true for scalar expressions and dyadic tensors.

sympy.vector (page 1473) supports the expression of vector/scalar quantities in different coordinate systems using the express function.

For purposes of this section, assume the following initializations:

from sympy.vector import CoordSys3D, express

from sympy.abc import a, b, c

N = CoordSys3D('N')
M = N.orient_new_axis('M', a, N.k)

Vector instances can be expressed in user defined systems using express.

v1 = N.i + N.j + N.k
express(v1, M)
(sin(a) + cos(a))*M.i + (-sin(a) + cos(a))*M.j + M.k

v2 = N.i + M.j
express(v2, N)
(1 - sin(a))*N.i + (cos(a))*N.j

1482 Chapter 5. API Reference
Apart from Vector instances, express also supports reexpression of scalars (general SymPy Expr) and Dyadic objects.

express also accepts a second coordinate system for re-expressing Dyadic instances.

```python
>>> d = 2*(M.i | N.j) + 3*(M.j | N.k)
>>> express(d, M)
(2*sin(a))*(M.i|M.i) + (2*cos(a))*(M.i|M.j) + 3*(M.j|M.k)
>>> express(d, M, N)
2*(M.i|N.j) + 3*(M.j|N.k)
```

**Coordinate Variables**

The location of a coordinate system’s origin does not affect the re-expression of BaseVector instances. However, it does affect the way BaseScalar instances are expressed in different systems.

BaseScalar instances, are coordinate ‘symbols’ meant to denote the variables used in the definition of vector/scalar fields in `sympy.vector` (page 1473).

For example, consider the scalar field \( T_N(x, y, z) = x + y + z \) defined in system \( N \). Thus, at a point with coordinates \( (a, b, c) \), the value of the field would be \( a + b + c \). Now consider system \( R \), whose origin is located at \((1, 2, 3)\) with respect to \( N \) (no change of orientation). A point with coordinates \( (a, b, c) \) in \( R \) has coordinates \((a + 1, b + 2, c + 3)\) in \( N \). Therefore, the expression for \( T_N \) in \( R \) becomes \( T_R(x, y, z) = x + y + z + 6 \).

Coordinate variables, if present in a vector/scalar/dyadic expression, can also be re-expressed in a given coordinate system, by setting the variables keyword argument of express to True.

The above mentioned example, done programmatically, would look like this -

```python
>>> R = N.locate_new('R', N.i + 2*N.j + 3*N.k)
>>> T_N = N.x + N.y + N.z
>>> express(T_N, R, variables=True)
R.x + R.y + R.z + 6
```

**Other expression-dependent methods**

The `to_matrix` method of Vector and `express_coordinates` method of Point also return different results depending on the coordinate system being provided.

```python
>>> P = R.origin.locate_new('P', a*R.i + b*R.j + c*R.k)
>>> P.express_coordinates(N)
(a + 1, b + 2, c + 3)
>>> P.express_coordinates(R)
(a, b, c)
>>> v = N.i + N.j + N.k
>>> v.to_matrix(M)
Matrix([[sin(a) + cos(a)], [-sin(a) + cos(a)], [1]])
>>> v.to_matrix(N)
```

(continues on next page)
Scalar and Vector Field Functionality

Implementation in sympy.vector

Scalar and vector fields

In sympy.vector (page 1473), every CoordSys3D instance is assigned basis vectors corresponding to the \( X \), \( Y \) and \( Z \) axes. These can be accessed using the properties named \( i \), \( j \) and \( k \) respectively. Hence, to define a vector \( \mathbf{v} \) of the form \( \mathbf{3i} + \mathbf{4j} + \mathbf{5k} \) with respect to a given frame \( \mathbf{R} \), you would do

\[
\mathbf{v} = 3\mathbf{R}.i + 4\mathbf{R}.j + 5\mathbf{R}.k
\]

Vector math and basic calculus operations with respect to vectors have already been elaborated upon in the earlier section of this module’s documentation.

On the other hand, base scalars (or coordinate variables) are implemented in a special class called BaseScalar, and are assigned to every coordinate system, one for each axis from \( X \), \( Y \) and \( Z \). These coordinate variables are used to form the expressions of vector or scalar fields in 3D space. For a system \( \mathbf{R} \), the \( X \), \( Y \) and \( Z \) BaseScalars instances can be accessed using the \( \mathbf{R}.x \), \( \mathbf{R}.y \) and \( \mathbf{R}.z \) expressions respectively.

Therefore, to generate the expression for the aforementioned electric potential field \( 2x^2y \), you would have to do

\[
\mathbf{electric\_potential} = 2\mathbf{R}.x*2\mathbf{R}.y
\]

It is to be noted that BaseScalar instances can be used just like any other SymPy Symbol, except that they store the information about the coordinate system and axis they correspond to.

Scalar fields can be treated just as any other SymPy expression, for any math/calculus functionality. Hence, to differentiate the above electric potential with respect to \( x \) (i.e. \( \mathbf{R}.x \)), you would use the diff method.

\[
diff(\mathbf{electric\_potential}, \mathbf{R}.x) = 4\mathbf{R}.x*\mathbf{R}.y
\]
It is worth noting that having a `BaseScalar` in the expression implies that a ‘field’ changes with position, in 3D space. Technically speaking, a simple Expr with no `BaseScalar` s is still a field, though constant.

Like scalar fields, vector fields that vary with position can also be constructed using `BaseScalar s` in the measure-number expressions.

```python
>>> from sympy.vector import CoordSys3D
>>> R = CoordSys3D('R')
>>> v = R.x**2*R.i + 2*R.x*R.z*R.k
```

**The Del operator**

The Del, or ‘Nabla’ operator - written as \(\nabla\) is commonly known as the vector differential operator. Depending on its usage in a mathematical expression, it may denote the gradient of a scalar field, the divergence of a vector field, or the curl of a vector field.

Essentially, \(\nabla\) is not technically an ‘operator’, but a convenient mathematical notation to denote any one of the aforementioned field operations.

In `sympy.vector` (page 1473), \(\nabla\) has been implemented as the `Del()` class. The instance of this class is independent of coordinate system. Hence, the \(\nabla\) operator would be accessible as `Del()`.

Given below is an example of usage of the `Del()` class.

```python
>>> from sympy.vector import CoordSys3D, Del
>>> C = CoordSys3D('C')
>>> delop = Del()
>>> gradient_field = delop(C.x*C.y*C.z)
>>> gradient_field
(Derivative(C.x*C.y*C.z, C.x))*C.i + (Derivative(C.x*C.y*C.z, C.y))*C.j + (Derivative(C.x*C.y*C.z, C.z))*C.k
```

The above expression can be evaluated using the SymPy `doit()` routine.

```python
>>> gradient_field.doit()
C.y*C.z*C.i + C.x*C.z*C.j + C.x*C.y*C.k
```

Usage of the \(\nabla\) notation in `sympy.vector` (page 1473) has been described in greater detail in the subsequent subsections.

**Field operators and related functions**

Here we describe some basic field-related functionality implemented in `sympy.vector` (page 1473).
Curl

A curl is a mathematical operator that describes an infinitesimal rotation of a vector in 3D space. The direction is determined by the right-hand rule (along the axis of rotation), and the magnitude is given by the magnitude of rotation.

In the 3D Cartesian system, the curl of a 3D vector \( \mathbf{F} \), denoted by \( \nabla \times \mathbf{F} \) is given by:
\[
\nabla \times \mathbf{F} = \left( \frac{\partial F_z}{\partial y} - \frac{\partial F_y}{\partial z} \right) \mathbf{i} + \left( \frac{\partial F_x}{\partial z} - \frac{\partial F_z}{\partial x} \right) \mathbf{j} + \left( \frac{\partial F_y}{\partial x} - \frac{\partial F_x}{\partial y} \right) \mathbf{k}
\]
where \( F_x \) denotes the \( X \) component of vector \( \mathbf{F} \).

Computing the curl of a vector field in `sympy.vector` (page 1473) can be accomplished in two ways.

One, by using the `Del()` class

```python
>>> from sympy.vector import CoordSys3D, Del
>>> C = CoordSys3D('C')
>>> delop = Del()
>>> delop.cross(C.x*C.y*C.z*C.i).doit()
C.x*C.y*C.j + (-C.x*C.z)*C.k
>>> (delop ^ C.x*C.y*C.z*C.i).doit()
C.x*C.y*C.j + (-C.x*C.z)*C.k
```

Or by using the dedicated function

```python
>>> from sympy.vector import curl
>>> curl(C.x*C.y*C.z*C.i)
C.x*C.y*C.j + (-C.x*C.z)*C.k
```

Divergence

Divergence is a vector operator that measures the magnitude of a vector field’s source or sink at a given point, in terms of a signed scalar.

The divergence operator always returns a scalar after operating on a vector.

In the 3D Cartesian system, the divergence of a 3D vector \( \mathbf{F} \), denoted by \( \nabla \cdot \mathbf{F} \) is given by:
\[
\nabla \cdot \mathbf{F} = \frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} + \frac{\partial W}{\partial z}
\]
where \( U, V \) and \( W \) denote the \( X, Y \) and \( Z \) components of \( \mathbf{F} \) respectively.

Computing the divergence of a vector field in `sympy.vector` (page 1473) can be accomplished in two ways.

One, by using the `Del()` class

```python
>>> from sympy.vector import CoordSys3D, Del
>>> C = CoordSys3D('C')
>>> delop = Del()
>>> delop.dot(C.x*C.y*C.z*(C.i + C.j + C.k)).doit()
C.x*C.y + C.x*C.z + C.y*C.z
>>> (delop & C.x*C.y*C.z*(C.i + C.j + C.k)).doit()
C.x*C.y + C.x*C.z + C.y*C.z
```
SymPy Documentation, Release 1.12.1

Or by using the dedicated function

```python
>>> from sympy import divergence
>>> divergence(C.x*C.y*C.z*(C.i + C.j + C.k))
C.x*C.y + C.x*C.z + C.y*C.z
```

**Gradient**

Consider a scalar field \( f(x, y, z) \) in 3D space. The gradient of this field is defined as the vector of the 3 partial derivatives of \( f \) with respect to \( x, y \) and \( z \) in the \( X, Y \) and \( Z \) axes respectively.

In the 3D Cartesian system, the divergence of a scalar field \( f \), denoted by \( \nabla f \) is given by:

\[
\nabla f = \frac{\partial f}{\partial x} \hat{i} + \frac{\partial f}{\partial y} \hat{j} + \frac{\partial f}{\partial z} \hat{k}
\]

Computing the divergence of a vector field in `sympy.vector` (page 1473) can be accomplished in two ways.

One, by using the `Del()` class

```python
>>> from sympy import CoordSys3D, Del
>>> C = CoordSys3D('C')
>>> delop = Del()
>>> delop.gradient(C.x*C.y*C.z).doit()
C.y*C.z*C.i + C.x*C.z*C.j + C.x*C.y*C.k
>>> delop(C.x*C.y*C.z).doit()
C.y*C.z*C.i + C.x*C.z*C.j + C.x*C.y*C.k
```

Or by using the dedicated function

```python
>>> from sympy import gradient
>>> gradient(C.x*C.y*C.z)
C.y*C.z*C.i + C.x*C.z*C.j + C.x*C.y*C.k
```

**Directional Derivative**

Apart from the above three common applications of \( \nabla \), it is also possible to compute the directional derivative of a field wrt a Vector in `sympy.vector` (page 1473).

By definition, the directional derivative of a field \( \mathbf{F} \) along a vector \( \mathbf{v} \) at point \( x \) represents the instantaneous rate of change of \( \mathbf{F} \) moving through \( x \) with the velocity \( \mathbf{v} \). It is represented mathematically as: \( (\mathbf{v} \cdot \nabla) \mathbf{F}(x) \).

Directional derivatives of vector and scalar fields can be computed in `sympy.vector` (page 1473) using the `Del()` class

```python
>>> from sympy import CoordSys3D, Del
>>> C = CoordSys3D('C')
>>> delop = Del()
>>> vel = C.i + C.j + C.k
>>> scalar_field = C.x*C.y*C.z
>>> vector_field = C.x*C.y*C.z*C.i
>>> (vel.dot(delop))(scalar_field)
(continues on next page)
C.x*C.y + C.x*C.z + C.y*C.z

```python
>>> (vel & delop)(vector_field)
(C.x*C.y + C.x*C.z + C.y*C.z)*C.i
```

Or by using the dedicated function

```python
>>> from sympy.vector import directional_derivative
>>> directional_derivative(C.x*C.y*C.z, 3*C.i + 4*C.j + C.k)
C.x*C.y + 4*C.x*C.z + 3*C.y*C.z
```

### Field operator in orthogonal curvilinear coordinate system

vector package supports calculation in different kind of orthogonal curvilinear coordinate system. To do that, scaling factor (also known as Lame coefficients) are used to express curl, divergence or gradient in desired type of coordinate system.

For example if we want to calculate gradient in cylindrical coordinate system all we need to do is to create proper coordinate system

```python
>>> from sympy.vector import CoordSys3D
>>> c = CoordSys3D('c', transformation='cylindrical', variable_names=("r", "theta", "z"))
>>> gradient(c.r*c.theta*c.z)
  c.theta*c.z*c.i + c.z*c.j + c.r*c.theta*c.k
```

### Conservative and Solenoidal fields

In vector calculus, a conservative field is a field that is the gradient of some scalar field. Conservative fields have the property that their line integral over any path depends only on the end-points, and is independent of the path travelled. A conservative vector field is also said to be 'irrotational', since the curl of a conservative field is always zero.

In physics, conservative fields represent forces in physical systems where energy is conserved.

To check if a vector field is conservative in `sympy.vector` (page 1473), the `is_conservative` function can be used.

```python
>>> from sympy.vector import CoordSys3D, is_conservative
>>> R = CoordSys3D('R')
>>> field = R.y*R.z*R.i + R.x*R.z*R.j + R.x*R.y*R.k
>>> is_conservative(field)
True
>>> curl(field)
0
```

A solenoidal field, on the other hand, is a vector field whose divergence is zero at all points in space.

To check if a vector field is solenoidal in `sympy.vector` (page 1473), the `is_solenoidal` function can be used.
Scalar potential functions

We have previously mentioned that every conservative field can be defined as the gradient of some scalar field. This scalar field is also called the ‘scalar potential field’ corresponding to the aforementioned conservative field.

The `scalar_potential` function in `sympy.vector` (page 1473) calculates the scalar potential field corresponding to a given conservative vector field in 3D space - minus the extra constant of integration, of course.

Example of usage -

```python
>>> from sympy.vector import CoordSys3D, scalar_potential
>>> R = CoordSys3D('R')
>>> conservative_field = 4*R.x*R.y*R.z*R.i + 2*R.x*R.y**2*R.z*R.j + 2*R.x*R.y**2*R.k
>>> scalar_potential(conservative_field, R)
2*R.x**2*R.y*R.z
```

Providing a non-conservative vector field as an argument to `scalar_potential` raises a `ValueError`.

The scalar potential difference, or simply ‘potential difference’, corresponding to a conservative vector field can be defined as the difference between the values of its scalar potential function at two points in space. This is useful in calculating a line integral with respect to a conservative function, since it depends only on the endpoints of the path.

This computation is performed as follows in `sympy.vector` (page 1473).

```python
>>> from sympy.vector import CoordSys3D, Point
>>> from sympy.vector import scalar_potential_difference
>>> R = CoordSys3D('R')
>>> P = R.origin.locate_new('P', 1*R.i + 2*R.j + 3*R.k)
>>> vectfield = 4*R.x*R.y*R.z*R.i + 2*R.x*R.y**2*R.j
>>> scalar_potential_difference(vectfield, R, R.origin, P)
4
```

If provided with a scalar expression instead of a vector field, `scalar_potential_difference` returns the difference between the values of that scalar field at the two given points in space.
Generalexamplesofusage

```python
>>> Q = A.locate_new('Q', B.position_wrt(A) / 2)
>>> R = B.locate_new('R', C.position_wrt(B) / 2)
>>> S = O.locate_new('R', C.position_wrt(O) / 2)
```

NowcomputethevectorsinthedirectionsspecifiedbyPQandSR.
>>> PQ = Q.position_wrt(P)
>>> SR = R.position_wrt(S)

Compute cross product

>>> PQ.cross(SR)
\[0\]

Since the cross product is a zero vector, the two vectors have to be parallel, thus proving that \(PQ \parallel SR\).

**Third product rule for Del operator**

*See*

**The Problem**

Prove the third rule - \(\nabla \cdot (f \vec{v}) = f(\nabla \cdot \vec{v}) + \vec{v} \cdot (\nabla f)\)

**Solution**

Start with a coordinate system

```python
>>> from sympy import CoordSys3D, Del
>>> delop = Del()
>>> C = CoordSys3D('C')
```

The scalar field \(f\) and the measure numbers of the vector field \(\vec{v}\) are all functions of the coordinate variables of the coordinate system in general. Hence, define SymPy functions that way.

```python
>>> from sympy import symbols, Function
>>> v1, v2, v3, f = symbols('v1 v2 v3 f', cls=Function)
```

\(v1, v2\) and \(v3\) are the \(X, Y\) and \(Z\) components of the vector field respectively. Define the vector field as `vfield` and the scalar field as `sfield`.

```python
>>> vfield = v1(C.x, C.y, C.z)*C.i + v2(C.x, C.y, C.z)*C.j + v3(C.x, C.y, C.z)*C.k
>>> sfield = f(C.x, C.y, C.z)
```

Construct the expression for the LHS of the equation using `Del()`.

```python
>>> lhs = (delop.dot(sfield * vfield)).doit()
```

Similarly, the RHS would be defined.

```python
>>> rhs = ((vfield.dot(delop(sfield))) + (sfield * (delop.dot(vfield)))).doit()
```
Now, to prove the product rule, we would just need to equate the expanded and simplified versions of the lhs and the rhs, so that the SymPy expressions match.

```python
>>> lhs.expand().simplify() == rhs.expand().doit().simplify()
True
```

Thus, the general form of the third product rule mentioned above can be proven using `symy.vector` (page 1473).

### Applications of Vector Integrals

To integrate a scalar or vector field over a region, we have to first define a region. SymPy provides three methods for defining a region:

2. Using Implicit Equation with `ImplicitRegion` (page 1509).
3. Using objects of geometry module.

The `vector_integrate()` (page 1520) function is used to integrate scalar or vector field over any type of region. It automatically determines the type of integration (line, surface, or volume) depending on the nature of the object.

We define a coordinate system and make necessary imports for examples.

```python
>>> from sympy import sin, cos, exp, pi, symbols
>>> from sympy.vector import CoordSys3D, ParametricRegion, ImplicitRegion,
...     vector_integrate
>>> from sympy.abc import r, x, y, z, theta, phi
>>> C = CoordSys3D('C')
```

### Calculation of Perimeter, Surface Area, and Volume

To calculate the perimeter of a circle, we need to define it. Let’s define it using its parametric equation.

```python
>>> param_circle = ParametricRegion(((4*cos(theta), 4*sin(theta)), (theta, 0, 2*pi))
```

We can also define a circle using its implicit equation.

```python
>>> implicit_circle = ImplicitRegion((x, y), x**2 + y**2 - 4)
```

The perimeter of a figure is equal to the absolute value of its integral over a unit scalar field.

```python
>>> vector_integrate(1, param_circle)
8*pi
>>> vector_integrate(1, implicit_circle)
4*pi
```

Suppose a user wants to calculate the perimeter of a triangle. Determining the parametric representation of a triangle can be difficult. Instead, the user can use an object of `Polygon` (page 2348) class in the geometry module.
To define a solid sphere, we need to use three parameters (r, theta and phi). For `ParametricRegion` (page 1508) `obextj`, the order of limits determine the sign of the integral.

```python
>>> solidsphere = ParametricRegion((r*sin(phi)*cos(theta),
   -r*sin(phi)*sin(theta), r*cos(phi)),
   ...
   (phi, 0, pi), (theta, 0, 2*pi), (r, 0, 3))
>>> vector_integrate(1, solidsphere)
36*pi
```

### Calculation of mass of a body

Consider a triangular lamina $R$ with vertices $(0,0)$, $(0, 5)$, $(5,0)$ and with density $\rho(x,y) = xy \text{ kg/m}^2$. Find the total mass.

```python
>>> triangle = ParametricRegion((x, y), (x, 0, 5), (y, 0, 5 - x))
>>> vector_integrate(C.x*C.y, triangle)
625/24
```

Find the mass of a cylinder centered on the z-axis which has height $h$, radius $a$, and density $\rho = x^2 + y^2 \text{ kg/m}^2$.

```python
>>> a, h = symbols('a h', positive=True)
>>> cylinder = ParametricRegion((r*cos(theta), r*sin(theta), z),
   ...
   (theta, 0, 2*pi), (z, 0, h), (r, 0, a))
>>> vector_integrate(C.x**2 + C.y**2, cylinder)
pi*a**4*h/2
```

### Calculation of Flux

1. Consider a region of space in which there is a constant vectorfield $E(x,y,z) = a\hat{k}$. A hemisphere of radius $r$ lies on the x-y plane. What is the flux of the field through the sphere?

```python
>>> semisphere = ParametricRegion((r*sin(phi)*cos(theta),
   -r*sin(phi)*sin(theta), r*cos(phi)),
   ...
   (phi, 0, pi/2), (theta, 0, 2*pi))
>>> flux = vector_integrate(a*C.k, semisphere)
>>> flux
pi*a*r**2
```

2. Consider a region of space in which there is a vector field $E(x,y,z) = x^2\hat{k}$ above the x-y plane, and a field $E(x,y,z) = y^2\hat{k}$ below the x-y plane. What is the flux of that vector field through a cube of side length $L$ with its center at the origin?"

The field is parallel to the z-axis so only the top and bottom face of the box will contribute to flux.
>>> L = symbols('L', positive=True)

>>> top_face = ParametricRegion((x, y, L/2), (x, -L/2, L/2), (y, -L/2, L/2))
>>> bottom_face = ParametricRegion((x, y, -L/2), (x, -L/2, L/2), (y, -L/2, L/2))

>>> flux = vector_integrate(C.x**2*C.k, top_face) + vector_integrate(C.y**2*C.k, bottom_face)

>>> flux
L**4/6

Verifying Stoke's Theorem

See https://en.wikipedia.org/wiki/Stokes%27_theorem

Example 1

```python
>>> from sympy.vector import curl

>>> curve = ParametricRegion((cos(theta), sin(theta)), (theta, 0, pi/2))
>>> surface = ParametricRegion((r*cos(theta), r*sin(theta)), (r, 0, 1), (theta, 0, pi/2))
>>> F = C.y*C.i + C.z*C.k + C.x*C.k

>>> vector_integrate(F, curve)
-pi/4

>>> vector_integrate(curl(F), surface)
-pi/4
```

Example 2

```python
>>> circle = ParametricRegion((cos(theta), sin(theta), 1), (theta, 0, 2*pi))
>>> cone = ParametricRegion((r*cos(theta), r*sin(theta), r), (r, 0, 1), (theta, 0, 2*pi))

>>> f = (-C.y**3/3 + sin(C.x))*C.i + (C.x**3/3 + cos(C.y))*C.j + C.x*C.y*C.z*C.k

>>> vector_integrate(f, circle)
pi/2

>>> vector_integrate(curl(f), cone)
pi/2
```

Verifying Divergence Theorem

See https://en.wikipedia.org/wiki/Divergence_theorem

Example 1

```python
>>> from sympy.vector import divergence

>>> sphere = ParametricRegion((4*sin(phi)*cos(theta), 4*sin(phi)*sin(theta), 4*cos(phi)), ...
(phi, 0, pi), (theta, 0, 2*pi))
```
(continues on next page)
Example 2

```python
>>> cube = ParametricRegion((x, y, z), (x, 0, 1), (y, 0, 1), (z, 0, 1))
>>> field = 2*C.x*C.y*C.i + 3*C.x*C.y*C.j + C.z*exp(C.x + C.y)*C.k
>>> vector_integrate(divergence(field), cube)
-E + 7/2 + E*(-1 + E)
```

Vector API

**Essential Classes in sympy.vector (docstrings)**

```python
class sympy.vector.coordsysrect.CoordSys3D(name, transformation=None,
                                          parent=None, location=None,
                                          rotation_matrix=None,
                                          vector_names=None,
                                          variable_names=None)
```

Represents a coordinate system in 3-D space.

```python
__init__(name, location=None, rotation_matrix=None, parent=None,
         vector_names=None, variable_names=None, latex_vecs=None,
         pretty_vecs=None, latex_scalars=None, pretty_scalars=None,
         transformation=None)
```

The orientation/location parameters are necessary if this system is being defined at a certain orientation or location wrt another.

**Parameters**

- **name** : str
  
  The name of the new CoordSys3D instance.

- **transformation** : Lambda, Tuple, str
  
  Transformation defined by transformation equations or chosen from predefined ones.

- **location** : Vector
  
  The position vector of the new system’s origin wrt the parent instance.

- **rotation_matrix** : SymPy ImmutableMatrix
  
  The rotation matrix of the new coordinate system with respect to the parent. In other words, the output of new_system.rotation_matrix(parent).
parent : CoordSys3D
The coordinate system wrt which the orientation/location (or both) is being defined.

vector_names, variable_names : iterable(optional)
Iterables of 3 strings each, with custom names for base vectors and base scalars of the new system respectively. Used for simple str printing.

create_new(name, transformation, variable_names=None, vector_names=None)
Returns a CoordSys3D which is connected to self by transformation.

Parameters
name : str
The name of the new CoordSys3D instance.

transformation : Lambda, Tuple, str
Transformation defined by transformation equations or chosen from predefined ones.

vector_names, variable_names : iterable(optional)
Iterables of 3 strings each, with custom names for base vectors and base scalars of the new system respectively. Used for simple str printing.

Examples

```python
from sympy.vector import CoordSys3D
a = CoordSys3D('a')
b = a.create_new('b', transformation='spherical')
b.transformation_to_parent()
(b.r*sin(b.theta)*cos(b.phi), b.r*sin(b.phi)*sin(b.theta), b.r*cos(b.theta))
b.transformation_from_parent()
(sqrt(a.x**2 + a.y**2 + a.z**2), acos(a.z/sqrt(a.x**2 + a.y**2 + a.z**2)), atan2(a.y, a.x))
```

locate_new(name, position, vector_names=None, variable_names=None)
Returns a CoordSys3D with its origin located at the given position wrt this coordinate system’s origin.

Parameters

name : str
The name of the new CoordSys3D instance.

position : Vector
The position vector of the new system’s origin wrt this one.

vector_names, variable_names : iterable(optional)
Iterables of 3 strings each, with custom names for base vectors and base scalars of the new system respectively. Used for simple str printing.
Examples

```python
>>> from sympy.vector import CoordSys3D
>>> A = CoordSys3D('A')
>>> B = A.locate_new('B', 10 * A.i)
>>> B.origin.position_wrt(A.origin)
10*A.i
```

**orient_new**(*name*, *orienters*, *location=None*, *vector_names=None*, *variable_names=None*)

Creates a new CoordSys3D oriented in the user-specified way with respect to this system.

Please refer to the documentation of the orienter classes for more information about the orientation procedure.

**Parameters**

- **name** : str
  The name of the new CoordSys3D instance.

- **orienters** : iterable/Orienter
  An Orienter or an iterable of Orienters for orienting the new coordinate system. If an Orienter is provided, it is applied to get the new system. If an iterable is provided, the orienters will be applied in the order in which they appear in the iterable.

- **location** : Vector(optional)
  The location of the new coordinate system’s origin wrt this system’s origin. If not specified, the origins are taken to be coincident.

- **vector_names**, **variable_names** : iterable(optional)
  Iterables of 3 strings each, with custom names for base vectors and base scalars of the new system respectively. Used for simple str printing.

Examples

```python
>>> from sympy.vector import CoordSys3D
>>> from sympy import symbols

>>> q0, q1, q2, q3 = symbols('q0 q1 q2 q3')

>>> N = CoordSys3D('N')

Using an AxisOrienter

```python
>>> from sympy.vector import AxisOrienter

>>> axis_orienter = AxisOrienter(q1, N.i + 2 * N.j)

>>> A = N.orient_new('A', (axis_orienter, ))

Using a BodyOrienter
```
>>> from sympy.vector import BodyOrienter
>>> body_orienter = BodyOrienter(q1, q2, q3, '123')
>>> B = N.orient_new('B', (body_orienter, ))

Using a SpaceOrienter

>>> from sympy.vector import SpaceOrienter
>>> space_orienter = SpaceOrienter(q1, q2, q3, '312')
>>> C = N.orient_new('C', (space_orienter, ))

Using a QuaternionOrienter

>>> from sympy.vector import QuaternionOrienter
>>> q_orienter = QuaternionOrienter(q0, q1, q2, q3)
>>> D = N.orient_new('D', (q_orienter, ))

orient_new_axis(name, angle, axis, location=None, vector_names=None, variable_names=None)

Axis rotation is a rotation about an arbitrary axis by some angle. The angle is supplied as a SymPy expr scalar, and the axis is supplied as a Vector.

Parameters

name : string
    The name of the new coordinate system

angle : Expr
    The angle by which the new system is to be rotated

axis : Vector
    The axis around which the rotation has to be performed

location : Vector(optional)
    The location of the new coordinate system’s origin wrt this system’s origin. If not specified, the origins are taken to be coincident.

vector_names, variable_names : iterable(optional)
    Iterables of 3 strings each, with custom names for base vectors and base scalars of the new system respectively. Used for simple str printing.

Examples

>>> from sympy.vector import CoordSys3D
>>> from sympy import symbols
>>> q1 = symbols('q1')
>>> N = CoordSys3D('N')
>>> B = N.orient_new_axis('B', q1, N.i + 2 * N.j)

orient_new_body(name, angle1, angle2, angle3, rotation_order, location=None, vector_names=None, variable_names=None)

Body orientation takes this coordinate system through three successive simple rotations.
Body fixed rotations include both Euler Angles and Tait-Bryan Angles, see https://en.wikipedia.org/wiki/Euler_angles.

**Parameters**

- **name**: string
  - The name of the new coordinate system
- **angle1, angle2, angle3**: Expr
  - Three successive angles to rotate the coordinate system by
- **rotation_order**: string
  - String defining the order of axes for rotation
- **location**: Vector(optional)
  - The location of the new coordinate system’s origin wrt this system’s origin. If not specified, the origins are taken to be coincident.
- **vector_names, variable_names**: iterable(optional)
  - Iterables of 3 strings each, with custom names for base vectors and base scalars of the new system respectively. Used for simple str printing.

**Examples**

```python
>>> from sympy.vector import CoordSys3D
>>> from sympy import symbols
>>> q1, q2, q3 = symbols('q1 q2 q3')
>>> N = CoordSys3D('N')

A 'Body' fixed rotation is described by three angles and three body-fixed rotation axes. To orient a coordinate system D with respect to N, each sequential rotation is always about the orthogonal unit vectors fixed to D. For example, a ‘123’ rotation will specify rotations about N.i, then D.j, then D.k. (Initially, D.i is same as N.i) Therefore,

```python
>>> D = N.orient_new_body('D', q1, q2, q3, '123')
``` is same as

```python
>>> D = N.orient_new_axis('D', q1, N.i)
>>> D = D.orient_new_axis('D', q2, D.j)
>>> D = D.orient_new_axis('D', q3, D.k)
```

Acceptable rotation orders are of length 3, expressed in XYZ or 123, and cannot have a rotation about about an axis twice in a row.

```python
>>> B = N.orient_new_body('B', q1, q2, q3, '123')
>>> B = N.orient_new_body('B', q1, q2, 0, 'ZXZ')
>>> B = N.orient_new_body('B', 0, 0, 0, 'XYX')
```

**orient_new_quaternion**

- **name, q0, q1, q2, q3, location=None, vector_names=None, variable_names=None**

  Quaternion orientation orients the new CoordSys3D with Quaternions, defined as a finite rotation about lambda, a unit vector, by some amount theta.
This orientation is described by four parameters:

\[
\begin{align*}
q_0 &= \cos(\theta/2) \\
q_1 &= \lambda_x \sin(\theta/2) \\
q_2 &= \lambda_y \sin(\theta/2) \\
q_3 &= \lambda_z \sin(\theta/2)
\end{align*}
\]

Quaternion does not take in a rotation order.

**Parameters**

- **name** : string
  - The name of the new coordinate system
- **q0, q1, q2, q3** : Expr
  - The quaternions to rotate the coordinate system by
- **location** : Vector(optional)
  - The location of the new coordinate system’s origin wrt this system’s origin. If not specified, the origins are taken to be coincident.
- **vector_names, variable_names** : iterable(optional)
  - Iterables of 3 strings each, with custom names for base vectors and base scalars of the new system respectively. Used for simple str printing.

**Examples**

```python
>>> from sympy.vector import CoordSys3D
>>> from sympy import symbols
>>> q0, q1, q2, q3 = symbols('q0 q1 q2 q3')
>>> N = CoordSys3D('N')
>>> B = N.orient_new_quaternion('B', q0, q1, q2, q3)
```

**orient_new_space**(*name*, *angle1*, *angle2*, *angle3*, *rotation_order*, *location=None*, *vector_names=None*, *variable_names=None*)

Space rotation is similar to Body rotation, but the rotations are applied in the opposite order.

**Parameters**

- **name** : string
  - The name of the new coordinate system
- **angle1, angle2, angle3** : Expr
  - Three successive angles to rotate the coordinate system by
- **rotation_order** : string
  - String defining the order of axes for rotation
- **location** : Vector(optional)
  - The location of the new coordinate system’s origin wrt this system’s origin. If not specified, the origins are taken to be coincident.
vector_names, variable_names : iterable(optional)

Iterables of 3 strings each, with custom names for base vectors and base scalars of the new system respectively. Used for simple str printing.

Examples

```python
>>> from sympy.vector import CoordSys3D
>>> q1, q2, q3 = symbols('q1 q2 q3')
>>> N = CoordSys3D('N')
```

To orient a coordinate system D with respect to N, each sequential rotation is always about N's orthogonal unit vectors. For example, a ‘123’ rotation will specify rotations about N.i, then N.j, then N.k. Therefore,

```python
>>> D = N.orient_new_space('D', q1, q2, q3, '312')
```

is same as

```python
>>> B = N.orient_new_axis('B', q1, N.i)
>>> C = B.orient_new_axis('C', q2, N.j)
>>> D = C.orient_new_axis('D', q3, N.k)
```

See also:

CoordSys3D.orient_new_body (page 1498) method to orient via Euler angles

position_wrt(other)

Returns the position vector of the origin of this coordinate system with respect to another Point/CoordSys3D.

Parameters

other : Point/CoordSys3D

If other is a Point, the position of this system’s origin wrt it is returned. If its an instance of CoordSyRect, the position wrt its origin is returned.

Examples

```python
>>> from sympy.vector import CoordSys3D
>>> N = CoordSys3D('N')
>>> N1 = N.locate_new('N1', 10 * N.i)
>>> N.position_wrt(N1)
```

rotation_matrix(other)

Returns the direction cosine matrix(DCM), also known as the ‘rotation matrix’ of this coordinate system with respect to another system.
If v_a is a vector defined in system 'A' (in matrix format) and v_b is the same vector defined in system 'B', then \( v_a = A.\text{rotation\_matrix}(B) \cdot v_b \).

A SymPy Matrix is returned.

**Parameters**

- **other**: CoordSys3D

  The system which the DCM is generated to.

**Examples**

```python
class sympy.vector.vector.Vector(*args)
```

Super class for all Vector classes. Ideally, neither this class nor any of its subclasses should be instantiated by the user.

**property components**

Returns the components of this vector in the form of a Python dictionary mapping BaseVector instances to the corresponding measure numbers.
Examples

```python
from sympy.vector import CoordSys3D
C = CoordSys3D('C')
v = 3*C.i + 4*C.j + 5*C.k
v.components
{C.i: 3, C.j: 4, C.k: 5}
```

cross(other)

Returns the cross product of this Vector with another Vector or Dyadic instance. The cross product is a Vector, if 'other' is a Vector. If 'other' is a Dyadic, this returns a Dyadic instance.

**Parameters**

other: Vector/Dyadic

The Vector or Dyadic we are crossing with.

Examples

```python
from sympy.vector import CoordSys3D
C = CoordSys3D('C')
C.i.cross(C.j)
C.k
C.i ^ C.i
0
v = 3*C.i + 4*C.j + 5*C.k
v ^ C.i
5*C.j + (-4)*C.k
d = C.i.outer(C.i)
C.j.cross(d)
(-1)*(C.k|C.i)
```

dot(other)

Returns the dot product of this Vector, either with another Vector, or a Dyadic, or a Del operator. If 'other' is a Vector, returns the dot product scalar (SymPy expression). If 'other' is a Dyadic, the dot product is returned as a Vector. If 'other' is an instance of Del, returns the directional derivative operator as a Python function. If this function is applied to a scalar expression, it returns the directional derivative of the scalar field wrt this Vector.

**Parameters**

other: Vector/Dyadic/Del

The Vector or Dyadic we are dotting with, or a Del operator.
Examples

```python
>>> from sympy.vector import CoordSys3D, Del
>>> C = CoordSys3D('C')
>>> delop = Del()
>>> C.i.dot(C.j)
0
>>> C.i & C.i
1
>>> v = 3*C.i + 4*C.j + 5*C.k
>>> v.dot(C.k)
5
>>> (C.i & delop)(C.x*C.y*C.z)
C.y*C.z
>>> d = C.i.outer(C.i)
>>> C.i.dot(d)
C.i
```

**magnitude()**

Returns the magnitude of this vector.

**normalize()**

Returns the normalized version of this vector.

**outer(other)**

Returns the outer product of this vector with another, in the form of a Dyadic instance.

Parameters

other : Vector

The Vector with respect to which the outer product is to be computed.

Examples

```python
>>> from sympy.vector import CoordSys3D
>>> N = CoordSys3D('N')
>>> N.i.outer(N.j)
(N.i|N.j)
```

**projection(other, scalar=False)**

Returns the vector or scalar projection of the ‘other’ on ‘self’.
Examples

```python
>>> from sympy.vector.coordsysrect import CoordSys3D
>>> C = CoordSys3D('C')
>>> i, j, k = C.base_vectors()
>>> v1 = i + j + k
>>> v2 = 3*i + 4*j
>>> v1.projection(v2)
7/3*C.i + 7/3*C.j + 7/3*C.k
>>> v1.projection(v2, scalar=True)
7/3
```

`separate()`

The constituents of this vector in different coordinate systems, as per its definition. Returns a dict mapping each CoordSys3D to the corresponding constituent Vector.

Examples

```python
>>> from sympy.vector import CoordSys3D
>>> R1 = CoordSys3D('R1')
>>> R2 = CoordSys3D('R2')
>>> v = R1.i + R2.i
>>> v.separate() == {R1: R1.i, R2: R2.i}
True
```

`to_matrix(system)`

Returns the matrix form of this vector with respect to the specified coordinate system.

Parameters

system : CoordSys3D

The system wrt which the matrix form is to be computed

Examples

```python
>>> from sympy.vector import CoordSys3D
>>> C = CoordSys3D('C')
>>> from sympy.abc import a, b, c
>>> v = a*C.i + b*C.j + c*C.k
>>> v.to_matrix(C)
Matrix(
[  a],
[  b],
[  c])
```

class sympy.vector.dyadic.Dyadic(*args)

Super class for all Dyadic-classes.
property components
Returns the components of this dyadic in the form of a Python dictionary mapping BaseDyadic instances to the corresponding measure numbers.

cross(other)
Returns the cross product between this Dyadic, and a Vector, as a Vector instance.

Parameters
other : Vector
    The Vector that we are crossing this Dyadic with

Examples

```python
>>> from sympy.vector import CoordSys3D
>>> N = CoordSys3D('N')
>>> d = N.i.outer(N.i)
>>> d.cross(N.j)
(N.i|N.k)
```

dot(other)
Returns the dot product (also called inner product) of this Dyadic, with another Dyadic or Vector. If ‘other’ is a Dyadic, this returns a Dyadic. Else, it returns a Vector (unless an error is encountered).

Parameters
other : Dyadic/Vector
    The other Dyadic or Vector to take the inner product with

Examples

```python
>>> from sympy.vector import CoordSys3D
>>> N = CoordSys3D('N')
>>> D1 = N.i.outer(N.j)
>>> D2 = N.j.outer(N.j)
>>> D1.dot(D2)
(N.i|N.j)
>>> D1.dot(N.j)
N.i
```

to_matrix(system, second_system=None)
Returns the matrix form of the dyadic with respect to one or two coordinate systems.

Parameters
system : CoordSys3D
    The coordinate system that the rows and columns of the matrix correspond to. If a second system is provided, this only corresponds to the rows of the matrix.
**second_system** : CoordSys3D, optional, default=None

The coordinate system that the columns of the matrix correspond to.

### Examples

```python
>>> from sympy.vector import CoordSys3D
>>> N = CoordSys3D('N')
>>> v = N.i + 2*N.j
>>> d = v.outer(N.i)
>>> d.to_matrix(N)
Matrix([[-1, 0, 0],
        [ 2, 0, 0],
        [ 0, 0, 0]])
```

### class sympy.vector.deloperator.Del

Represents the vector differential operator, usually represented in mathematical expressions as the ‘nabla’ symbol.

**cross(vect, doit=False)**

Represents the cross product between this operator and a given vector - equal to the curl of the vector field.

**Parameters**

- **vect** : Vector
  
The vector whose curl is to be calculated.

- **doit** : bool
  
  If True, the result is returned after calling .doit() on each component. Else, the returned expression contains Derivative instances

### Examples

```python
>>> from sympy.vector import CoordSys3D, Del
>>> C = CoordSys3D('C')
>>> delop = Del()
>>> v = C.x*C.y*C.z * (C.i + C.j + C.k)
>>> delop.cross(v, doit=True)
(-C.x*C.y + C.x*C.z)*C.i + (C.x*C.y - C.y*C.z)*C.j + (-C.x*C.z + C.y*C.z)*C.k
>>> (delop ^ C.i).doit()
0
```
**dot**(*vect*, *doit=False*)

Represents the dot product between this operator and a given vector - equal to the divergence of the vector field.

**Parameters**

- **vect**: Vector
  
The vector whose divergence is to be calculated.

- **doit**: bool
  
  If True, the result is returned after calling .doit() on each component. Else, the returned expression contains Derivative instances.

**Examples**

```python
>>> from sympy.vector import CoordSys3D, Del
>>> delop = Del()
>>> C = CoordSys3D('C')
>>> delop.dot(C.x*C.i)
Derivative(C.x, C.x)
>>> v = C.x*C.y*C.z * (C.i + C.j + C.k)
>>> (delop & v).doit()
C.x*C.y + C.x*C.z + C.y*C.z
```

**gradient**(*scalar_field*, *doit=False*)

Returns the gradient of the given scalar field, as a Vector instance.

**Parameters**

- **scalar_field**: SymPy expression
  
  The scalar field to calculate the gradient of.

- **doit**: bool
  
  If True, the result is returned after calling .doit() on each component. Else, the returned expression contains Derivative instances.

**Examples**

```python
>>> from sympy.vector import CoordSys3D, Del
>>> C = CoordSys3D('C')
>>> delop = Del()
>>> delop.gradient(9)
0
>>> delop(C.x*C.y*C.z).doit()
C.y*C.z*C.i + C.x*C.z*C.j + C.x*C.y*C.k
```

**class** sympy.vector.parametricregion.**ParametricRegion**(definition, *bounds)

Represents a parametric region in space.

**Parameters**

- **definition**: tuple to define base scalars in terms of parameters.

- **bounds**: Parameter or a tuple of length 3 to define parameter and corresponding lower and upper bound.
Examples

```python
>>> from sympy import cos, sin, pi
>>> from sympy.abc import r, theta, t, a, b, x, y
>>> from sympy.vector import ParametricRegion

>>> ParametricRegion((t, t**2), (t, -1, 2))
ParametricRegion((t, t**2), (t, -1, 2))
>>> ParametricRegion((x, y), (x, 3, 4), (y, 5, 6))
ParametricRegion((x, y), (x, 3, 4), (y, 5, 6))
>>> ParametricRegion((r*cos(theta), r*sin(theta)), (r, -2, 2), (theta, 0, pi))
ParametricRegion((r*cos(theta), r*sin(theta)), (r, -2, 2), (theta, 0, pi))
>>> ParametricRegion((a*cos(t), b*sin(t)), t)
ParametricRegion((a*cos(t), b*sin(t)), t)

>>> circle = ParametricRegion((r*cos(theta), r*sin(theta)), r, (theta, 0, pi))
>>> circle.parameters
(r, theta)
>>> circle.definition
(r*cos(theta), r*sin(theta))
>>> circle.limits
{theta: (0, pi)}
```

Dimension of a parametric region determines whether a region is a curve, surface or volume region. It does not represent its dimensions in space.

```python
>>> circle.dimensions
1
```

**class** sympy.vector.implicitregion.ImplicitRegion(variables, equation)**

Represents an implicit region in space.

**Parameters**

- **variables**: tuple to map variables in implicit equation to base scalars.
- **equation**: An expression or Eq denoting the implicit equation of the region.

Examples

```python
>>> from sympy import Eq
>>> from sympy.abc import x, y, z, t
>>> from sympy.vector import ImplicitRegion

>>> ImplicitRegion((x, y), x**2 + y**2 - 4)
ImplicitRegion((x, y), x**2 + y**2 - 4)
>>> ImplicitRegion((x, y), Eq(y*x, 1))
ImplicitRegion((x, y), x*y - 1)
```
>>> parabola = ImplicitRegion((x, y), y**2 - 4*x)
>>> parabola.degree
2
>>> parabola.equation
-4*x + y**2
>>> parabola.rational_parametrization(t)
(4/t**2, 4/t)

>>> r = ImplicitRegion((x, y, z), Eq(z, x**2 + y**2))
>>> r.variables
(x, y, z)
>>> r.singular_points()
EmptySet
>>> r.regular_point()
(-10, -10, 200)

multiplicity(point)
Returns the multiplicity of a singular point on the region.
A singular point (x,y) of region is said to be of multiplicity m if all the partial derivatives off to order m - 1 vanish there.

Examples

>>> from sympy.abc import x, y, z
>>> I = ImplicitRegion((x, y, z), x**2 + y**3 - z**4)
>>> I.singular_points()
{(0, 0, 0)}
>>> I.multiplicity((0, 0, 0))
2

rational_parametrization(parameters=('t', 's'), reg_point=None)
Returns the rational parametrization of implicit region.

Examples

>>> from sympy import Eq
>>> parabola = ImplicitRegion((x, y), y**2 - 4*x)
>>> parabola.rational_parametrization()
(4/t**2, 4/t)

>>> circle = ImplicitRegion((x, y), Eq(x**2 + y**2, 4))
>>> circle.rational_parametrization()
(4*t/(t**2 + 1), 4*t**2/(t**2 + 1) - 2)
>>> I = ImplicitRegion((x, y), x**3 + x**2 - y**2)
>>> I.rational_parametrization()
(t**2 - 1, t*(t**2 - 1))

>>> cubic_curve = ImplicitRegion((x, y), x**3 + x**2 - y**2)
>>> cubic_curve.rational_parametrization(parameters=(t))
(t**2 - 1, t*(t**2 - 1))

>>> sphere = ImplicitRegion((x, y, z), x**2 + y**2 + z**2 - 4)
>>> sphere.rational_parametrization(parameters=(t, s))
(-2 + 4/(s**2 + t**2 + 1), 4*s/(s**2 + t**2 + 1), 4*t/(s**2 + t**2 + 1))

For some conics, regular_points() is unable to find a point on curve. To calulate the parametric representation in such cases, user need to determine a point on the region and pass it using reg_point.

>>> c = ImplicitRegion((x, y), (x - 1/2)**2 + (y)**2 - (1/4)**2)
>>> c.rational_parametrization(reg_point=(3/4, 0))
(0.5 - 0.5/(t**2 + 1), -0.5*t/(t**2 + 1))

References

regular_point()
Returns a point on the implicit region.

Examples

>>> from sympy.abc import x, y, z
>>> from sympy.vector import ImplicitRegion
>>> circle = ImplicitRegion((x, y), (x + 2)**2 + (y - 3)**2 - 16)
>>> circle.regular_point()
(-2, -1)
>>> parabola = ImplicitRegion((x, y), x**2 - 4*y)
>>> parabola.regular_point()
(0, 0)
>>> r = ImplicitRegion((x, y, z), (x + y + z)**4)
>>> r.regular_point()
(-10, -10, 20)
References

**singular_points()**

Returns a set of singular points of the region.

The singular points are those points on the region where all partial derivatives vanish.

**Examples**

```python
>>> from sympy.abc import x, y
>>> from sympy.vector import ImplicitRegion
>>> I = ImplicitRegion((x, y), (y - 1)**2 - x**3 + 2*x**2 - x)
>>> I.singular_points()
{(1, 1)}
```

class sympy.vector.integrals.ParametricIntegral(field, parametricregion)

Represents integral of a scalar or vector field over a Parametric Region

**Examples**

```python
>>> from sympy import cos, sin, pi
>>> from sympy.vector import CoordSys3D, ParametricRegion, ParametricIntegral
>>> from sympy.abc import r, t, theta, phi

>>> C = CoordSys3D('C')
>>> curve = ParametricRegion((3*t - 2, t + 1), (t, 1, 2))
>>> ParametricIntegral(C.x, curve)
5*sqrt(10)/2
>>> length = ParametricIntegral(1, curve)
>>> length
sqrt(10)
>>> semisphere = ParametricRegion((2*sin(phi)*cos(theta), -2*sin(phi)*sin(theta), 2*cos(phi)), (theta, 0, 2*pi), (phi, 0, pi/2))
>>> ParametricIntegral(C.z, semisphere)
8*pi
```

```python
>>> ParametricIntegral(C.j + C.k, ParametricRegion((r*cos(theta), -r*sin(theta)), (r, theta))
0
```
Orienter classes (docstrings)

class sympy.vector.orienters.Orienter(*args)
   Super-class for all orienter classes.
   rotation_matrix()
      The rotation matrix corresponding to this orienter instance.

class sympy.vector.orienters.AxisOrienter(angle, axis)
   Class to denote an axis orienter.
   __init__(angle, axis)
      Axis rotation is a rotation about an arbitrary axis by some angle. The angle is supplied as a SymPy expr scalar, and the axis is supplied as a Vector.

      Parameters
         angle : Expr
            The angle by which the new system is to be rotated
         axis : Vector
            The axis around which the rotation has to be performed

Examples

>>> from sympy.vector import CoordSys3D
>>> from sympy import symbols
>>> q1 = symbols('q1')
>>> N = CoordSys3D('N')
>>> from sympy.vector import AxisOrienter
>>> orienter = AxisOrienter(q1, N.i + 2 * N.j)
>>> B = N.orient_new('B', (orienter, ))

rotation_matrix(system)
   The rotation matrix corresponding to this orienter instance.

      Parameters
         system : CoordSys3D
            The coordinate system wrt which the rotation matrix is to be computed

class sympy.vector.orienters.BodyOrienter(angle1, angle2, angle3, rot_order)
   Class to denote a body-orienter.
   __init__(angle1, angle2, angle3, rot_order)
      Body orientation takes this coordinate system through three successive simple rotations.

      Body fixed rotations include both Euler Angles and Tait-Bryan Angles, see https://en.wikipedia.org/wiki/Euler_angles.

      Parameters
         angle1, angle2, angle3 : Expr
            Three successive angles to rotate the coordinate system by
rotation_order : string

String defining the order of axes for rotation

Examples

```python
>>> from sympy.vector import CoordSys3D, BodyOrienter
>>> from sympy import symbols
>>> q1, q2, q3 = symbols('q1 q2 q3')
>>> N = CoordSys3D('N')

A ‘Body’ fixed rotation is described by three angles and three body-fixed rotation axes. To orient a coordinate system D with respect to N, each sequential rotation is always about the orthogonal unit vectors fixed to D. For example, a ‘123’ rotation will specify rotations about N.i, then D.j, then D.k. (Initially, D.i is same as N.i) Therefore,

```python
>>> body_orienter = BodyOrienter(q1, q2, q3, '123')
>>> D = N.orient_new('D', (body_orienter, ))
```

is same as

```python
>>> from sympy.vector import AxisOrienter
>>> axis_orienter1 = AxisOrienter(q1, N.i)
>>> D = N.orient_new('D', (axis_orienter1, ))
>>> axis_orienter2 = AxisOrienter(q2, D.j)
>>> D = D.orient_new('D', (axis_orienter2, ))
>>> axis_orienter3 = AxisOrienter(q3, D.k)
>>> D = D.orient_new('D', (axis_orienter3, ))
```

Acceptable rotation orders are of length 3, expressed in XYZ or 123, and cannot have a rotation about about an axis twice in a row.

```python
>>> body_orienter1 = BodyOrienter(q1, q2, q3, '123')
>>> body_orienter2 = BodyOrienter(q1, q2, 0, 'ZXZ')
>>> body_orienter3 = BodyOrienter(0, 0, 0, 'XYX')
```

class sympy.vector.orienters.SpaceOrienter(angle1, angle2, angle3, rot_order)

Class to denote a space-orienter.

__init__(angle1, angle2, angle3, rot_order)

Space rotation is similar to Body rotation, but the rotations are applied in the opposite order.

Parameters

- **angle1, angle2, angle3** : Expr
  - Three successive angles to rotate the coordinate system by

- **rotation_order** : string
  - String defining the order of axes for rotation
Examples

```python
>>> from sympy.vector import CoordSys3D, SpaceOrienter
>>> from sympy import symbols
>>> q1, q2, q3 = symbols('q1 q2 q3')
>>> N = CoordSys3D('N')
```

To orient a coordinate system D with respect to N, each sequential rotation is always about N’s orthogonal unit vectors. For example, a ‘123’ rotation will specify rotations about N.i, then N.j, then N.k. Therefore,

```python
>>> space_orienter = SpaceOrienter(q1, q2, q3, '312')
>>> D = N.orient_new('D', (space_orienter, ))
```

is same as

```python
>>> from sympy.vector import AxisOrienter
>>> axis_orienter1 = AxisOrienter(q1, N.i)
>>> B = N.orient_new('B', (axis_orienter1, ))
>>> axis_orienter2 = AxisOrienter(q2, N.j)
>>> C = B.orient_new('C', (axis_orienter2, ))
>>> axis_orienter3 = AxisOrienter(q3, N.k)
>>> D = C.orient_new('C', (axis_orienter3, ))
```

See also:

*BodyOrienter* (page 1513)

Orienter to orient systems wrt Euler angles.

class sympy.vector.orienters.QuaternionOrienter(q0, q1, q2, q3)

Class to denote a quaternion-orienter.

__init__(angle1, angle2, angle3, rot_order)

Quaternion orientation orients the new CoordSys3D with Quaternions, defined as a finite rotation about lambda, a unit vector, by some amount theta.

This orientation is described by four parameters:

q0 = cos(theta/2)
q1 = lambda_x sin(theta/2)
q2 = lambda_y sin(theta/2)
q3 = lambda_z sin(theta/2)

Quaternion does not take in a rotation order.

Parameters

q0, q1, q2, q3 : Expr

The quaternions to rotate the coordinate system by
Examples

```python
>>> from sympy.vector import CoordSys3D
>>> from sympy import symbols
>>> q0, q1, q2, q3 = symbols('q0 q1 q2 q3')
>>> N = CoordSys3D('N')
>>> from sympy.vector import QuaternionOrienter
>>> q_orienter = QuaternionOrienter(q0, q1, q2, q3)
>>> B = N.orient_new('B', (q_orienter, ))
```

Essential Functions in sympy.vector (docstrings)

**sympy.vector.matrix_to_vector**(matrix, system)

Converts a vector in matrix form to a Vector instance.

It is assumed that the elements of the Matrix represent the measure numbers of the components of the vector along basis vectors of 'system'.

**Parameters**

- **matrix** : SymPy Matrix, Dimensions: (3, 1)
  
  The matrix to be converted to a vector

- **system** : CoordSys3D
  
  The coordinate system the vector is to be defined in

**Examples**

```python
>>> from sympy import ImmutableMatrix as Matrix
>>> m = Matrix([1, 2, 3])
>>> from sympy.vector import CoordSys3D, matrix_to_vector
>>> C = CoordSys3D('C')
>>> v = matrix_to_vector(m, C)
>>> v
C.i + 2*C.j + 3*C.k
>>> v.to_matrix(C) == m
True
```

**sympy.vector.express**(expr, system, system2=None, variables=False)

Global function for ‘express’ functionality.

Re-expresses a Vector, Dyadic or scalar(sympyfiable) in the given coordinate system.

If ‘variables’ is True, then the coordinate variables (base scalars) of other coordinate systems present in the vector/scalar field or dyadic are also substituted in terms of the base scalars of the given system.

**Parameters**

- **expr** : Vector/Dyadic/scalar(sympyfiable)
  
  The expression to re-express in CoordSys3D ‘system’

- **system** : CoordSys3D
The coordinate system the expr is to be expressed in

**system2: CoordSys3D**

The other coordinate system required for re-expression (only for a Dyadic Expr)

**variables**: boolean

Specifies whether to substitute the coordinate variables present in expr, in terms of those of parameter system

**Examples**

```python
>>> from sympy.vector import CoordSys3D
>>> from sympy import Symbol, cos, sin
>>> N = CoordSys3D('N')
>>> q = Symbol('q')
>>> B = N.orient_new_axis('B', q, N.k)
>>> from sympy.vector import express
>>> express(B.i, N)
(cos(q))*N.i + (sin(q))*N.j
>>> express(N.x, B, variables=True)
B.x*cos(q) - B.y*sin(q)
>>> d = N.i.outer(N.i)
>>> express(d, B, N)
(cos(q))*(B.i|N.i) + (-sin(q))*(B.j|N.i)
True
```

**sympy.vector.curl(vect, doit=True)**

Returns the curl of a vector field computed wrt the base scalars of the given coordinate system.

**Parameters**

- **vect**: Vector
  
  The vector operand

- **doit**: bool
  
  If True, the result is returned after calling .doit() on each component. Else, the returned expression contains Derivative instances

**Examples**

```python
>>> from sympy.vector import CoordSys3D, curl
>>> R = CoordSys3D('R')
>>> v1 = R.y*R.z*R.i + R.x*R.z*R.j + R.x*R.y*R.k
>>> curl(v1)
0
>>> v2 = R.x*R.y*R.z*R.i
>>> curl(v2)
R.x*R.y*R.j + (-R.x*R.z)*R.k
```
sympy.vector.divergence(vect, doit=True)
Returns the divergence of a vector field computed wrt the base scalars of the given coordinate system.

Parameters
vector : Vector
The vector operand
doit : bool
If True, the result is returned after calling .doit() on each component. Else, the returned expression contains Derivative instances

Examples

```python
>>> from sympy.vector import CoordSys3D, divergence
>>> R = CoordSys3D('R')
>>> v1 = R.x*R.y*R.z * (R.i+R.j+R.k)

>>> divergence(v1)
R.x*R.y + R.x*R.z + R.y*R.z
>>> v2 = 2*R.y*R.z*R.j
>>> divergence(v2)
2*R.z
```

sympy.vector.gradient(scalar_field, doit=True)
Returns the vector gradient of a scalar field computed wrt the base scalars of the given coordinate system.

Parameters
scalar_field : SymPy Expr
The scalar field to compute the gradient of
doit : bool
If True, the result is returned after calling .doit() on each component. Else, the returned expression contains Derivative instances

Examples

```python
>>> from sympy.vector import CoordSys3D, gradient
>>> R = CoordSys3D('R')
>>> s1 = R.x*R.y*R.z
>>> gradient(s1)
R.y*R.z*R.i + R.x*R.z*R.j + R.x*R.y*R.k
>>> s2 = 5*R.x**2*R.z
>>> gradient(s2)
10*R.x*R.z*R.i + 5*R.x**2*R.k
```

sympy.vector.is_conservative(field)
Checks if a field is conservative.
Parameters

field : Vector

The field to check for conservative property

Examples

```python
>>> from sympy.vector import CoordSys3D
>>> from sympy.vector import is_conservative
>>> R = CoordSys3D('R')
>>> is_conservative(R.y*R.z*R.i + R.x*R.z*R.j + R.x*R.y*R.k)
True
>>> is_conservative(R.z*R.j)
False
```

sympy.vector.is_solenoidal(field)

Checks if a field is solenoidal.

Parameters

field : Vector

The field to check for solenoidal property

Examples

```python
>>> from sympy.vector import CoordSys3D
>>> from sympy.vector import is_solenoidal
>>> R = CoordSys3D('R')
>>> is_solenoidal(R.y*R.z*R.i + R.x*R.z*R.j + R.x*R.y*R.k)
True
>>> is_solenoidal(R.y*R.j)
False
```

sympy.vector.scalar_potential(field, coord_sys)

Returns the scalar potential function of a field in a given coordinate system (without the added integration constant).

Parameters

field : Vector

The vector field whose scalar potential function is to be calculated

coord_sys : CoordSys3D

The coordinate system to do the calculation in
Examples

```python
>>> from sympy.vector import CoordSys3D
>>> R = CoordSys3D('R')
>>> scalar_potential(R.k, R) == R.z
True
>>> scalar_field = 2*R.x**2*R.y*R.z
>>> grad_field = gradient(scalar_field)
>>> scalar_potential_difference(grad_field, R)
2*R.x**2*R.y*R.z
```

**sympy.vector.scalar_potential_difference**(*field, coord_sys, point1, point2*)

Returns the scalar potential difference between two points in a certain coordinate system, wrt a given field.

If a scalar field is provided, its values at the two points are considered. If a conservative vector field is provided, the values of its scalar potential function at the two points are used.

Returns (potential at point2) - (potential at point1)

The position vectors of the two Points are calculated wrt the origin of the coordinate system provided.

**Parameters**

- **field**: Vector/Expr
  The field to calculate wrt
- **coord_sys**: CoordSys3D
  The coordinate system to do the calculations in
- **point1**: Point
  The initial Point in given coordinate system
- **position2**: Point
  The second Point in the given coordinate system

Examples

```python
>>> from sympy.vector import CoordSys3D
>>> R = CoordSys3D('R')
>>> P = R.origin.locate_new('P', R.x*R.i + R.y*R.j + R.z*R.k)
>>> vectfield = 4*R.x*R.y*R.i + 2*R.x**2*R.j
>>> scalar_potential_difference(vectfield, R, R.origin, P)
2*R.x**2*R.y
>>> Q = R.origin.locate_new('O', 3*R.i + R.j + 2*R.k)
>>> scalar_potential_difference(vectfield, R, P, Q)
-2*R.x**2*R.y + 18
```

**sympy.vector.integrals.vector_integrate**(*field, *region*)

Compute the integral of a vector/scalar field over a a region or a set of parameters.
Examples

```python
>>> from sympy.vector import CoordSys3D, ParametricRegion, vector_integrate
>>> from sympy import x, y, t
>>> C = CoordSys3D('C')

>>> region = ParametricRegion((t, t**2), (t, 1, 5))
>>> vector_integrate(C.x*C.i, region)
12

Integrals over some objects of geometry module can also be calculated.

```python
>>> from sympy.geometry import Point, Circle, Triangle
>>> c = Circle(Point(0, 2), 5)
>>> vector_integrate(C.x**2 + C.y**2, c)
290*pi

```python
>>> triangle = Triangle(Point(-2, 3), Point(2, 3), Point(0, 5))
>>> vector_integrate(3*C.x**2*C.y*C.i + C.j, triangle)
-8
```

Integrals over some simple implicit regions can be computed. But in most cases, it takes too long to compute over them. This is due to the expressions of parametric representation becoming large.

```python
>>> from sympy.vector import ImplicitRegion

```python
>>> c2 = ImplicitRegion((x, y), (x - 2)**2 + (y - 1)**2 - 9)
>>> vector_integrate(1, c2)
6*pi
```

Integral of fields with respect to base scalars:

```python
>>> vector_integrate(12*C.y**3, (C.y, 1, 3))
240
>>> vector_integrate(C.x**2*C.z, C.x)
C.x**3*C.z/3
>>> vector_integrate(C.x*C.i - C.y*C.k, C.x)
(Integral(C.x, C.x))*C.i + (Integral(-C.y, C.x))*C.k
>>> _.doit()
C.x**2/2*C.i + (-C.x*C.y)*C.k
```

5.8.5 Number Theory

Contents
Number Theory

Ntheory Class Reference

class sympy.ntheory.generate.Sieve
An infinite list of prime numbers, implemented as a dynamically growing sieve of Eratosthenes. When a lookup is requested involving an odd number that has not been sieved, the sieve is automatically extended up to that number.

Examples

>>> from sympy import sieve
>>> sieve._reset() # this line for doctest only
>>> 25 in sieve
False
>>> sieve._list
array('l', [2, 3, 5, 7, 11, 13, 17, 19, 23])

extend(n)
Grow the sieve to cover all primes <= n (a real number).

Examples

>>> from sympy import sieve
>>> sieve._reset() # this line for doctest only
>>> sieve.extend(30)
>>> sieve[10] == 29
True

extend_to_no(i)
Extend to include the ith prime number.

Parameters
  i: integer

Examples

>>> from sympy import sieve
>>> sieve._reset() # this line for doctest only
>>> sieve.extend_to_no(9)
>>> sieve._list
array('l', [2, 3, 5, 7, 11, 13, 17, 19, 23])
Notes

The list is extended by 50% if it is too short, so it is likely that it will be longer than requested.

mobiusrange(a, b)
Generate all mobius numbers for the range [a, b).

Parameters

a : integer
First number in range

b : integer
First number outside of range

Examples

```python
>>> from sympy import sieve
>>> print([i for i in sieve.mobiusrange(7, 18)])
[-1, 0, 0, 1, -1, 0, -1, 1, 1, 0, -1]
```

primerange(a, b=None)
Generate all prime numbers in the range [2, a) or [a, b).

Examples

```python
>>> from sympy import sieve, prime

All primes less than 19:
```print([i for i in sieve.primerange(19)])
[2, 3, 5, 7, 11, 13, 17]
```

All primes greater than or equal to 7 and less than 19:
```print([i for i in sieve.primerange(7, 19)])
[7, 11, 13, 17]
```

All primes through the 10th prime
```print(list(sieve.primerange(prime(10) + 1)))
[2, 3, 5, 7, 11, 13, 17, 19, 23, 29]
```

search(n)
Return the indices i, j of the primes that bound n.

If n is prime then i == j.

Although n can be an expression, if ceiling cannot convert it to an integer then an n error will be raised.
Examples

```python
>>> from sympy import sieve
>>> sieve.search(25)  
(9, 10)
>>> sieve.search(23)  
(9, 9)
```

totientrange\((a, b)\)

Generate all totient numbers for the range \([a, b)\).

Examples

```python
>>> from sympy import sieve
>>> print([i for i in sieve.totientrange(7, 18)])
[6, 4, 6, 4, 10, 4, 12, 6, 8, 8, 16]
```

Ntheory Functions Reference

sympy.ntheory.generate.prime\((nth)\)

Return the \(n\)th prime, with the primes indexed as prime(1) = 2, prime(2) = 3, etc.... The \(n\)th prime is approximately \(n \log(n)\).

Logarithmic integral of \(x\) is a pretty nice approximation for number of primes \(\leq x\), i.e. \(\text{li}(x) \sim \pi(x)\) In fact, for the numbers we are concerned about( \(x<1e11\) ), \(\text{li}(x) - \pi(x) < 50000\)

Also, \(\text{li}(x) > \pi(x)\) can be safely assumed for the numbers which can be evaluated by this function.

Here, we find the least integer \(m\) such that \(\text{li}(m) > n\) using binary search. Now \(\pi(m-1) < \text{li}(m-1) \leq n\),

We find \(\pi(m - 1)\) using primepi function.

Starting from \(m\), we have to find \(n - \pi(m-1)\) more primes.

For the inputs this implementation can handle, we will have to test primality for at max about \(10^{**5}\) numbers, to get our answer.

Examples

```python
>>> from sympy import prime
>>> prime(10)  
29
>>> prime(1)  
2
>>> prime(100000)  
1299709
```

sympy.ntheory.generate.primepi(n)

Represents the prime counting function $\pi(n) = \text{the number of prime numbers less than or equal to } n$.

**Algorithm Description:**

In sieve method, we remove all multiples of prime $p$ except $p$ itself.

Let $\phi(i,j)$ be the number of integers $2 \leq k \leq i$ which remain after sieving from primes less than or equal to $j$. Clearly, $\pi(n) = \phi(n, \sqrt{n})$

If $j$ is not a prime, $\phi(i,j) = \phi(i,j-1)$

if $j$ is a prime, We remove all numbers(except $j$) whose smallest prime factor is $j$.

Let $x = j \times a$ be such a number, where $2 \leq a \leq i/j$ Now, after sieving from primes $\leq j - 1$, $a$ must remain (because $x$, and hence $a$ has no prime factor $\leq j - 1$) Clearly, there are $\phi(i/j, j - 1)$ such $a$ which remain on sieving from primes $\leq j - 1$

Now, if $a$ is a prime less than equal to $j - 1$, $x = j \times a$ has smallest prime factor = $a$, and has already been removed(by sieving from $a$). So, we do not need to remove it again. (Note: there will be $\pi(j - 1)$ such $x$)

Thus, number of $x$, that will be removed are: $\phi(i/j, j - 1) - \phi(i - 1, j - 1)$ (Note that $\pi(j - 1) = \phi(j - 1, j - 1)$)

$\Rightarrow \phi(i,j) = \phi(i, j - 1) - \phi(i/j, j - 1) + \phi(j - 1, j - 1)$

So, following recursion is used and implemented as dp:

$\phi(a, b) = \phi(a, b - 1)$, if $b$ is not a prime $\phi(a, b) = \phi(a, b-1)-\phi(a/b, b-1) + \phi(b-1, b-1)$, if $b$ is prime

Clearly $a$ is always of the form floor($n/k$), which can take at most $2\sqrt{n}$ values. Two arrays arr1,arr2 are maintained $\text{arr1[i]} = \phi(i, j)$, $\text{arr2[i]} = \phi(n // i, j)$

Finally the answer is arr2[1]
Examples

```python
>>> from sympy import primepi, prime, prevprime, isprime

>>> primepi(25)
9

So there are 9 primes less than or equal to 25. Is 25 prime?

```python
>>> isprime(25)
False
```

It is not. So the first prime less than 25 must be the 9th prime:

```python
>>> prevprime(25) == prime(9)
True
```

See also:

- sympy.ntheory.primetest.isprime (page 1562)
  Test if n is prime

- primerange (page 1527)
  Generate all primes in a given range

- prime (page 1524)
  Return the nth prime

sympy.ntheory.generate.nextprime(n, ith=1)
Return the ith prime greater than n.
  i must be an integer.

Notes

Potential primes are located at $6j +/- 1$. This property is used during searching.

```python
>>> from sympy import nextprime

>>> [(i, nextprime(i)) for i in range(10, 15)]
[(10, 11), (11, 13), (12, 13), (13, 17), (14, 17)]

>>> nextprime(2, ith=2)  # the 2nd prime after 2
5
```

- prevprime (page 1526)
  Return the largest prime smaller than n

- primerange (page 1527)
  Generate all primes in a given range

sympy.ntheory.generate.prevprime(n)
Return the largest prime smaller than n.
Notes

Potential primes are located at 6*j +/- 1. This property is used during searching.

```python
>>> from sympy import prevprime
>>> [(i, prevprime(i)) for i in range(10, 15)]
[(10, 7), (11, 7), (12, 11), (13, 11), (14, 13)]
```

See also:

nextprime (page 1526)

Return the ith prime greater than n

primerange (page 1527)

Generates all primes in a given range

```python
sympy.ntheory.generate.primerange(a, b=None)
```

Generate a list of all prime numbers in the range [2, a), or [a, b).

If the range exists in the default sieve, the values will be returned from there; otherwise values will be returned but will not modify the sieve.

Examples

```python
>>> from sympy import primerange, prime

All primes less than 19:

```python
>>> list(primerange(19))
[2, 3, 5, 7, 11, 13, 17]
```

All primes greater than or equal to 7 and less than 19:

```python
>>> list(primerange(7, 19))
[7, 11, 13, 17]
```

All primes through the 10th prime

```python
>>> list(primerange(prime(10) + 1))
[2, 3, 5, 7, 11, 13, 17, 19, 23, 29]
```

The Sieve method, primerange, is generally faster but it will occupy more memory as the sieve stores values. The default instance of Sieve, named sieve, can be used:

```python
>>> from sympy import sieve
>>> list(sieve.primerange(1, 30))
[2, 3, 5, 7, 11, 13, 17, 19, 23, 29]
```
Notes

Some famous conjectures about the occurrence of primes in a given range are [1]:

- **Twin primes:** though often not, the following will give 2 primes
  an infinite number of times:
  \[ \text{primerange}(6n - 1, 6n + 2) \]

- **Legendre’s:** the following always yields at least one prime
  \[ \text{primerange}(n^2, (n+1)^2+1) \]

- **Bertrand’s (proven):** there is always a prime in the range
  \[ \text{primerange}(n, 2n) \]

- **Brocard’s:** there are at least four primes in the range
  \[ \text{primerange}(\text{prime}(n)^2, \text{prime}(n+1)^2) \]

The average gap between primes is \( \log(n) \) [2]; the gap between primes can be arbitrarily large since sequences of composite numbers are arbitrarily large, e.g. the numbers in the sequence \( n! + 2, n! + 3 \ldots n! + n \) are all composite.

See also:

- **`prime`** (page 1524)
  Return the nth prime

- **`nextprime`** (page 1526)
  Return the ith prime greater than n

- **`prevprime`** (page 1526)
  Return the largest prime smaller than n

- **`randprime`** (page 1528)
  Returns a random prime in a given range

- **`primorial`** (page 1529)
  Returns the product of primes based on condition

- **`sieve.primerange`** (page 1523)
  Return range from already computed primes or extend the sieve to contain the requested range.

[R621], [R622]

sympy.ntheory.generate.randprime\((a, b)\)

Return a random prime number in the range \( [a, b] \).

Bertrand’s postulate assures that randprime\((a, 2a)\) will always succeed for \( a > 1 \).
Examples

```python
>>> from sympy import randprime, isprime
>>> randprime(1, 30)
13
>>> isprime(randprime(1, 30))
True
```

See also:

`primerange` (page 1527)

Generate all primes in a given range

References

[R623]

`sympy.ntheory.generate.primorial(n, nth=True)`

Returns the product of the first n primes (default) or the primes less than or equal to n (when nth=False).

Examples

```python
>>> from sympy.ntheory.generate import primorial, primerange
>>> from sympy import factorint, Mul, primefactors, sqrt
>>> primorial(4) # the first 4 primes are 2, 3, 5, 7
210
>>> primorial(4, nth=False) # primes <= 4 are 2 and 3
6
>>> primorial(1)
2
>>> primorial(1, nth=False)
1
>>> primorial(sqrt(101), nth=False)
210
```

One can argue that the primes are infinite since if you take a set of primes and multiply them together (e.g. the primorial) and then add or subtract 1, the result cannot be divided by any of the original factors, hence either 1 or more new primes must divide this product of primes.

In this case, the number itself is a new prime:

```python
>>> factorint(primorial(4) + 1)
{211: 1}
```

In this case two new primes are the factors:

```python
>>> factorint(primorial(4) - 1)
{11: 1, 19: 1}
```

Here, some primes smaller and larger than the primes multiplied together are obtained:
>>> p = list(primerange(10, 20))
>>> sorted(set(primefactors(Mul(*p) + 1)).difference(set(p)))
[2, 5, 31, 149]

primerange (page 1527)
Generate all primes in a given range

sympy.ntheory.generate.cycle_length(f, x0, nmax=None, values=False)
For a given iterated sequence, return a generator that gives the length of the iterated
sequence (lambda) and the length of terms before the cycle begins (mu); if values is True
then the terms of the sequence will be returned instead. The sequence is started with
value x0.

Note: more than the first lambda + mu terms may be returned and this is the cost of
cycle detection with Brent’s method; there are, however, generally less terms calculated
than would have been calculated if the proper ending point were determined, e.g. by
using Floyd’s method.

>>> from sympy.ntheory.generate import cycle_length
This will yield successive values of i <- func(i):

>>> def iter(func, i):
...     while 1:
...         ii = func(i)
...         yield ii
...         i = ii

A function is defined:

>>> func = lambda i: (i**2 + 1) % 51

and given a seed of 4 and the mu and lambda terms calculated:

>>> next(cycle_length(func, 4))
(6, 2)

We can see what is meant by looking at the output:

>>> n = cycle_length(func, 4, values=True)
>>> list(n for ni in n)
[17, 35, 2, 5, 26, 14, 44, 50, 2, 5, 26, 14]

There are 6 repeating values after the first 2.

If a sequence is suspected of being longer than you might wish, nmax can be used to exit
early (and mu will be returned as None):

>>> next(cycle_length(func, 4, nmax = 4))
(4, None)
>>> [ni for ni in cycle_length(func, 4, nmax = 4, values=True)]
[17, 35, 2, 5]
SymPy Documentation, Release 1.12.1

Code modified from:

sympy.ntheory.generate.composite(nth)
Return the nth composite number, with the composite numbers indexed as composite(1) = 4, composite(2) = 6, etc....

Examples

```python
>>> from sympy import composite
>>> composite(36)
52
>>> composite(1)
4
>>> composite(17737)
20000
```

primerange (page 1527)
Generate all primes in a given range

primepi (page 1525)
Return the number of primes less than or equal to n

prime (page 1524)
Return the nth prime

compositepi (page 1531)
Return the number of positive composite numbers less than or equal to n

sympy.ntheory.generate.compositepi(n)
Return the number of positive composite numbers less than or equal to n. The first positive composite is 4, i.e. compositepi(4) = 1.

Examples

```python
>>> from sympy import compositepi
>>> compositepi(25)
15
>>> compositepi(1000)
831
```

primerange (page 1527)
Generate all primes in a given range

5.8. Topics 1531
**prime** *(page 1524)*
Return the nth prime

**primepi** *(page 1525)*
Return the number of primes less than or equal to n

**composite** *(page 1531)*
Return the nth composite number

**sympy.ntheory.factor_.smoothness** *(page 1529)*
Return the B-smooth and B-powersmooth values of n.
The smoothness of n is the largest prime factor of n; the power-smoothness is the largest divisor raised to its multiplicity.

**Examples**

```python
>>> from sympy.ntheory.factor_ import smoothness
>>> smoothness(2**7*3**2)
(3, 128)
>>> smoothness(2**4*13)
(13, 16)
>>> smoothness(2)
(2, 2)
```

**See also:**

**factorint** *(page 1539), smoothness_p** *(page 1532)*

**sympy.ntheory.factor_.smoothness_p** *(n, m=-1, power=0, visual=None)*
Return a list of \([m, \{p, (M, sm(p + m), psm(p + m))\}...]\) where:

1. \(p^M\) is the base-p divisor of n
2. \(sm(p + m)\) is the smoothness of \(p + m\) (\(m = -1\) by default)
3. \(psm(p + m)\) is the power smoothness of \(p + m\)
The list is sorted according to smoothness (default) or by power smoothness if power=1.
The smoothness of the numbers to the left (\(m = -1\)) or right (\(m = 1\)) of a factor govern the results that are obtained from the \(+/- 1\) type factoring methods.

```python
>>> from sympy.ntheory.factor_ import smoothness_p, factorint
>>> smoothness_p(10431, m=1)
(1, [(3, (2, 2, 2)), (19, (1, 3, 9)), (61, (1, 31, 31))])
>>> smoothness_p(10431)
(-1, [(3, (2, 2, 2)), (19, (1, 3, 9)), (61, (1, 5, 5))])
>>> smoothness_p(10431, power=1)
(-1, [(3, (2, 2, 2)), (61, (1, 5, 5)), (19, (1, 3, 9))])
```

If visual=True then an annotated string will be returned:

```python
>>> print(smoothness_p(21477639576571, visual=1))
p**i=4410317**1 has p-1 B=1787, B-pow=1787
p**i=4869863**1 has p-1 B=2434931, B-pow=2434931
```

This string can also be generated directly from a factorization dictionary and vice versa:
The table of the output logic is:

<table>
<thead>
<tr>
<th>Input</th>
<th>Visual</th>
<th>True</th>
<th>False</th>
<th>other</th>
</tr>
</thead>
<tbody>
<tr>
<td>dict</td>
<td>str</td>
<td>tuple</td>
<td>str</td>
<td></td>
</tr>
<tr>
<td>str</td>
<td>str</td>
<td>tuple</td>
<td>dict</td>
<td></td>
</tr>
<tr>
<td>tuple</td>
<td>str</td>
<td>tuple</td>
<td></td>
<td>tuple</td>
</tr>
<tr>
<td>n</td>
<td>str</td>
<td>tuple</td>
<td>str</td>
<td></td>
</tr>
<tr>
<td>mul</td>
<td>str</td>
<td>tuple</td>
<td>tuple</td>
<td></td>
</tr>
</tbody>
</table>

**See also:**

`factorint` (page 1539), `smoothness` (page 1532)

sympy.ntheory.factor_.trailing(n)

Count the number of trailing zero digits in the binary representation of n, i.e. determine the largest power of 2 that divides n.

**Examples**

```python
>>> from sympy import trailing
>>> trailing(128)
7
>>> trailing(63)
0
```

sympy.ntheory.factor_.multiplicity(p, n)

Find the greatest integer m such that p**m divides n.

**Examples**

```python
>>> from sympy import multiplicity, Rational
>>> [multiplicity(5, n) for n in [8, 5, 25, 125, 250]]
[0, 1, 2, 3, 3]
>>> multiplicity(3, Rational(1, 9))
-2
```

Note: when checking for the multiplicity of a number in a large factorial it is most efficient to send it as an unevaluated factorial or to call multiplicity_in_factorial directly:
```python
>>> from sympy.ntheory import multiplicity_in_factorial
>>> from sympy import factorial
>>> p = factorial(25)
>>> n = 2**100
>>> nfac = factorial(n, evaluate=False)
>>> multiplicity(p, nfac)
5281877500950955839569596887
>>> _ == multiplicity_in_factorial(p, n)
True
```

**sympy.ntheory.factor_.perfect_power(n, candidates=None, big=True, factor=True)**

Return \((b, e)\) such that \(n = b^e\) if \(n\) is a unique perfect power with \(e > 1\), else False (e.g. 1 is not a perfect power). A ValueError is raised if \(n\) is not Rational.

By default, the base is recursively decomposed and the exponents collected so the largest possible \(e\) is sought. If \(\text{big}=\text{False}\) then the smallest possible \(e\) (thus prime) will be chosen.

If \(\text{factor}=\text{True}\) then simultaneous factorization of \(n\) is attempted since finding a factor indicates the only possible root for \(n\). This is True by default since only a few small factors will be tested in the course of searching for the perfect power.

The use of \(\text{candidates}\) is primarily for internal use; if provided, False will be returned if \(n\) cannot be written as a power with one of the candidates as an exponent and factoring (beyond testing for a factor of 2) will not be attempted.

**Examples**

```python
>>> from sympy import perfect_power, Rational
>>> perfect_power(16)
(2, 4)
>>> perfect_power(16, big=False)
(4, 2)
```

Negative numbers can only have odd perfect powers:

```python
>>> perfect_power(-4)
False
>>> perfect_power(-8)
(-2, 3)
```

Rationals are also recognized:

```python
>>> perfect_power(Rational(1, 2)**3)
(1/2, 3)
>>> perfect_power(Rational(-3, 2)**3)
(-3/2, 3)
```
Notes

To know whether an integer is a perfect power of 2 use

```python
>>> is2pow = lambda n: bool(n and not n & (n - 1))
>>> [(i, is2pow(i)) for i in range(5)]
[(0, False), (1, True), (2, True), (3, False), (4, True)]
```

It is not necessary to provide candidates. When provided it will be assumed that they are ints. The first one that is larger than the computed maximum possible exponent will signal failure for the routine.

```python
>>> perfect_power(3**8, [9])
False
>>> perfect_power(3**8, [2, 4, 8])
(3, 8)
>>> perfect_power(3**8, [4, 8], big=False)
(9, 4)
```

See also:

- `sympy.core.power.integer_nthroot` (page 1057), `sympy.ntheory.primetest.is_square` (page 1559)

```python
import cycle_length
n = 16843009
F = lambda x: (2048*pow(x, 2, n) + 32767) % n
for s in range(5):
    print('loop length = %4i; leader length = %3i' %
          next(cycle_length(F, s)))
... loop length = 2489; leader length = 42
... loop length = 78; leader length = 120
... loop length = 1482; leader length = 99
... loop length = 1482; leader length = 285
... loop length = 1482; leader length = 100
```

Here is an explicit example where there is a two element leadup to a sequence of 3 numbers (11, 14, 4) that then repeat:
```python
>>> x=2
>>> for i in range(9):
...     x=(x**2+12)%17
...     print(x)
... 16
 13
 11
 14
 4
 11
 14
 4
 11
>>> next(cycle_length(lambda x: (x**2+12)%17, 2))
(3, 2)
>>> list(cycle_length(lambda x: (x**2+12)%17, 2, values=True))
[16, 13, 11, 14, 4]
```

Instead of checking the differences of all generated values for a gcd with n, only the kth and 2*kth numbers are checked, e.g. 1st and 2nd, 2nd and 4th, 3rd and 6th until it has been detected that the loop has been traversed. Loops may be many thousands of steps long before rho finds a factor or reports failure. If max_steps is specified, the iteration is cancelled with a failure after the specified number of steps.

**Examples**

```python
>>> from sympy import pollard_rho
>>> n=16843009
>>> F=lambda x: (2048* pow(x, 2, n) + 32767) % n
>>> pollard_rho(n, F=F)
257
```

Use the default setting with a bad value of a and no retries:

```python
>>> pollard_rho(n, a=n-2, retries=0)
```

If retries is > 0 then perhaps the problem will correct itself when new values are generated for a:

```python
>>> pollard_rho(n, a=n-2, retries=1)
257
```
Use Pollard’s p-1 method to try to extract a nontrivial factor of \( n \). Either a divisor (perhaps composite) or None is returned.

The value of \( a \) is the base that is used in the test \( \text{gcd}(a^{M}-1, n) \). The default is 2. If \( \text{retries} > 0 \) then if no factor is found after the first attempt, a new \( a \) will be generated randomly (using the seed) and the process repeated.

Note: the value of \( M \) is \( \text{lcm}(1..B) = \text{reduce}(\text{lcm}, \text{range}(2, B+1)) \).

A search is made for factors next to even numbers having a power smoothness less than \( B \). Choosing a larger \( B \) increases the likelihood of finding a larger factor but takes longer. Whether a factor of \( n \) is found or not depends on \( a \) and the power smoothness of the even number just less than the factor \( p \) (hence the name \( p-1 \)).

Although some discussion of what constitutes a good \( a \) some descriptions are hard to interpret. At the modular.math site referenced below it is stated that if \( \text{gcd}(a^{M}-1, n) = N \) then \( a^{M} \% q^{\ast} r \) is 1 for every prime power divisor of \( N \). But consider the following:

```
>>> from sympy.ntheory.factor_. import smoothness_p, pollard_pm1
>>> n=257*1009
>>> smoothness_p(n)
(-1, [(257, (1, 2, 256)), (1009, (1, 7, 16))])
```

So we should (and can) find a root with \( B=16 \):

```
>>> pollard_pm1(n, B=16, a=3)
1009
```

If we attempt to increase \( B \) to 256 we find that it does not work:

```
>>> pollard_pm1(n, B=256)
```

But if the value of \( a \) is changed we find that only multiples of 257 work, e.g.:

```
>>> pollard_pm1(n, B=256, a=257)
1009
```

Checking different \( a \) values shows that all the ones that did not work had a \( \text{gcd} \) value not equal to \( n \) but equal to one of the factors:

```
>>> from sympy import ilcm, igcd, factorint, Pow
>>> M = 1
>>> for i in range(2, 256):
...    M = ilcm(M, i)
...   ...
...    for a in range(2, 256) if
...       igcd(pow(a, M, n) - 1, n) != n)
... (1009)
```

But does \( aM \% d \) for every divisor of \( n \) give 1?
>>> aM = pow(255, M, n)
>>> [(d, aM % Pow(*d.args)) for d in factorint(n, visual=True).args]
[(257**1, 1), (1009**1, 1)]

No, only one of them. So perhaps the principle is that a root will be found for a given value of B provided that:

1) the power smoothness of the p - 1 value next to the root does not exceed B
2) a**M % p != 1 for any of the divisors of n.

By trying more than one a it is possible that one of them will yield a factor.

Examples

With the default smoothness bound, this number cannot be cracked:

```python
>>> from sympy.ntheory import pollard_pm1
>>> pollard_pm1(21477639576571)
```

Increasing the smoothness bound helps:

```python
>>> pollard_pm1(21477639576571, B=2000)
4410317
```

Looking at the smoothness of the factors of this number we find:

```python
>>> from sympy.ntheory.factor_ import smoothness_p, factorint
>>> print(smoothness_p(21477639576571, visual=1))
p**i=4410317**1 has p-1 B=1787, B-pow=1787
p**i=4869863**1 has p-1 B=2434931, B-pow=2434931
```

The B and B-pow are the same for the p - 1 factorizations of the divisors because those factorizations had a very large prime factor:

```python
>>> factorint(4410317 - 1)
{2: 2, 617: 1, 1787: 1}
>>> factorint(4869863-1)
{2: 1, 2434931: 1}
```

Note that until B reaches the B-pow value of 1787, the number is not cracked;

```python
>>> pollard_pm1(21477639576571, B=1786)
>>> pollard_pm1(21477639576571, B=1787)
4410317
```

The B value has to do with the factors of the number next to the divisor, not the divisors themselves. A worst case scenario is that the number next to the factor p has a large prime divisor or is a perfect power. If these conditions apply then the power-smoothness will be about p/2 or p. The more realistic is that there will be a large prime factor next to p requiring a B value on the order of p/2. Although primes may have been searched for up to this level, the p/2 is a factor of p - 1, something that we do not know. The modular.math reference below states that 15% of numbers in the range of 10**15 to 15**15 + 10**4 are 10**6 power smooth so a B of 10**6 will fail 85% of the time in
that range. From $10^8$ to $10^8 + 10^3$ the percentages are nearly reversed...but in that range the simple trial division is quite fast.

**References**

sympy.ntheory.factorint\( \text{factorint}(n, \text{limit=None, use_trial=True, use_rho=True, use_pm1=True, use_ecm=True, verbose=False, visual=None, multiple=False}) \)

Given a positive integer \( n \), \text{factorint}(n) returns a dict containing the prime factors of \( n \) as keys and their respective multiplicities as values. For example:

```python
>>> from sympy.ntheory import factorint
>>> factorint(2000)  # 2000 = (2**4) * (5**3)
{2: 4, 5: 3}
>>> factorint(65537)  # This number is prime
{65537: 1}
```

For input less than 2, \text{factorint} behaves as follows:

- \text{factorint}(1) returns the empty factorization, {}
- \text{factorint}(0) returns {0: 1}
- \text{factorint}(-n) adds -1:1 to the factors and then factors \( n \)

**Partial Factorization:**

If \text{limit} (> 3) is specified, the search is stopped after performing trial division up to (and including) the limit (or taking a corresponding number of rho/p-1 steps). This is useful if one has a large number and only is interested in finding small factors (if any). Note that setting a limit does not prevent larger factors from being found early; it simply means that the largest factor may be composite. Since checking for perfect power is relatively cheap, it is done regardless of the limit setting.

This number, for example, has two small factors and a huge semi-prime factor that cannot be reduced easily:

```python
>>> from sympy.ntheory import isprime
>>> a = 140763371726233095743069721446883
>>> f = factorint(a, limit=10000)
>>> f == {991: 1, int(202916782076162456022877024859): 1, 7: 1}
True
>>> isprime(max(f))
False
```

This number has a small factor and a residual perfect power whose base is greater than the limit:

```python
>>> factorint(3*101**7, limit=5)
{3: 1, 101: 7}
```

**List of Factors:**

If \text{multiple} is set to \text{True} then a list containing the prime factors including multiplicities is returned.
>>> factorint(24, multiple=True)
[2, 2, 2, 3]

Visual Factorization:

If visual is set to True, then it will return a visual factorization of the integer. For example:

```python
>>> from sympy import pprint
>>> pprint(factorint(4200, visual=True))
3 1 2 1
2 *3 *5 *7
```

Note that this is achieved by using the evaluate=False flag in Mul and Pow. If you do other manipulations with an expression where evaluate=False, it may evaluate. Therefore, you should use the visual option only for visualization, and use the normal dictionary returned by visual=False if you want to perform operations on the factors.

You can easily switch between the two forms by sending them back to factorint:

```python
>>> from sympy import Mul
>>> regular = factorint(1764); regular
{2: 2, 3: 2, 7: 2}
>>> pprint(factorint(regular))
2 2
2 *3 *7
```

```python
>>> visual = factorint(1764, visual=True); pprint(visual)
2 2
2 *3 *7
>>> pprint(factorint(visual))
{2: 2, 3: 2, 7: 2}
```

If you want to send a number to be factored in a partially factored form you can do so with a dictionary or unevaluated expression:

```python
>>> factorint(factorint({4: 2, 12: 3})) # twice to toggle to dict form
{2: 10, 3: 3}
>>> factorint(Mul(4, 12, evaluate=False))
{2: 4, 3: 1}
```

The table of the output logic is:

<table>
<thead>
<tr>
<th>Input</th>
<th>True</th>
<th>False</th>
<th>other</th>
</tr>
</thead>
<tbody>
<tr>
<td>dict</td>
<td>mul</td>
<td>dict</td>
<td>mul</td>
</tr>
<tr>
<td>n</td>
<td>mul</td>
<td>dict</td>
<td>dict</td>
</tr>
<tr>
<td>mul</td>
<td>mul</td>
<td>dict</td>
<td>dict</td>
</tr>
</tbody>
</table>
Notes

Algorithm:

The function switches between multiple algorithms. Trial division quickly finds small factors (of the order 1-5 digits), and finds all large factors if given enough time. The Pollard rho and p-1 algorithms are used to find large factors ahead of time; they will often find factors of the order of 10 digits within a few seconds:

```python
>>> factors = factorint(1234567891011213141516)
>>> for base, exp in sorted(factors.items()):
...     print('%s %s % (base, exp))
...
2 2
2507191691 1
1231026625769 1
```

Any of these methods can optionally be disabled with the following boolean parameters:

- `use_trial`: Toggle use of trial division
- `use_rho`: Toggle use of Pollard’s rho method
- `use_pm1`: Toggle use of Pollard’s p-1 method

`factorint` also periodically checks if the remaining part is a prime number or a perfect power, and in those cases stops.

For unevaluated factorial, it uses Legendre’s formula (theorem).

If `verbose` is set to True, detailed progress is printed.

See also:

- `smoothness` (page 1532), `smoothness_p` (page 1532), `divisors` (page 1542)
- `sympy.ntheory.factor_.factorrat(rat, limit=None, use_trial=True, use_rho=True, use_pm1=True, verbose=False, visual=None, multiple=False)`

Given a Rational `r`, `factorrat(r)` returns a dict containing the prime factors of `r` as keys and their respective multiplicities as values. For example:

```python
>>> from sympy import factorrat, S
>>> factorrat(S(8)/9)  # 8/9 = (2**3) * (3**-2)
{2: 3, 3: -2}
>>> factorrat(S(-1)/987)  # -1/789 = -1 * (3**-1) * (7**-1) * (47**-1)
{-1: 1, 3: -1, 7: -1, 47: -1}
```

Please see the docstring for `factorint` for detailed explanations and examples of the following keywords:

- `limit`: Integer limit up to which trial division is done
- `use_trial`: Toggle use of trial division
- `use_rho`: Toggle use of Pollard’s rho method
- `use_pm1`: Toggle use of Pollard’s p-1 method
- `verbose`: Toggle detailed printing of progress
- `multiple`: Toggle returning a list of factors or dict
• visual: Toggle product form of output

sympy.ntheory.factor_.primesfactors\( (n, \text{limit=None, } \text{verbose=False}) \)

Return a sorted list of n’s prime factors, ignoring multiplicity and any composite factor that remains if the limit was set too low for complete factorization. Unlike factorint(), primefactors() does not return -1 or 0.

**Examples**

```python
>>> from sympy.ntheory import primefactors, factorint, isprime
>>> primefactors(6)
[2, 3]
>>> primefactors(-5)
[5]

>>> sorted(factorint(123456).items())
[(2, 6), (3, 1), (643, 1)]
>>> primefactors(123456)
[2, 3, 643]

>>> sorted(factorint(10000000001, limit=200).items())
[(101, 1), (99009901, 1)]
>>> isprime(99009901)
False
>>> primefactors(10000000001, limit=300)
[101]
```

**See also:**
divisors (page 1542)

sympy.ntheory.factor_.divisors\( (n, \text{generator=False, proper=False}) \)

Return all divisors of n sorted from 1..n by default. If generator is True an unordered generator is returned.

The number of divisors of n can be quite large if there are many prime factors (counting repeated factors). If only the number of factors is desired use divisor_count(n).

**Examples**

```python
>>> from sympy import divisors, divisor_count
>>> divisors(24)
[1, 2, 3, 4, 6, 8, 12, 24]
>>> divisor_count(24)
8

>>> list(divisors(120, generator=True))
[1, 2, 4, 8, 3, 6, 12, 24, 5, 10, 20, 40, 15, 30, 60, 120]
```
Notes

This is a slightly modified version of Tim Peters referenced at: https://stackoverflow.com/questions/1010381/python-factorization

See also:

primefactors (page 1542), factorint (page 1539), divisor_count (page 1543)

sympy.ntheory.factor_.proper_divisors(n, generator=False)

Return all divisors of n except n, sorted by default. If generator is True an unordered generator is returned.

Examples

>>> from sympy import proper_divisors, proper_divisor_count
>>> proper_divisors(24)
[1, 2, 3, 4, 6, 8, 12]
>>> proper_divisor_count(24)
7
>>> list(proper_divisors(120, generator=True))
[1, 2, 4, 8, 3, 6, 12, 24, 5, 10, 20, 40, 15, 30, 60]

See also:

factorint (page 1539), divisors (page 1542), proper_divisor_count (page 1543)

sympy.ntheory.factor_.divisor_count(n, modulus=1, proper=False)

Return the number of divisors of n. If modulus is not 1 then only those that are divisible by modulus are counted. If proper is True then the divisor of n will not be counted.

Examples

>>> from sympy import divisor_count
>>> divisor_count(6)
4
>>> divisor_count(6, 2)
2
>>> divisor_count(6, proper=True)
3

See also:

factorint (page 1539), divisors (page 1542), totient (page 1546), proper_divisor_count (page 1543)

sympy.ntheory.factor_.proper_divisor_count(n, modulus=1)

Return the number of proper divisors of n.
Examples

```python
>>> from sympy import proper_divisor_count
>>> proper_divisor_count(6)
3
>>> proper_divisor_count(6, modulus=2)
1
```

See also:

- `divisors` (page 1542), `proper_divisors` (page 1543), `divisor_count` (page 1543)

```python
>>> from sympy.ntheory.factor_ import udivisors, udivisor_count
>>> udivisors(15)
[1, 3, 5, 15]
>>> udivisor_count(15)
4
```

```python
>>> sorted(udivisors(120, generator=True))
[1, 3, 5, 8, 15, 24, 40, 120]
```

See also:

- `primefactors` (page 1542), `factorint` (page 1539), `divisors` (page 1542),
  `divisor_count` (page 1543), `udivisor_count` (page 1544)

References

- [R628], [R629]

```python
sympy.ntheory.factor_.udivisor_count(n)
```

Return the number of unitary divisors of `n`.

Parameters

- `n` : integer
Examples

```python
>>> from sympy.ntheory.factor_ import udivisor_count
>>> udivisor_count(120)
8
```

[R630]
sympy.ntheory.factor_.antidivisors(n, generator=False)

Return all antidivisors of n sorted from 1..n by default.

Antidivisors [R631] of n are numbers that do not divide n by the largest possible margin. If generator is True an unordered generator is returned.

Examples

```python
>>> from sympy.ntheory.factor_ import antidivisors
>>> antidivisors(24)
[7, 16]
>>> sorted(antidivisors(128, generator=True))
[3, 5, 15, 17, 51, 85]
```

`primefactors` (page 1542), `factorint` (page 1539), `divisors` (page 1542), `divisor_count` (page 1543), `antidivisor_count` (page 1545)

References

[R631]
sympy.ntheory.factor_.antidivisor_count(n)

Return the number of antidivisors [R632] of n.

Parameters

- **n**: integer
SymPy Documentation, Release 1.12.1

Examples

```python
>>> from sympy.ntheory.factor_ import antidivisor_count
>>> antidivisor_count(13)
4
>>> antidivisor_count(27)
5
```

  `divisor_count` (page 1543), `totient` (page 1546)

References

[R632]

```python
class sympy.ntheory.factor_.totient(n)
```

Calculate the Euler totient function $\phi(n)$

$\phi(n)$ or $\phi(n)$ is the number of positive integers $\leq n$ that are relatively prime to $n$.

Parameters

- **n**: integer

Examples

```python
>>> from sympy.ntheory import totient
>>> totient(1)
1
>>> totient(25)
20
>>> totient(45) == totient(5)*totient(9)
True
```

See also:

* `divisor_count` (page 1543)

References

[R633], [R634]

```python
class sympy.ntheory.factor_.reduced_totient(n)
```

Calculate the Carmichael reduced totient function $\lambda(n)$

$\lambda(n)$ or $\lambda(n)$ is the smallest $m > 0$ such that $k^m \equiv 1 \mod n$ for all $k$

relatively prime to $n$. 

```
Examples

```python
>>> from sympy.ntheory import reduced_totient
>>> reduced_totient(1)
1
>>> reduced_totient(8)
2
>>> reduced_totient(30)
4
```

See also:

totient (page 1546)

References

[R635], [R636]

```python
class sympy.ntheory.factor_.divisor_sigma(n, k=1)
```

Calculate the divisor function \( \sigma_k(n) \) for positive integer \( n \)

\[
\text{divisor}_\sigma(n, k) = \text{sum}([x**k for x in \text{divisors}(n)])
\]

If \( n \)'s prime factorization is:

\[
n = \prod_{i=1}^{\omega} p_i^{m_i},
\]

then

\[
\sigma_k(n) = \prod_{i=1}^{\omega} (1 + p_i^k + p_i^{2k} + \cdots + p_i^{m_i k}).
\]

Parameters

- **n**: integer
- **k**: integer, optional

  power of divisors in the sum

  for \( k = 0, 1 \): \( \text{divisor}_\sigma(n, 0) \) is equal to \( \text{divisor}_\text{count}(n) \)

  \( \text{divisor}_\sigma(n, 1) \) is equal to \( \text{sum}(\text{divisors}(n)) \)

  Default for \( k \) is 1.

Examples

```python
>>> from sympy.ntheory import divisor_sigma
>>> divisor_sigma(18, 0)
6
>>> divisor_sigma(39, 1)
56
>>> divisor_sigma(12, 2)
210
>>> divisor_sigma(37)
38
```
class sympy.ntheory.factor_.udivisor_sigma(n, k=1)

Calculate the unitary divisor function $\sigma_k^u(n)$ for positive integer $n$

$\text{udivisor}_\sigma(n, k)$ is equal to $\sum([x**k \text{ for } x \text{ in } udivisors(n)])$

If $n$'s prime factorization is:

$$n = \prod_{i=1}^{\omega} p_i^{m_i},$$

then

$$\sigma_k^u(n) = \prod_{i=1}^{\omega} (1 + p_i^{m_i/k}).$$

Parameters

- **k**: power of divisors in the sum

  for $k = 0, 1$: $\text{udivisor}_\sigma(n, 0)$ is equal to $\text{udivisor}_\text{count}(n)$
  $\text{udivisor}_\sigma(n, 1)$ is equal to $\sum(\text{udivisors}(n))$

Default for $k$ is $1$.

Examples

```python
>>> from sympy.ntheory.factor_ import udivisor_sigma
>>> udivisor_sigma(18, 0)
4
>>> udivisor_sigma(74, 1)
114
>>> udivisor_sigma(36, 3)
47450
>>> udivisor_sigma(111)
152
```

See also:

- $\text{divisor}_\text{count}$ (page 1543), $\text{totient}$ (page 1546), $\text{divisors}$ (page 1542), $\text{factorint}$ (page 1539)
References

[R638]
sympy.ntheory.factor_.core(n, t=2)
Calculate \( \text{core}(n, t) = \text{core}_t(n) \) of a positive integer \( n \)
core_2(n) is equal to the squarefree part of \( n \)
If \( n \)'s prime factorization is:
\[
n = \prod_{i=1}^{\omega} p_i^{m_i},
\]
then
\[
\text{core}_t(n) = \prod_{i=1}^{\omega} p_i^{m_i \mod t}.
\]

Parameters
- \( n \): integer
- \( t \): integer
  core\( n, t \) calculates the \( t \)-th power free part of \( n \)
  core\( n, 2 \) is the squarefree part of \( n \) core\( n, 3 \) is the cubefree part of \( n \)
  Default for \( t \) is 2.

Examples

```python
>>> from sympy.ntheory.factor_ import core
>>> core(24, 2)
6
>>> core(9424, 3)
1178
>>> core(379238)
379238
>>> core(15**11, 10)
15
```

See also:
- factorint (page 1539), sympy.solvers.diophantine.diophantine.square_factor (page 785)
References

[R639]
sympy.ntheory.factor_.digits(n, b=10, digits=None)
Return a list of the digits of n in base b. The first element in the list is b (or -b if n is negative).

Parameters
n: integer
   The number whose digits are returned.
b: integer
   The base in which digits are computed.
digits: integer (or None for all digits)
   The number of digits to be returned (padded with zeros, if necessary).

Examples

>>> from sympy.ntheory.digits import digits
>>> digits(35)
[10, 3, 5]
If the number is negative, the negative sign will be placed on the base (which is the first element in the returned list):

>>> digits(-35)
[-10, 3, 5]
Bases other than 10 (and greater than 1) can be selected with b:

>>> digits(27, b=2)
[2, 1, 1, 0, 1, 1]
Use the digits keyword if a certain number of digits is desired:

>>> digits(35, digits=4)
[10, 0, 0, 3, 5]

class sympy.ntheory.factor_.primenu(n)
Calculate the number of distinct prime factors for a positive integer n.
If n's prime factorization is:

\[ n = \prod_{i=1}^{k} p_i^{m_i}, \]

then primenu(n) or \( \nu(n) \) is:

\[ \nu(n) = k. \]
Examples

```python
>>> from sympy.ntheory.factor_ import primenu
>>> primenu(1)
0
>>> primenu(30)
3
```

See also:
`factorint` (page 1539)

References

[R640]

**class** sympy.ntheory.factor_.primeomega(n)

Calculate the number of prime factors counting multiplicities for a positive integer n.

If n’s prime factorization is:

\[ n = \prod_{i=1}^{k} p_i^{m_i}, \]

then primeomega(n) or \( \Omega(n) \) is:

\[ \Omega(n) = \sum_{i=1}^{k} m_i. \]

Examples

```python
>>> from sympy.ntheory.factor_ import primeomega
>>> primeomega(1)
0
>>> primeomega(20)
3
```

See also:
`factorint` (page 1539)

References

[R641]

sympy.ntheory.factor_.mersenne_prime_exponent(nth)

Returns the exponent i for the nth Mersenne prime (which has the form \( 2^i - 1 \)).
Examples

```python
>>> from sympy.ntheory.factor_ import mersenne_prime_exponent
>>> mersenne_prime_exponent(1)
2
>>> mersenne_prime_exponent(20)
4423
```

sympy.ntheory.factor_.is_perfect(n)

Returns True if n is a perfect number, else False.

A perfect number is equal to the sum of its positive, proper divisors.

Examples

```python
>>> from sympy.ntheory.factor_ import is_perfect, divisors, divisor_sigma
>>> is_perfect(20)
False
>>> is_perfect(6)
True
>>> 6 == divisor_sigma(6) - 6 == sum(divisors(6)[:-1])
True
```

References

[R642], [R643]

sympy.ntheory.factor_.is_mersenne_prime(n)

Returns True if n is a Mersenne prime, else False.

A Mersenne prime is a prime number having the form $2^i - 1$.

Examples

```python
>>> from sympy.ntheory.factor_ import is_mersenne_prime
>>> is_mersenne_prime(6)
False
>>> is_mersenne_prime(127)
True
```
**References**

[R644]

sympy.ntheory.factor_.abundance\((n)\)

Returns the difference between the sum of the positive proper divisors of a number and the number.

**Examples**

```python
>>> from sympy.ntheory import abundance, is_perfect, is_abundant
>>> abundance(6)
0
>>> is_perfect(6)
True
>>> abundance(10)
-2
>>> is_abundant(10)
False
```

sympy.ntheory.factor_.is_abundant\((n)\)

Returns True if \(n\) is an abundant number, else False.

A abundant number is smaller than the sum of its positive proper divisors.

**Examples**

```python
>>> from sympy.ntheory.factor_ import is_abundant
>>> is_abundant(20)
True
>>> is_abundant(15)
False
```

**References**

[R645]

sympy.ntheory.factor_.is_deficient\((n)\)

Returns True if \(n\) is a deficient number, else False.

A deficient number is greater than the sum of its positive proper divisors.
**SymPy Documentation, Release 1.12.1**

### Examples

```python
>>> from sympy.ntheory.factor_ import is_deficient
>>> is_deficient(20)
False
>>> is_deficient(15)
True
```

### References

[R646]

sympy.ntheory.factor_.is_amicable(m, n)

Returns True if the numbers \( m \) and \( n \) are “amicable”, else False.

Amicable numbers are two different numbers so related that the sum of the proper divisors of each is equal to that of the other.

### Examples

```python
>>> from sympy.ntheory.factor_ import is_amicable, divisor_sigma
>>> is_amicable(220, 284)
True
>>> divisor_sigma(220) == divisor_sigma(284)
True
```

### References

[R647]

sympy.ntheory.modular.symmetric_residue(a, m)

Return the residual mod \( m \) such that it is within half of the modulus.

```python
>>> from sympy.ntheory.modular import symmetric_residue
>>> symmetric_residue(1, 6)
1
>>> symmetric_residue(4, 6)
-2
```

sympy.ntheory.modular.crt(m, v, symmetric=False, check=True)

Chinese Remainder Theorem.

The moduli in \( m \) are assumed to be pairwise coprime. The output is then an integer \( f \), such that \( f = v_i \mod m_i \) for each pair out of \( v \) and \( m \). If symmetric is False a positive integer will be returned, else \(|f|\) will be less than or equal to the LCM of the moduli, and thus \( f \) may be negative.

If the moduli are not co-prime the correct result will be returned if/when the test of the result is found to be incorrect. This result will be None if there is no solution.

The keyword check can be set to False if it is known that the moduli are coprime.
Examples

As an example consider a set of residues \( U = [49, 76, 65] \) and a set of moduli \( M = [99, 97, 95] \). Then we have:

```python
from sympy.ntheory.modular import crt

crt([99, 97, 95], [49, 76, 65])  # (639985, 912285)
```

This is the correct result because:

```python
[639985 % m for m in [99, 97, 95]]  # [49, 76, 65]
```

If the moduli are not co-prime, you may receive an incorrect result if you use `check=False`:

```python
crt([[12, 6, 17], [3, 4, 2]], check=False)  # (954, 1224)

crt([[12, 6, 17], [3, 4, 2]])  # is None
```

Note: the order of \( \text{gf} \cdot \text{crt} \)'s arguments is reversed relative to \( \text{crt} \), and that \( \text{solve} \cdot \text{congruence} \) takes residue, modulus pairs.

Programmer’s note: rather than checking that all pairs of moduli share no GCD (an \( O(n^2) \) test) and rather than factoring all moduli and seeing that there is no factor in common, a check that the result gives the indicated residuals is performed – an \( O(n) \) operation.

See also:

- solve_congruence (page 1556)
- sympy.polys.galoistools.gf_crt (page 2684)
  - low level \( \text{crt} \) routine used by this routine
- sympy.ntheory.modular.crt1 \( (m) \)
  - First part of Chinese Remainder Theorem, for multiple application.

Examples

```python
from sympy.ntheory.modular import crt1
crt1([18, 42, 6])  # (4536, [252, 108, 756], [0, 2, 0])
```

sympy.ntheory.modular.crt2 \( (m, v, mm, e, s, \text{symmetric=}False) \)
  - Second part of Chinese Remainder Theorem, for multiple application.
sympy.ntheory.modular.solve_congruence(*remainder_modulus_pairs, **hint)

Compute the integer \( n \) that has the residual \( a_i \) when it is divided by \( m_i \) where the \( a_i \) and \( m_i \) are given as pairs to this function: \( ((a_1, m_1), (a_2, m_2), ...) \). If there is no solution, return None. Otherwise return \( n \) and its modulus.

The \( m_i \) values need not be co-prime. If it is known that the moduli are not co-prime then the hint check can be set to False (default=True) and the check for a quicker solution via \( \text{crt}() \) (valid when the moduli are co-prime) will be skipped.

If the hint symmetric is True (default is False), the value of \( n \) will be within 1/2 of the modulus, possibly negative.

Examples

```python
>>> from sympy.ntheory.modular import solve_congruence

What number is 2 mod 3, 3 mod 5 and 2 mod 7?

>>> solve_congruence((2, 3), (3, 5), (2, 7))
(23, 105)
>>> [23 % m for m in [3, 5, 7]]
[2, 3, 2]

If you prefer to work with all remainder in one list and all moduli in another, send the arguments like this:

>>> solve_congruence(*zip(((2, 3), (2, 7))))
(23, 105)

The modulie need not be co-prime; in this case there may or may not be a solution:

>>> solve_congruence((2, 3), (4, 6)) is None
True

>>> solve_congruence((2, 3), (5, 6))
(5, 6)

The symmetric flag will make the result be within 1/2 of the modulus:

>>> solve_congruence((2, 3), (5, 6), symmetric=True)
(-1, 6)
```

See also:

crt (page 1554)  
high level routine implementing the Chinese Remainder Theorem
sympy.ntheory.multinomial.binomial_coefficients(n)
Return a dictionary containing pairs \((k_1, k_2) : C_{kn}\) where \(C_{kn}\) are binomial coefficients and \(n = k_1 + k_2\).

**Examples**

```python
>>> from sympy.ntheory import binomial_coefficients
>>> binomial_coefficients(9)
```

**See also:**
- `binomial_coefficients_list` (page 1557), `multinomial_coefficients_list` (page 1557)

sympy.ntheory.multinomial.binomial_coefficients_list(n)
Return a list of binomial coefficients as rows of the Pascal’s triangle.

**Examples**

```python
>>> from sympy.ntheory import binomial_coefficients_list
>>> binomial_coefficients_list(9)
[1, 9, 36, 84, 126, 126, 84, 36, 9, 1]
```

**See also:**
- `binomial_coefficients` (page 1556), `multinomial_coefficients` (page 1557)

sympy.ntheory.multinomial.multinomial_coefficients(m, n)
Return a dictionary containing pairs \(\{(k_1, k_2, \ldots, k_m) : C_{kn}\}\) where \(C_{kn}\) are multinomial coefficients such that \(n = k_1 + k_2 + \ldots + k_m\).

**Examples**

```python
>>> from sympy.ntheory import multinomial_coefficients
>>> multinomial_coefficients(2, 5) # indirect doctest
{(0, 5): 1, (1, 4): 5, (2, 3): 10, (3, 2): 10, (4, 1): 5, (5, 0): 1}
```

**Notes**
The algorithm is based on the following result:

\[
\binom{n}{k_1, \ldots, k_m} = \frac{k_1 + 1}{n - k_1} \sum_{i=2}^{m} \binom{n}{k_1 + 1, \ldots, k_i - 1, \ldots}
\]

**SymPy Documentation, Release 1.12.1**

`multinomial_coefficients_iterator(m, n, _tuple=<class 'tuple'>)`

This function takes an m-tuple of non-negative integers and returns an iterator over the multinomial coefficients for that tuple.

It has been optimized for large m with respect to n by taking advantage of the fact that when the monomial tuples t are stripped of zeros, their coefficient is the same as that of the monomial tuples from `multinomial_coefficients(n, n)`. Therefore, the latter coefficients are precomputed to save memory and time.

```python
>>> from sympy.ntheory.multinomial import multinomial_coefficients
>>> m53, m33 = multinomial_coefficients(5, 3), multinomial_coefficients(3, 3)
>>> m53[(0,0,0,1,2)] == m53[(0,0,1,0,2)] == m53[(1,0,2,0,0)] == m33[(0,1,2)]
True
```

**Examples**

```python
>>> from sympy.ntheory.multinomial import multinomial_coefficients_iterator
>>> it = multinomial_coefficients_iterator(20,3)
>>> next(it)
((3, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0), 1)
```

`npartitions(n, verbose=False)`

This function calculates the partition function P(n), i.e. the number of ways that n can be written as a sum of positive integers.

P(n) is computed using the Hardy-Ramanujan-Rademacher formula [R648]. The correctness of this implementation has been tested through $10^{10}$.

**Examples**

```python
>>> from sympy.ntheory import npartitions
>>> npartitions(25)
1958
```

**References**

[R648]

`is_euler_pseudoprime(n, b)`

This function returns True if n is prime or an Euler pseudoprime to base b, else False.

Euler Pseudoprime: In arithmetic, an odd composite integer n is called an euler pseudoprime to base a, if a and n are coprime and satisfy the modular arithmetic congruence relation:

\[ a^{(n-1)/2} = +1 \mod n \text{ or } a^{(n-1)/2} = -1 \mod n \]

(where mod refers to the modulo operation).
Examples

```python
>>> from sympy.ntheory.primeutil import is_euler_pseudoprime
>>> is_euler_pseudoprime(2, 5)
True
```

References

[R649] sympy.ntheory.primeutil.is_square(n, prep=True)
Return True if \( n = a \cdot a \) for some integer \( a \), else False. If \( n \) is suspected of not being a square then this is a quick method of confirming that it is not.

Examples

```python
>>> from sympy.ntheory.primeutil import is_square
>>> is_square(25)
True
>>> is_square(2)
False
```

See also:
sympy.core.power.integer_nthroot (page 1057)

References

[R650] sympy.ntheory.primeutil.mr(n, bases)
Perform a Miller-Rabin strong pseudoprime test on \( n \) using a given list of bases/witnesses.

Examples

```python
>>> from sympy.ntheory.primeutil import mr
>>> mr(1373651, [2, 3])
False
>>> mr(479001599, [31, 73])
True
```
References

A list of thresholds and the bases they require are here: https://en.wikipedia.org/wiki/Miller%E2%80%93Rabin_primality_test#Deterministic_variants

[R651]
sympy.ntheory.primetest.is_lucas_prp(n)

Standard Lucas compositeness test with Selfridge parameters. Returns False if n is definitely composite, and True if n is a Lucas probable prime.

This is typically used in combination with the Miller-Rabin test.

Examples

```python
>>> from sympy.ntheory.primetest import isprime, is_lucas_prp
>>> for i in range(10000):
...     if is_lucas_prp(i) and not isprime(i):
...         print(i)
323
377
1159
1829
3827
5459
5777
9071
9179
```

References

- OEIS A217120: Lucas Pseudoprimes https://oeis.org/A217120

sympy.ntheory.primetest.is_strong_lucas_prp(n)

Strong Lucas compositeness test with Selfridge parameters. Returns False if n is definitely composite, and True if n is a strong Lucas probable prime.

This is often used in combination with the Miller-Rabin test, and in particular, when combined with M-R base 2 creates the strong BPSW test.
Examples

```python
>>> from sympy.ntheory.primetest import isprime, is_strong_lucas_prp
>>> for i in range(20000):
...     if is_strong_lucas_prp(i) and not isprime(i):
...         print(i)
5459
5777
10877
16109
18971
```

References

- OEIS A217255: Strong Lucas Pseudoprimes [https://oeis.org/A217255](https://oeis.org/A217255)
- [https://en.wikipedia.org/wiki/Baillie-PSW_primality_test](https://en.wikipedia.org/wiki/Baillie-PSW_primality_test)

```python
sympy.ntheory.primetest.is_extra_strong_lucas_prp(n)
```

Extra Strong Lucas compositeness test. Returns False if n is definitely composite, and True if n is a “extra strong” Lucas probable prime.

The parameters are selected using P = 3, Q = 1, then incrementing P until (D|n) == -1. The test itself is as defined in Grantham 2000, from the Mo and Jones preprint. The parameter selection and test are the same as used in OEIS A217719, Perl's Math::Prime::Util, and the Lucas pseudoprime page on Wikipedia.

With these parameters, there are no counterexamples below $2^{64}$ nor any known above that range. It is 20-50% faster than the strong test.

Because of the different parameters selected, there is no relationship between the strong Lucas pseudoprimes and extra strong Lucas pseudoprimes. In particular, one is not a subset of the other.

Examples

```python
>>> from sympy.ntheory.primetest import isprime, is_extra_strong_lucas_prp
>>> for i in range(20000):
...     if is_extra_strong_lucas_prp(i) and not isprime(i):
...         print(i)
989
3239
5777
10877
```
References

- OEIS A217719: Extra Strong Lucas Pseudoprimes https://oeis.org/A217719

```python
>>> from sympy.ntheory import isprime
>>> isprime(13)
True
>>> isprime(13.0)  # limited precision
False
>>> isprime(15)
False
```

Examples

```
>>> from sympy.ntheory import isprime
>>> isprime(13)
True
>>> isprime(13.0)  # limited precision
False
>>> isprime(15)
False
```

Notes

This routine is intended only for integer input, not numerical expressions which may represent numbers. Floats are also rejected as input because they represent numbers of limited precision. While it is tempting to permit 7.0 to represent an integer there are errors that may “pass silently” if this is allowed:

```
>>> from sympy import Float, S
>>> int(1e3) == 1e3 == 10**3
True
>>> int(1e23) == 1e23
True
>>> int(1e23) == 10**23
False
```

```
>>> near_int = 1 + S(1)/10**19
>>> near_int == int(near_int)
False
>>> n = Float(near_int, 10)  # truncated by precision
>>> n == int(n)
```

(continues on next page)
True
>>> n = Float(near_int, 20)
>>> n == int(n)
False

[R652]

**sympy.ntheory.residue_ntheory.n_order***(a, n)
Returns the order of a modulo n.
The order of a modulo n is the smallest integer k such that a**k leaves a remainder of 1 with n.

Parameters

- **a** : integer
- **n** : integer, n > 1. a and n should be relatively prime

Examples

```python
>>> from sympy.ntheory import n_order
>>> n_order(3, 7)
6
>>> n_order(4, 7)
3
```
sympy.ntheory.residue_ntheory.is_primitive_root(a, p)
  Returns True if a is a primitive root of p.
  a is said to be the primitive root of p if \( \gcd(a, p) = 1 \) and \( \text{totient}(p) \) is the smallest positive number s.t.
  \[ a^{\text{totient}(p)} \equiv 1 \pmod{p} \]

  **Parameters**
  - a : integer
  - p : integer, \( p > 1 \). a and p should be relatively prime

  **Examples**

  ```
  >>> from sympy.ntheory import is_primitive_root, n_order, totient
  >>> is_primitive_root(3, 10)
  True
  >>> is_primitive_root(9, 10)
  False
  >>> n_order(3, 10) == totient(10)
  True
  >>> n_order(9, 10) == totient(10)
  False
  ```

sympy.ntheory.residue_ntheory.primitive_root(p)
  Returns the smallest primitive root or None.

  **Parameters**
  - p : positive integer

  **Examples**

  ```
  >>> from sympy.ntheory.residue_ntheory import primitive_root
  >>> primitive_root(19)
  2
  ```

  **References**

  [R653], [R654]

sympy.ntheory.residue_ntheory.sqrt_mod(a, p, all_roots=False)
  Find a root of \( x^2 = a \pmod{p} \).

  **Parameters**
  - a : integer
  - p : positive integer
  - all_roots : if True the list of roots is returned or None
Notes

If there is no root it is returned None; else the returned root is less or equal to \( p \div 2 \); in general is not the smallest one. It is returned \( p \div 2 \) only if it is the only root.

Use `all_roots` only when it is expected that all the roots fit in memory; otherwise use `sqrt_mod_iter`.

Examples

```python
>>> from sympy.ntheory import sqrt_mod
>>> sqrt_mod(11, 43)
21
>>> sqrt_mod(17, 32, True)
[7, 9, 23, 25]
```

```python
sympy.ntheory.residue_ntheory.sqrt_mod_iter(a, p, domain=<class 'int'>)
Iterate over solutions to \( x^2 = a \mod p \).
```

**Parameters**

- `a`: integer
- `p`: positive integer
- `domain`: integer domain, int, ZZ or Integer

Examples

```python
>>> from sympy.ntheory.residue_ntheory import sqrt_mod_iter
>>> list(sqrt_mod_iter(11, 43))
[21, 22]
```

```python
sympy.ntheory.residue_ntheory.quadratic_residues(p) \rightarrow \text{list[int]}
Returns the list of quadratic residues.
```

Examples

```python
>>> from sympy.ntheory.residue_ntheory import quadratic_residues
>>> quadratic_residues(7)
[0, 1, 2, 4]
```

```python
sympy.ntheory.residue_ntheory.nthroot_mod(a, n, p, all_roots=False)
Find the solutions to \( x^n = a \mod p \).
```

**Parameters**

- `a`: integer
- `n`: positive integer
- `p`: positive integer
- `all_roots`: if False returns the smallest root, else the list of roots
Examples

```python
>>> from sympy.ntheory.residue_ntheory import nthroot_mod
>>> nthroot_mod(11, 4, 19)
8
>>> nthroot_mod(11, 4, 19, True)
[8, 11]
>>> nthroot_mod(68, 3, 109)
23
```

eysympy.ntheory.residue_ntheory.is_nthpow_residue(a, n, m)

Returns True if \( x^n = a \pmod{m} \) has solutions.

References

[R655]

sympy.ntheory.residue_ntheory.is_quad_residue(a, p)

Returns True if \( a \pmod{p} \) is in the set of squares mod \( p \), i.e \( a \) is a quadratic residue modulo \( p \).

Examples

If \( p \) is an odd prime, an iterative method is used to make the determination:

```python
>>> from sympy.ntheory import is_quad_residue
>>> sorted(set([i**2 % 7 for i in range(7)]))
[0, 1, 2, 4]
>>> [j for j in range(7) if is_quad_residue(j, 7)]
[0, 1, 2, 4]
```

See also:

legendre_symbol (page 1566), jacobi_symbol (page 1567)

sympy.ntheory.residue_ntheory.legendre_symbol(a, p)

Returns the Legendre symbol \( (a/p) \).

For an integer \( a \) and an odd prime \( p \), the Legendre symbol is defined as

\[
\left( \frac{a}{p} \right) = \begin{cases} 
0 & \text{if } p \text{ divides } a \\
1 & \text{if } a \text{ is a quadratic residue modulo } p \\
-1 & \text{if } a \text{ is a quadratic nonresidue modulo } p
\end{cases}
\]

Parameters

- \( a \) : integer
- \( p \) : odd prime
Examples

```python
>>> from sympy.ntheory import legendre_symbol
>>> [legendre_symbol(i, 7) for i in range(7)]
[0, 1, 1, -1, 1, -1, -1]
>>> sorted(set([i**2 % 7 for i in range(7)]))
[0, 1, 2, 4]
```

See also:

- `is_quad_residue` (page 1566), `jacobi_symbol` (page 1567)

`sympy.ntheory.residue_ntheory.jacobi_symbol(m, n)`

Returns the Jacobi symbol \((m/n)\).

For any integer \(m\) and any positive odd integer \(n\) the Jacobi symbol is defined as the product of the Legendre symbols corresponding to the prime factors of \(n\):

\[
\left(\frac{m}{n}\right) = \left(\frac{m}{p_1}\right)^{\alpha_1} \left(\frac{m}{p_2}\right)^{\alpha_2} \cdots \left(\frac{m}{p_k}\right)^{\alpha_k}
\]

where \(n = p_1^{\alpha_1} p_2^{\alpha_2} \cdots p_k^{\alpha_k}\).

Like the Legendre symbol, if the Jacobi symbol \((\frac{m}{n}) = -1\) then \(m\) is a quadratic nonresidue modulo \(n\).

But, unlike the Legendre symbol, if the Jacobi symbol \((\frac{m}{n}) = 1\) then \(m\) may or may not be a quadratic residue modulo \(n\).

Parameters

- \(m\) : integer
- \(n\) : odd positive integer

Examples

```python
>>> from sympy.ntheory import jacobi_symbol, legendre_symbol
>>> from sympy import S
>>> jacobi_symbol(45, 77)
-1
>>> jacobi_symbol(60, 121)
1
```

The relationship between the `jacobi_symbol` and `legendre_symbol` can be demonstrated as follows:

```python
>>> L = legendre_symbol
>>> S(45).factors()
{3: 2, 5: 1}
>>> jacobi_symbol(7, 45) == L(7, 3)**2 * L(7, 5)**1
True
```

See also:

- `is_quad_residue` (page 1566), `legendre_symbol` (page 1566)
sympy.ntheory.residue_ntheory.discrete_log(n, a, b, order=None, prime_order=None)
Compute the discrete logarithm of a to the base b modulo n.
This is a recursive function to reduce the discrete logarithm problem in cyclic groups of
composite order to the problem in cyclic groups of prime order.
It employs different algorithms depending on the problem (subgroup order size, prime
order or not):
• Trial multiplication
• Baby-step giant-step
• Pollard’s Rho
• Pohlig-Hellman

Examples

```python
>>> from sympy.ntheory import discrete_log
>>> discrete_log(41, 15, 7)
3
```

References

[R656], [R657]
sympy.ntheory.continued_fraction.continued_fraction(a) → list
Return the continued fraction representation of a Rational or quadratic irrational.

Examples

```python
>>> from sympy.ntheory.continued_fraction import continued_fraction
>>> from sympy import sqrt
>>> continued_fraction((1 + 2*sqrt(3))/5)
[0, 1, [8, 3, 34, 3]]
```

See also:

continued_fraction_periodic (page 1570), continued_fraction_reduce
(page 1571), continued_fraction_convergents (page 1568)
sympy.ntheory.continued_fraction.continued_fraction_convergents(cf)
Return an iterator over the convergents of a continued fraction (cf).
The parameter should be an iterable returning successive partial quotients of the con-
tinued fraction, such as might be returned by continued_fraction_iterator. In computing
the convergents, the continued fraction need not be strictly in canonical form (all integers,
all but the first positive). Rational and negative elements may be present in the expansion.
### Examples

```python
>>> from sympy.core import pi
>>> from sympy import S
>>> from sympy.ntheory.continued_fraction import continued_fraction_convergents, continued_fraction_iterator

>>> list(continued_fraction_convergents([0, 2, 1, 2]))
[0, 1/2, 1/3, 3/8]

>>> list(continued_fraction_convergents([1, S('1/2'), -7, S('1/4')])))
[1, 3, 19/5, 7]

>>> it = continued_fraction_convergents(continued_fraction_iterator(pi))
>>> for n in range(7):
...     print(next(it))
3
22/7
333/106
355/113
103993/33102
104348/33215
208341/66317
```

See also:

*continued_fraction_iterator* (page 1569)

Sympy.ntheory.continued_fraction.continued_fraction_iterator(x)

Return continued fraction expansion of x as iterator.

### Examples

```python
>>> from sympy import Rational, pi
>>> from sympy.ntheory.continued_fraction import continued_fraction_iterator

>>> list(continued_fraction_iterator(Rational(3, 8)))
[0, 2, 1, 2]

>>> list(continued_fraction_iterator(Rational(-3, 8)))
[-1, 1, 1, 2]

>>> for i, v in enumerate(continued_fraction_iterator(pi)):
...     if i > 7:
...         break
...     print(v)
3
7
15
1
292
(continues on next page)
```
References

[R658] sympy.ntheory.continued_fraction.continued_fraction_periodic(p, q, d=0, s=1) → list

Find the periodic continued fraction expansion of a quadratic irrational.
Compute the continued fraction expansion of a rational or a quadratic irrational number, i.e. \( \frac{p + s\sqrt{d}}{q} \), where \( p, q \neq 0 \) and \( d \geq 0 \) are integers.
Returns the continued fraction representation (canonical form) as a list of integers, optionally ending (for quadratic irrationals) with list of integers representing the repeating digits.

Parameters

- **p**: int
  - the rational part of the number’s numerator
- **q**: int
  - the denominator of the number
- **d**: int, optional
  - the irrational part (discriminator) of the number’s numerator
- **s**: int, optional
  - the coefficient of the irrational part

Examples

```python
>>> from sympy.ntheory.continued_fraction import continued_fraction_periodic
>>> continued_fraction_periodic(3, 2, 7)
[2, [1, 4, 1, 1]]
```
Golden ratio has the simplest continued fraction expansion:

```python
>>> continued_fraction_periodic(1, 2, 5)
[[1]]
```
If the discriminator is zero or a perfect square then the number will be a rational number:

```python
>>> continued_fraction_periodic(4, 3, 0)
[1, 3]
>>> continued_fraction_periodic(4, 3, 49)
[3, 1, 2]
```
See also:

`continued_fraction_iterator` (page 1569), `continued_fraction_reduce` (page 1571)

References

[R659], [R660]

```python
sympy.ntheory.continued_fraction.continued_fraction_reduce(cf)
```
Reduce a continued fraction to a rational or quadratic irrational.

Compute the rational or quadratic irrational number from its terminating or periodic continued fraction expansion. The continued fraction expansion (cf) should be supplied as a terminating iterator supplying the terms of the expansion. For terminating continued fractions, this is equivalent to `list(continued_fraction_convergents(cf))[-1]`, only a little more efficient. If the expansion has a repeating part, a list of the repeating terms should be returned as the last element from the iterator. This is the format returned by `continued_fraction_periodic`.

For quadratic irrationals, returns the largest solution found, which is generally the one sought, if the fraction is in canonical form (all terms positive except possibly the first).

Examples

```python
>>> from sympy.ntheory.continued_fraction import continued_fraction_reduce
>>> continued_fraction_reduce([1, 2, 3, 4, 5])
225/157
>>> continued_fraction_reduce([-2, 1, 9, 7, 1, 2])
-256/233
>>> continued_fraction_reduce([2, 1, 2, 1, 4, 1, 1, 6, 1, 1, 8]).n(10)
2.718281835
>>> continued_fraction_reduce([1, 4, 2, [3, 1]])
(\sqrt{21} + 287)/238
>>> continued_fraction_reduce([[1]])
(1 + \sqrt{5})/2
>>> from sympy.ntheory.continued_fraction import continued_fraction_periodic
>>> continued_fraction_reduce(continued_fraction_periodic(8, 5, 13))
(sqrt(13) + 8)/5
```

See also:

`continued_fraction_periodic` (page 1570)

```python
sympy.ntheory.digits.count_digits(n, b=10)
```
Return a dictionary whose keys are the digits of \( n \) in the given base, \( b \), with keys indicating the digits appearing in the number and values indicating how many times that digit appeared.
Examples

```python
from sympy.ntheory import count_digits

count_digits(1111339)
{1: 4, 3: 2, 9: 1}
```

The digits returned are always represented in base-10 but the number itself can be entered in any format that is understood by Python; the base of the number can also be given if it is different than 10:

```python
n = 0xFA; n
250
count_digits(_)
{0: 1, 2: 1, 5: 1}
count_digits(n, 16)
{10: 1, 15: 1}
```

The default dictionary will return a 0 for any digit that did not appear in the number. For example, which digits appear 7 times in 77!:

```python
from sympy import factorial

c77 = count_digits(factorial(77))
[i for i in range(10) if c77[i] == 7]
[1, 3, 7, 9]
```

**sympy.ntheory.digits.digits(n, b=10, digits=None)**

Return a list of the digits of n in base b. The first element in the list is b (or -b if n is negative).

**Parameters**

- **n**: integer
  
  The number whose digits are returned.

- **b**: integer
  
  The base in which digits are computed.

- **digits**: integer (or None for all digits)
  
  The number of digits to be returned (padded with zeros, if necessary).

Examples

```python
from sympy.ntheory.digits import digits
digits(35)
[10, 3, 5]
```

If the number is negative, the negative sign will be placed on the base (which is the first element in the returned list):

```python
digits(-35)
[-10, 3, 5]
```
Bases other than 10 (and greater than 1) can be selected with \( b \):

```python
>>> digits(27, b=2)
[2, 1, 1, 0, 1, 1]
```

Use the `digits` keyword if a certain number of digits is desired:

```python
>>> digits(35, digits=4)
[10, 0, 0, 3, 5]
```

`sympy.ntheory.digits.is_palindromic(n, b=10)`

Returns True if \( n \) is the same when read from left to right or right to left in the given base, \( b \).

**Examples**

```python
>>> from sympy.ntheory import is_palindromic

>>> all(is_palindromic(i) for i in (-11, 1, 22, 121))
True
```

The second argument allows you to test numbers in other bases. For example, 88 is palindromic in base-10 but not in base-8:

```python
>>> is_palindromic(88, 8)
False
```

On the other hand, a number can be palindromic in base-8 but not in base-10:

```python
>>> 0o121, is_palindromic(0o121)
(81, False)
```

Or it might be palindromic in both bases:

```python
>>> oct(121), is_palindromic(121, 8) and is_palindromic(121)
('0o171', True)
```

**class sympy.ntheory.mobius(n)**

Mobius function maps natural number to \{-1, 0, 1\}

**It is defined as follows:**

1) \( 1 \) if \( n = 1 \).
2) \( 0 \) if \( n \) has a squared prime factor.
3) \( (-1)^k \) if \( n \) is a square-free positive integer with \( k \) number of prime factors.

It is an important multiplicative function in number theory and combinatorics. It has applications in mathematical series, algebraic number theory and also physics (Fermion operator has very concrete realization with Mobius Function model).

**Parameters**

- \( n \) : positive integer
Examples

```python
>>> from sympy.ntheory import mobius
>>> mobius(13*7)
1
>>> mobius(1)
1
>>> mobius(13*7*5)
-1
>>> mobius(13**2)
0
```

References

[R661], [R662]

sympy.ntheory.egyptian_fraction.egyptian_fraction(r, algorithm='Greedy')

Return the list of denominators of an Egyptian fraction expansion \[ R663 \] of the said rational \( r \).

Parameters

- \( r \) : Rational or \((p, q)\)
  
  a positive rational number; \( p/q \).

- \( \text{algorithm} \) : \{“Greedy”, “Graham Jewett”, “Takenouchi”, “Golomb”\}, optional
  
  Denotes the algorithm to be used (the default is “Greedy”).

Examples

```python
>>> from sympy import Rational
>>> from sympy.ntheory.egyptian_fraction import egyptian_fraction
>>> egyptian_fraction(Rational(3, 7))
[3, 11, 231]
>>> egyptian_fraction((3, 7), "Graham Jewett")
[7, 8, 9, 56, 57, 72, 3192]
>>> egyptian_fraction((3, 7), "Takenouchi")
[4, 7, 28]
>>> egyptian_fraction((3, 7), "Golomb")
[3, 15, 35]
>>> egyptian_fraction((11, 5), "Golomb")
[1, 2, 3, 4, 9, 234, 1118, 2580]
```
Notes

Currently the following algorithms are supported:

1) Greedy Algorithm

Also called the Fibonacci-Sylvester algorithm [R664]. At each step, extract the largest unit fraction less than the target and replace the target with the remainder.

It has some distinct properties:

a) Given \( p/q \) in lowest terms, generates an expansion of maximum length \( p \). Even as the numerators get large, the number of terms is seldom more than a handful.

b) Uses minimal memory.

c) The terms can blow up (standard examples of this are 5/121 and 31/311). The denominator is at most squared at each step (doubly-exponential growth) and typically exhibits singly-exponential growth.

2) Graham Jewett Algorithm

The algorithm suggested by the result of Graham and Jewett. Note that this has a tendency to blow up: the length of the resulting expansion is always \( 2^{**}\left(\frac{x}{\gcd(x, y)}\right) - 1 \). See [R665].

3) Takenouchi Algorithm

The algorithm suggested by Takenouchi (1921). Differs from the Graham-Jewett algorithm only in the handling of duplicates. See [R665].

4) Golomb’s Algorithm

A method given by Golumb (1962), using modular arithmetic and inverses. It yields the same results as a method using continued fractions proposed by Bleicher (1972). See [R666].

If the given rational is greater than or equal to 1, a greedy algorithm of summing the harmonic sequence \( 1/1 + 1/2 + 1/3 + \ldots \) is used, taking all the unit fractions of this sequence until adding one more would be greater than the given number. This list of denominators is prefixed to the result from the requested algorithm used on the remainder. For example, if \( r \) is 8/3, using the Greedy algorithm, we get \([1, 2, 3, 4, 5, 6, 7, 14, 420]\), where the beginning of the sequence, \([1, 2, 3, 4, 5, 6, 7]\) is part of the harmonic sequence summing to 363/140, leaving a remainder of 31/420, which yields \([14, 420]\) by the Greedy algorithm. The result of \( \text{egyptian fraction}(\text{Rational}(8, 3), \text{"Golomb"}) \) is \([1, 2, 3, 4, 5, 6, 7, 14, 574, 2788, 6460, 11590, 33062, 113820]\), and so on.

See also:

`sympy.core.numbers.Rational` (page 1036)
sympy.ntheory.bbp_pi.pi_hex_digits(n, prec=14)

Returns a string containing prec (default 14) digits starting at the nth digit of pi in hex. Counting of digits starts at 0 and the decimal is not counted, so for n = 0 the returned value starts with 3; n = 1 corresponds to the first digit past the decimal point (which in hex is 2).

Examples

```python
>>> from sympy.ntheory.bbp_pi import pi_hex_digits
>>> pi_hex_digits(0)
'3243f6a8885a30'
>>> pi_hex_digits(0, 3)
'324'
```

[R667]

**ECM function**

The `ecm` function is a subexponential factoring algorithm capable of factoring numbers of around ~35 digits comfortably within few seconds. The time complexity of `ecm` is dependent on the smallest proper factor of the number. So even if the number is really large but its factors are comparatively smaller then `ecm` can easily factor them. For example we take N with 15 digit factors 15154262241479, 15423094826093, 799333555511111, 809709509409109, 88888877777777, 914148152112161. Now N is a 87 digit number. ECM takes under around 47s to factorise this.

```python
>>> from sympy.ntheory.ecm import ecm
```

This function repeatedly calls `ecm_nofactor` to compute the factors of n. First all the small factors are taken out using trial division. Then `ecm_nofactor` is used to compute one factor at a time.

**Parameters**

- `n` : Number to be Factored
- `B1` : Stage 1 Bound
- `B2` : Stage 2 Bound
- `max_curve` : Maximum number of curves generated
- `seed` : Initialize pseudorandom generator
Examples

```python
>>> from sympy.ntheory import ecm
>>> ecm(25645121643901801)
{5394769, 4753701529}
>>> ecm(9804659461513846513)
{4641991, 2112166839943}
```

Examples

```python
>>> from sympy.ntheory import ecm
>>> ecm(706000565815754299976961394452809, B1=100000, B2=1000000)
{698869966998001, 1010203040506070809}
>>> ecm(12292144854388396743090809142276189861834971360425638440320228256086473494959648313, B1=100000, B2=1000000)
{15154262241479, 15423094826093, 79933355511111, 80979959409109, 88888887777777, 914148152112161}
```

**QS function**

The `qs` function is a subexponential factoring algorithm, the fastest factoring algorithm for numbers within 100 digits. The time complexity of `qs` is dependent on the size of the number so it is used if the number contains large factors. Due to this while factoring numbers first `ecm` is used to get smaller factors of around ~15 digits then `qs` is used to get larger factors.

For factoring `2709077133180915240135586837960864768806330782747` which is a semi-prime number with two 25 digit factors. `qs` is able to factorize this in around 248s.

```python
sympy.ntheory.qs.qs(N, prime_bound, M, ERROR_TERM=25, seed=1234)
```

Performs factorization using Self-Initializing Quadratic Sieve. In SIQS, let N be a number to be factored, and this N should not be a perfect power. If we find two integers such that \(X**2 = Y**2 \mod N\) and \(X \neq \pm Y \mod N\), then \(\gcd(X + Y, N)\) will reveal a proper factor of N. In order to find these integers X and Y we try to find relations of form \(t**2 = u \mod N\) where u is a product of small primes. If we have enough of these relations then we can form \((t1*t2...ti)**2 = u1*u2...ui \mod N\) such that the right hand side is a square, thus we found a relation of \(X**2 = Y**2 \mod N\).

Here, several optimizations are done like using multiple polynomials for sieving, fast changing between polynomials and using partial relations. The use of partial relations can speed up the factoring by 2 times.

**Parameters**

- \(N\) : Number to be Factored
- \(prime\_bound\) : upper bound for primes in the factor base
- \(M\) : Sieve Interval
**ERROR_TERM**: Error term for checking smoothness

**threshold**: Extra smooth relations for factorization

**seed**: Generate pseudo prime numbers

### Examples

```python
>>> from sympy.ntheory import qs
>>> qs(25645121643901801, 2000, 10000)
{5394769, 4753701529}
>>> qs(9804659461513846513, 2000, 10000)
{4641991, 2112166839943}
```

### References

[R668], [R669]

### Examples

```python
>>> from sympy.ntheory import qs
>>> qs(5915587277*3267000013, 1000, 10000)
{3267000013, 5915587277}
```

### 5.8.6 Physics

A module that helps solving problems in physics.

**Contents**

**Hydrogen Wavefunctions**

sympy.physics.hydrogen.E_nl(n, Z=1)

Returns the energy of the state (n, l) in Hartree atomic units.

The energy does not depend on “l”.

**Parameters**

- **n**: integer
  
  Principal Quantum Number which is an integer with possible values as 1, 2, 3, 4,...

- **Z**: Atomic number (1 for Hydrogen, 2 for Helium, ...)
Examples

```python
>>> from sympy.physics.hydrogen import E_nl
>>> from sympy.abc import n, Z
>>> E_nl(n, Z)
-Z**2/(2*n**2)
>>> E_nl(1)
-1/2
>>> E_nl(2)
-1/8
>>> E_nl(3)
-1/18
>>> E_nl(3, 47)
-2209/18

sympy.physics.hydrogen.E_nl_dirac(n, l, spin_up=True, Z=1, c=137.035999037000)

Returns the relativistic energy of the state (n, l, spin) in Hartree atomic units.
The energy is calculated from the Dirac equation. The rest mass energy is not included.

Parameters

- **n**: integer
  Principal Quantum Number which is an integer with possible values as 1, 2, 3, 4, ...

- **l**: integer
  l is the Angular Momentum Quantum Number with values ranging from 0 to n-1.

- **spin_up**: True if the electron spin is up (default), otherwise down

- **Z**: Atomic number (1 for Hydrogen, 2 for Helium, ...)

- **c**: Speed of light in atomic units. Default value is 137.035999037, taken from https://arxiv.org/abs/1012.3627

Examples

```python
>>> from sympy.physics.hydrogen import E_nl_dirac
>>> E_nl_dirac(1, 0)
-0.500006656595360
>>> E_nl_dirac(2, 0)
-0.125002080189006
>>> E_nl_dirac(2, 1)
-0.125000416028342
>>> E_nl_dirac(2, 1, False)
-0.125002080189006
```
sympy.physics.hydrogen.Psi_nlm(n, l, m, r, phi, theta, Z=1)

Returns the Hydrogen wave function \( \psi_{nlm} \). It’s the product of the radial wavefunction \( R_{nl} \) and the spherical harmonic \( Y_{l}^{m} \).

**Parameters**

- **n**: integer
  - Principal Quantum Number which is an integer with possible values as 1, 2, 3, 4,...

- **l**: integer
  - \( l \) is the Angular Momentum Quantum Number with values ranging from 0 to \( n-1 \).

- **m**: integer
  - \( m \) is the Magnetic Quantum Number with values ranging from \( -l \) to \( l \).

- **r**: radial coordinate

- **phi**: azimuthal angle

- **theta**: polar angle

- **Z**: atomic number (1 for Hydrogen, 2 for Helium, ...)

**Everything is in Hartree atomic units.**

**Examples**

```python
>>> from sympy.physics.hydrogen import Psi_nlm
>>> from sympy import Symbol
>>> r=Symbol("r", positive=True)
>>> phi=Symbol("phi", real=True)
>>> theta=Symbol("theta", real=True)
>>> Z=Symbol("Z", positive=True, integer=True, nonzero=True)
>>> Psi_nlm(1,0,0,r,phi,theta,Z)
```
Z**(3/2)*exp(-Z*r)/sqrt(pi)

>>> Psi_nlm(2,1,1,r,phi,theta,Z)
-Z**(5/2)*r*exp(I*phi)*exp(-Z*r/2)*sin(theta)/(8*sqrt(pi))

Integrating the absolute square of a hydrogen wavefunction psi_{nlm} over the whole space leads 1.

The normalization of the hydrogen wavefunctions Psi_nlm is:

```python
from sympy import integrate, conjugate, pi, oo, sin
wf = Psi_nlm(2,1,1,r,phi,theta,Z)
abs_sqrd = wf*conjugate(wf)
jacobi = r*2*sin(theta)
integrate(abs_sqrd*jacobi, (r,0,oo), (phi,0,2*pi), (theta,0,pi))
```

```python
1
```

sympy.physics.hydrogen.R_nl(n,l,r,Z=1)

Returns the Hydrogen radial wavefunction R_{nl}.

Parameters

**n**: integer

Principal Quantum Number which is an integer with possible values as 1, 2, 3, 4, ...

**l**: integer

l is the Angular Momentum Quantum Number with values ranging from 0 to n-1.

**r**: Radial coordinate.

**Z**: Atomic number (1 for Hydrogen, 2 for Helium, ...)

Everything is in Hartree atomic units.

Examples

```python
>>> from sympy.physics.hydrogen import R_nl
>>> from sympy import r, Z
>>> R_nl(1, 0, r, Z)
2*sqrt(Z**3)*exp(-Z*r)
>>> R_nl(2, 0, r, Z)
sqrt(2)*(-Z*r + 2)*sqrt(Z**3)*exp(-Z*r/2)/4
>>> R_nl(2, 1, r, Z)
sqrt(6)*Z*r*sqrt(Z**3)*exp(-Z*r/2)/12
```

For Hydrogen atom, you can just use the default value of Z=1:

```python
>>> R_nl(1, 0, r)
2*exp(-r)
```

```python
>>> R_nl(2, 0, r)
```
sqrt(2)*(2 - r)*exp(-r/2)/4

```python
>>> R_nl(3, 0, r)
2*sqrt(3)*(2*r**2/9 - 2*r + 3)*exp(-r/3)/27
```

For Silver atom, you would use \( Z = 47 \):

```python
>>> R_nl(1, 0, r, Z=47)
94*sqrt(47)*exp(-47*r)

>>> R_nl(2, 0, r, Z=47)
47*sqrt(94)*(2 - 47*r)*exp(-47*r/2)/4

>>> R_nl(3, 0, r, Z=47)
94*sqrt(141)*(4418*r**2/9 - 94*r + 3)*exp(-47*r/3)/27
```

The normalization of the radial wavefunction is:

```python
>>> from sympy import integrate, oo
>>> integrate(R_nl(1, 0, r)**2 * r**2, (r, 0, oo))
1

>>> integrate(R_nl(2, 0, r)**2 * r**2, (r, 0, oo))
1

>>> integrate(R_nl(2, 1, r)**2 * r**2, (r, 0, oo))
1
```

It holds for any atomic number:

```python
>>> integrate(R_nl(1, 0, r, Z=2)**2 * r**2, (r, 0, oo))
1

>>> integrate(R_nl(2, 0, r, Z=3)**2 * r**2, (r, 0, oo))
1

>>> integrate(R_nl(2, 1, r, Z=4)**2 * r**2, (r, 0, oo))
1
```

**Matrices**

Known matrices related to physics

- `sympy.physics.matrices.mdft(n)`
  - Deprecated since version 1.9: Use DFT from `sympy.matrices.expressions.fourier` instead.
  - To get identical behavior to `mdft(n)`, use `DFT(n).as_explicit()`.

- `sympy.physics.matrices.mgamma(mu, lower=False)`
  - Returns a Dirac gamma matrix \( \gamma^\mu \) in the standard (Dirac) representation.
Explanation

If you want $\gamma_\mu$, use $\text{gamma}(\mu, \text{True})$.

We use a convention:

$\gamma^5 = i \cdot \gamma^0 \cdot \gamma^1 \cdot \gamma^2 \cdot \gamma^3$

$\gamma_5 = i \cdot \gamma_0 \cdot \gamma_1 \cdot \gamma_2 \cdot \gamma_3 = -\gamma^5$

Examples

```python
>>> from sympy.physics.matrices import mgamma
>>> mgamma(1)
Matrix([[0, 0, 0, 1],
       [0, 0, 1, 0],
       [0, -1, 0, 0],
       [-1, 0, 0, 0]])
```

References

[R677] sympy.physics.matrices.msigma(i)

Returns a Pauli matrix $\sigma_i$ with $i = 1, 2, 3$.

Examples

```python
>>> from sympy.physics.matrices import msigma
>>> msigma(1)
Matrix([[0, 1],
       [1, 0]])
```

References

[R678] sympy.physics.matrices.pat_matrix($m, dx, dy, dz$)

Returns the Parallel Axis Theorem matrix to translate the inertia matrix a distance of $(dx, dy, dz)$ for a body of mass $m$.  

5.8. Topics
Examples

To translate a body having a mass of 2 units a distance of 1 unit along the \( x \)-axis we get:

```python
>>> from sympy.physics.matrices import pat_matrix
>>> pat_matrix(2, 1, 0, 0)
Matrix([[0, 0, 0],
       [0, 2, 0],
       [0, 0, 2]])
```

Pauli Algebra

This module implements Pauli algebra by subclassing Symbol. Only algebraic properties of Pauli matrices are used (we do not use the Matrix class).

See the documentation to the class Pauli for examples.

References

`sympy.physics.paulialgebra.evaluate_pauli_product(arg)`

Help function to evaluate Pauli matrices product with symbolic objects.

Parameters

- **arg**: symbolic expression that contains Pauli matrices

Examples

```python
>>> from sympy.physics.paulialgebra import Pauli, evaluate_pauli_product
>>> from sympy import I
>>> evaluate_pauli_product(I*Pauli(1)*Pauli(2))
-sigma3
```

Quantum Harmonic Oscillator in 1-D

`sympy.physics.qho_1d.E_n(n, omega)`

Returns the Energy of the One-dimensional harmonic oscillator.

Parameters

- **n**: The “nodal” quantum number.
- **omega**: The harmonic oscillator angular frequency.
**Notes**

The unit of the returned value matches the unit of \(hw\), since the energy is calculated as:

\[
E_n = \hbar \omega (n + 1/2)
\]

**Examples**

```python
>>> from sympy.physics.qho_1d import E_n
>>> from sympy.abc import x, omega
>>> E_n(x, omega)
hbar*omega*(x + 1/2)
```

**sympy.physics.qho_1d.coherent_state\(n, \alpha\)**

Returns \(\langle n|\alpha\rangle\) for the coherent states of 1D harmonic oscillator. See [https://en.wikipedia.org/wiki/Coherent_states](https://en.wikipedia.org/wiki/Coherent_states)

**Parameters**

- \(n\):
  The “nodal” quantum number.
- \(\alpha\):
  The eigen value of annihilation operator.

**sympy.physics.qho_1d.psi\(n, x, m, \omega\)**

Returns the wavefunction \(\psi_n\) for the One-dimensional harmonic oscillator.

**Parameters**

- \(n\):
  the “nodal” quantum number. Corresponds to the number of nodes in the wavefunction. \(n \geq 0\)
- \(x\):
  \(x\) coordinate.
- \(m\):
  Mass of the particle.
- \(\omega\):
  Angular frequency of the oscillator.

**Examples**

```python
>>> from sympy.physics.qho_1d import psi_n
>>> from sympy.abc import m, x, omega
>>> psi_n(0, x, m, omega)
(m*omega)**(1/4)*exp(-m*omega*x**2/(2*hbar))/(hbar**(1/4)*pi**(1/4))
```
Quantum Harmonic Oscillator in 3-D

sympy.physics.sho.E_nl(n, l, hw)

Returns the Energy of an isotropic harmonic oscillator.

**Parameters**

- **n**: The “nodal” quantum number.
- **l**: The orbital angular momentum.
- **hw**: The harmonic oscillator parameter.

**Notes**

The unit of the returned value matches the unit of hw, since the energy is calculated as:

\[ E_{nl} = (2n + l + 3/2)*hw \]

**Examples**

```python
>>> from sympy.physics.sho import E_nl
>>> from sympy import symbols
>>> x, y, z = symbols('x, y, z')
>>> E_nl(x, y, z)
z*(2*x + y + 3/2)
```

sympy.physics.sho.R_nl(n, l, nu, r)

Returns the radial wavefunction \( R_{nl} \) for a 3D isotropic harmonic oscillator.

**Parameters**

- **n**: The “nodal” quantum number. Corresponds to the number of nodes in the wavefunction. \( n \geq 0 \)
- **l**: The quantum number for orbital angular momentum.
- **nu**: mass-scaled frequency: \( nu = m*\omega/(2*hbar) \) where \( m \) is the mass and \( \omega \) the frequency of the oscillator. (in atomic units \( nu == \omega/2 \))
- **r**: Radial coordinate.
Examples

```python
>>> from sympy.physics.sho import R_nl
>>> from sympy.abc import r, nu, l
>>> R_nl(0, 0, 1, r)
2*2**(3/4)*exp(-r**2)/pi**(1/4)
>>> R_nl(1, 0, 1, r)
4*2**(1/4)*sqrt(3)*(3/2 - 2*r**2)*exp(-r**2)/(3*pi**(1/4))
l, nu and r may be symbolic:
```  
```python
>>> R_nl(0, 0, nu, r)
2*2**(3/4)*sqrt(nu**(3/2))*exp(-nu*r**2)/pi**(1/4)
>>> R_nl(0, l, 1, r)
r**l*sqrt(2**(l + 3/2)*2**(l + 2)/factorial2(2*l + 1))*exp(-r**2)/pi**(1/4)
```  
The normalization of the radial wavefunction is:

```python
>>> from sympy import Integral, oo
>>> Integral(R_nl(0, 0, 1, r)**2*r, (r, 0, oo)).n()
1.0
>>> Integral(R_nl(1, 0, 1, r)**2*r, (r, 0, oo)).n()
1.0
>>> Integral(R_nl(1, 1, 1, r)**2*r, (r, 0, oo)).n()
1.0
```

Second Quantization

Second quantization operators and states for bosons.

This follow the formulation of Fetter and Walecka, “Quantum Theory of Many-Particle Systems.”

```python
class sympy.physics.secondquant.AnnihilateBoson(k)
    Bosonic annihilation operator.
```

Examples

```python
>>> from sympy.physics.secondquant import B
>>> from sympy.abc import x
>>> B(x)
AnnihilateBoson(x)
```

apply_operator(state)

Apply state to self if self is not symbolic and state is a FockStateKet, else multiply self by state.
Examples

```python
>>> from sympy.physics.secondquant import B, BKet
>>> from sympy import x, y, n
>>> B(x).apply_operator(y)
y*AnnihilateBoson(x)
>>> B(0).apply_operator(BKet((n,)))
sqrt(n)*FockStateBosonKet((n - 1,))
```

```
class sympy.physics.secondquant.AnnihilateFermion(k)
Fermionic annihilation operator.

apply_operator(state)
Apply state to self if self is not symbolic and state is a FockStateKet, else multiply
self by state.

Examples

```python
>>> from sympy.physics.secondquant import B, Dagger, BKet
>>> from sympy import x, y, n
>>> Dagger(B(x)).apply_operator(y)
y*CreateBoson(x)
>>> B(0).apply_operator(BKet((n,)))
sqrt(n)*FockStateBosonKet((n - 1,))
```

property is_only_q_annihilator
Always destroy a quasi-particle? (annihilate hole or annihilate particle)

Examples

```python
>>> from sympy import Symbol
>>> from sympy.physics.secondquant import F
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')
```

```python
>>> F(a).is_only_q_annihilator
True
>>> F(i).is_only_q_annihilator
False
>>> F(p).is_only_q_annihilator
False
```

property is_only_q_creator
Always create a quasi-particle? (create hole or create particle)
Examples

>>> from sympy import Symbol
>>> from sympy.physics.secondquant import F
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')

>>> F(a).is_only_q_creator
False
>>> F(i).is_only_q_creator
True
>>> F(p).is_only_q_creator
False

property is_q_annihilator
Can we destroy a quasi-particle? (annihilate hole or annihilate particle) If so, would that be above or below the fermi surface?

Examples

>>> from sympy import Symbol
>>> from sympy.physics.secondquant import F
>>> a = Symbol('a', above_fermi=1)
>>> i = Symbol('i', below_fermi=1)
>>> p = Symbol('p')

>>> F(a).is_q_annihilator
1
>>> F(i).is_q_annihilator
0
>>> F(p).is_q_annihilator
1

property is_q_creator
Can we create a quasi-particle? (create hole or create particle) If so, would that be above or below the fermi surface?

Examples

>>> from sympy import Symbol
>>> from sympy.physics.secondquant import F
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')

>>> F(a).is_q_creator
0
>>> F(i).is_q_creator
(continues on next page)
class sympy.physics.secondquant.AntiSymmetricTensor(symbol, upper, lower)
Stores upper and lower indices in separate Tuple’s.
Each group of indices is assumed to be antisymmetric.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.secondquant import AntiSymmetricTensor
>>> i, j = symbols('i,j', below_fermi=True)
>>> a, b = symbols('a,b', above_fermi=True)
>>> AntiSymmetricTensor('v', (a, i), (b, j))
AntiSymmetricTensor(v, (a, i), (b, j))
>>> AntiSymmetricTensor('v', (i, a), (b, j))
-AntiSymmetricTensor(v, (a, i), (b, j))
```

As you can see, the indices are automatically sorted to a canonical form.

**property lower**
Returns the lower indices.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.secondquant import AntiSymmetricTensor
>>> i, j = symbols('i,j', below_fermi=True)
>>> a, b = symbols('a,b', above_fermi=True)
>>> AntiSymmetricTensor('v', (a, i), (b, j)).lower
(b, j)
```

**property symbol**
Returns the symbol of the tensor.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.secondquant import AntiSymmetricTensor
>>> i, j = symbols('i,j', below_fermi=True)
>>> a, b = symbols('a,b', above_fermi=True)
>>> AntiSymmetricTensor('v', (a, i), (b, j))
AntiSymmetricTensor(v, (a, i), (b, j))
>>> AntiSymmetricTensor('v', (a, i), (b, j)).symbol
v
```
**property upper**

Returns the upper indices.

**Examples**

```python
>>> from sympy import symbols
>>> from sympy.physics.secondquant import AntiSymmetricTensor
>>> i, j = symbols('i,j', below_fermi=True)
>>> a, b = symbols('a,b', above_fermi=True)
>>> AntiSymmetricTensor('v', (a, i), (b, j))
AntiSymmetricTensor(v, (a, i), (b, j)).upper
(a, i)
```

`sympy.physics.secondquant.B`  
alias of `AnnihilateBoson` (page 1587)

`sympy.physics.secondquant.BBra`  
alias of `FockStateBosonBra` (page 1596)

`sympy.physics.secondquant.BKet`  
alias of `FockStateBosonKet` (page 1597)

`sympy.physics.secondquant.Bd`  
alias of `CreateBoson` (page 1592)

**class** `sympy.physics.secondquant.BosonicBasis`

Base class for a basis set of bosonic Fock states.

**class** `sympy.physics.secondquant.Commutator(a,b)`

The Commutator: \([A, B] = A*B - B*A\)

The arguments are ordered according to \._cmp_()\.

**Examples**

```python
>>> from sympy import symbols
>>> from sympy.physics.secondquant import Commutator
>>> A, B = symbols('A,B', commutative=False)
>>> Commutator(B, A)
-Commutator(A, B)
```

Evaluate the commutator with `doit()`

```python
>>> comm = Commutator(A,B); comm
Commutator(A, B)
>>> comm.doit()
A*B - B*A
```

For two second quantization operators the commutator is evaluated immediately:
>>> from sympy.physics.secondquant import Fd, F
>>> a = symbols('a', above_fermi=True)
>>> i = symbols('i', below_fermi=True)
>>> p, q = symbols('p,q')

>>> Commutator(Fd(a),Fd(i))
2*NO(CreateFermion(a)*CreateFermion(i))

But for more complicated expressions, the evaluation is triggered by a call to .doit()

>>> comm = Commutator(Fd(p)*Fd(q),F(i)); comm
Commutator(CreateFermion(p)*CreateFermion(q), AnnihilateFermion(i))

>>> comm.doit(wicks=True)
-KroneckerDelta(i, p)*CreateFermion(q) +
  KroneckerDelta(i, q)*CreateFermion(p)

doit(**hints)

  Enables the computation of complex expressions.

Examples

>>> from sympy.physics.secondquant import Commutator, F, Fd
>>> from sympy import symbols
>>> i, j = symbols('i,j', below_fermi=True)
>>> a, b = symbols('a,b', above_fermi=True)
>>> c = Commutator(Fd(a)*F(i),Fd(b)*F(j))

>>> c.doit(wicks=True)
0

classmethod eval(a, b)

  The Commutator [A,B] is on canonical form if A < B.

Examples

>>> from sympy.physics.secondquant import Commutator, F, Fd
>>> from sympy import symbols, x

>>> c1 = Commutator(F(x), Fd(x))
>>> c2 = Commutator(Fd(x), F(x))

>>> Commutator.eval(c1, c2)
0

class sympy.physics.secondquant.CreateBoson(k)

  Bosonic creation operator:

  apply_operator(state)

    Apply state to self if self is not symbolic and state is a FockStateKet, else multiply
    self by state.
Examples

```python
>>> from sympy.physics.secondquant import B, Dagger, BKet
>>> from sympy import x, y, n
>>> Dagger(B(x)).apply_operator(y)
y*CreateBoson(x)
>>> B(0).apply_operator(BKet((n,)))
sqrt(n)*FockStateBosonKet((n - 1,))
```

class sympy.physics.secondquant.CreateFermion(k)

Fermionic creation operator:

```python
apply_operator(state)
```

Apply state to self if self is not symbolic and state is a FockStateKet, else multiply self by state.

Examples

```python
>>> from sympy.physics.secondquant import B, Dagger, BKet
>>> from sympy import x, y, n
>>> Dagger(B(x)).apply_operator(y)
y*CreateBoson(x)
>>> B(0).apply_operator(BKet((n,)))
sqrt(n)*FockStateBosonKet((n - 1,))
```

property is_only_q_annihilator

Always destroy a quasi-particle? (annihilate hole or annihilate particle)

Examples

```python
>>> from sympy import Symbol
>>> from sympy.physics.secondquant import Fd
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')

>>> Fd(a).is_only_q_annihilator
False
>>> Fd(i).is_only_q_annihilator
True
>>> Fd(p).is_only_q_annihilator
False
```

property is_only_q_creator

Always create a quasi-particle? (create hole or create particle)
Examples

```python
>>> from sympy import Symbol
>>> from sympy.physics.secondquant import Fd
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')

>>> Fd(a).is_only_q_creator
True
>>> Fd(i).is_only_q_creator
False
>>> Fd(p).is_only_q_creator
False
```

**property is_q_annihilator**

Can we destroy a quasi-particle? (annihilate hole or annihilate particle) If so, would that be above or below the fermi surface?

Examples

```python
>>> from sympy import Symbol
>>> from sympy.physics.secondquant import Fd
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')

>>> Fd(a).is_q_annihilator
0
>>> Fd(i).is_q_annihilator
-1
>>> Fd(p).is_q_annihilator
-1
```

**property is_q_creator**

Can we create a quasi-particle? (create hole or create particle) If so, would that be above or below the fermi surface?

Examples

```python
>>> from sympy import Symbol
>>> from sympy.physics.secondquant import Fd
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')

>>> Fd(a).is_q_creator
1
>>> Fd(i).is_q_creator
```

(continues on next page)
class sympy.physics.secondquant.Dagger(arg)
Hermitian conjugate of creation/annihilation operators.

Examples

```python
>>> from sympy import I
>>> from sympy.physics.secondquant import Dagger, B, Bd
>>> Dagger(2*I)
-2*I
>>> Dagger(B(0))
CreateBoson(0)
>>> Dagger(Bd(0))
AnnihilateBoson(0)
```

classmethod eval(arg)
Evaluates the Dagger instance.

Examples

```python
>>> from sympy import I
>>> from sympy.physics.secondquant import Dagger, B, Bd
>>> Dagger(2*I)
-2*I
>>> Dagger(B(0))
CreateBoson(0)
>>> Dagger(Bd(0))
AnnihilateBoson(0)
```

The eval() method is called automatically.

sympy.physics.secondquant.F
alias of AnnihilateFermion (page 1588)
sympy.physics.secondquant.FBra
alias of FockStateFermionBra (page 1597)
sympy.physics.secondquant.FKet
alias of FockStateFermionKet (page 1597)
sympy.physics.secondquant.Fd
alias of CreateFermion (page 1593)
class sympy.physics.secondquant.FixedBosonicBasis(n_particles, n_levels)
Fixed particle number basis set.
Examples

```python
>>> from sympy.physics.secondquant import FixedBosonicBasis
>>> b = FixedBosonicBasis(2, 2)
>>> state = b.state(1)
>>> b
[|FockState((2, 0)), FockState((1, 1)), FockState((0, 2))|
>>> state
FockStateBosonKet((1, 1))
>>> b.index(state)
1
```

**index(state)**

Returns the index of state in basis.

Examples

```python
>>> from sympy.physics.secondquant import FixedBosonicBasis
>>> b = FixedBosonicBasis(2, 3)
>>> b.index(b.state(3))
3
```

**state(i)**

Returns the state that lies at index i of the basis

Examples

```python
>>> from sympy.physics.secondquant import FixedBosonicBasis
>>> b = FixedBosonicBasis(2, 3)
>>> b.state(3)
FockStateBosonKet((1, 0, 1))
```

**class** sympy.physics.secondquant.FockState(occupations)

Many particle Fock state with a sequence of occupation numbers.

Anywhere you can have a FockState, you can also have `S.Zero`. All code must check for this!

Base class to represent FockStates.

**class** sympy.physics.secondquant.FockStateBosonBra(occupations)

Describes a collection of BosonBra particles.
Examples

```python
>>> from sympy.physics.secondquant import BBra
>>> BBra([1, 2])
FockStateBosonBra((1, 2))
```

class sympy.physics.secondquant.FockStateBosonKet(occupations)

Many particle Fock state with a sequence of occupation numbers.
Occupation numbers can be any integer >= 0.

Examples

```python
>>> from sympy.physics.secondquant import BKet
>>> BKet([1, 2])
FockStateBosonKet((1, 2))
```

class sympy.physics.secondquant.FockStateBra(occupations)

Representation of a bra.

class sympy.physics.secondquant.FockStateFermionBra(occupations, fermi_level=0)

Examples

```python
>>> from sympy.physics.secondquant import FBra
>>> FBra([1, 2])
FockStateFermionBra((1, 2))
```

See also:

FockStateFermionKet (page 1597)

class sympy.physics.secondquant.FockStateFermionKet(occupations, fermi_level=0)

Many-particle Fock state with a sequence of occupied orbits.

Explanation

Each state can only have one particle, so we choose to store a list of occupied orbits rather than a tuple with occupation numbers (zeros and ones).
states below fermi level are holes, and are represented by negative labels in the occupation list.
For symbolic state labels, the fermi_level caps the number of allowed hole- states.
Examples

```python
>>> from sympy.physics.secondquant import FKet
>>> FKet([1, 2])
FockStateFermionKet((1, 2))
```

class sympy.physics.secondquant.FockStateKet(occupations)
Representation of a ket.

class sympy.physics.secondquant.InnerProduct(bra, ket)
An unevaluated inner product between a bra and ket.

Explanation

Currently this class just reduces things to a product of Kronecker Deltas. In the future, we could introduce abstract states like \(|a>\) and \(|b>\), and leave the inner product unevaluated as \(<a|b>\).

property bra
Returns the bra part of the state

property ket
Returns the ket part of the state

class sympy.physics.secondquant.KroneckerDelta(i, j, delta_range=None)
The discrete, or Kronecker, delta function.

Parameters

- i : Number, Symbol
  The first index of the delta function.
- j : Number, Symbol
  The second index of the delta function.

Explanation

A function that takes in two integers \(i\) and \(j\). It returns 0 if \(i\) and \(j\) are not equal, or it returns 1 if \(i\) and \(j\) are equal.

Examples

An example with integer indices:

```python
>>> from sympy import KroneckerDelta
>>> KroneckerDelta(1, 2)
0
>>> KroneckerDelta(3, 3)
1
```

Symbolic indices:
```python
>>> from sympy.abc import i, j, k
>>> KroneckerDelta(i, j)
KroneckerDelta(i, j)
>>> KroneckerDelta(i, i)
1
>>> KroneckerDelta(i, i + 1)
0
>>> KroneckerDelta(i, i + 1 + k)
KroneckerDelta(i, i + k + 1)
```

See also:

`eval` (page 1599), `DiracDelta` (page 506)

References

[R710]

classmethod `eval`(i, j, delta_range=None)

Evaluates the discrete delta function.

Examples

```python
>>> from sympy import KroneckerDelta
>>> from sympy.abc import i, j, k
```

```python
>>> KroneckerDelta(i, j)
KroneckerDelta(i, j)
>>> KroneckerDelta(i, i)
1
>>> KroneckerDelta(i, i + 1)
0
>>> KroneckerDelta(i, i + 1 + k)
KroneckerDelta(i, i + k + 1)
```

# indirect doctest

property `indices_contain_equal_information`

Returns True if indices are either both above or below fermi.

Examples

```python
>>> from sympy import KroneckerDelta, Symbol
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')
>>> q = Symbol('q')
>>> KroneckerDelta(p, q).indices_contain_equal_information
True
>>> KroneckerDelta(p, q+1).indices_contain_equal_information
```

(continues on next page)
property is_above_fermi

True if Delta can be non-zero above fermi.

Examples

```python
>>> from sympy import KroneckerDelta, Symbol
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')
>>> q = Symbol('q')
>>> KroneckerDelta(p, a).is_above_fermi
True
>>> KroneckerDelta(p, i).is_above_fermi
False
>>> KroneckerDelta(p, q).is_above_fermi
True
```

See also:

`is_below_fermi` (page 1600), `is_only_below_fermi` (page 1601), `is_only_above_fermi` (page 1600)

property is_below_fermi

True if Delta can be non-zero below fermi.

Examples

```python
>>> from sympy import KroneckerDelta, Symbol
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')
>>> q = Symbol('q')
>>> KroneckerDelta(p, a).is_below_fermi
False
>>> KroneckerDelta(p, i).is_below_fermi
True
>>> KroneckerDelta(p, q).is_below_fermi
True
```

See also:

`is_above_fermi` (page 1600), `is_only_above_fermi` (page 1600), `is_only_below_fermi` (page 1600)

property is_only_above_fermi

True if Delta is restricted to above fermi.
Examples

```python
>>> from sympy import KroneckerDelta, Symbol
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')
>>> q = Symbol('q')
>>> KroneckerDelta(p, a).is_only_above_fermi
True
>>> KroneckerDelta(p, q).is_only_above_fermi
False
>>> KroneckerDelta(p, i).is_only_above_fermi
False
```

See also:

`is_above_fermi` (page 1600), `is_below_fermi` (page 1600), `is_only_below_fermi` (page 1601)

**property is_only_below_fermi**

True if Delta is restricted to below fermi.

Examples

```python
>>> from sympy import KroneckerDelta, Symbol
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> p = Symbol('p')
>>> q = Symbol('q')
>>> KroneckerDelta(p, i).is_only_below_fermi
True
>>> KroneckerDelta(p, q).is_only_below_fermi
False
>>> KroneckerDelta(p, a).is_only_below_fermi
False
```

See also:

`is_above_fermi` (page 1600), `is_below_fermi` (page 1600), `is_only_above_fermi` (page 1600)

**property killable_index**

Returns the index which is preferred to substitute in the final expression.
**Explanation**

The index to substitute is the index with less information regarding fermi level. If indices contain the same information, ‘a’ is preferred before ‘b’.

**Examples**

```python
>>> from sympy import KroneckerDelta, Symbol
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> j = Symbol('j', below_fermi=True)
>>> p = Symbol('p')
>>> KroneckerDelta(p, i).killable_index
p
>>> KroneckerDelta(p, a).killable_index
p
>>> KroneckerDelta(i, j).killable_index
j
```

**See also:**

`preferred_index` (page 1602)

**property preferred_index**

Returns the index which is preferred to keep in the final expression.

**Explanation**

The preferred index is the index with more information regarding fermi level. If indices contain the same information, ‘a’ is preferred before ‘b’.

**Examples**

```python
>>> from sympy import KroneckerDelta, Symbol
>>> a = Symbol('a', above_fermi=True)
>>> i = Symbol('i', below_fermi=True)
>>> j = Symbol('j', below_fermi=True)
>>> p = Symbol('p')
>>> KroneckerDelta(p, i).preferred_index
i
>>> KroneckerDelta(p, a).preferred_index
a
>>> KroneckerDelta(i, j).preferred_index
i
```

**See also:**

`killable_index` (page 1601)

**class sympy.physics.secondquant.NO(arg)**

This Object is used to represent normal ordering brackets.

i.e. {abcd} sometimes written :abcd:
**Explanation**

Applying the function `NO(arg)` to an argument means that all operators in the argument will be assumed to anticommute, and have vanishing contractions. This allows an immediate reordering to canonical form upon object creation.

**Examples**

```python
>>> from sympy import symbols
>>> from sympy.physics.secondquant import NO, F, Fd
>>> p, q = symbols('p, q')
>>> NO(Fd(p)*F(q))
NO(CreateFermion(p)*AnnihilateFermion(q))
>>> NO(F(q)*Fd(p))
-NO(CreateFermion(p)*AnnihilateFermion(q))
```

**Note**

If you want to generate a normal ordered equivalent of an expression, you should use the function `wicks()`. This class only indicates that all operators inside the brackets anticommute, and have vanishing contractions. Nothing more, nothing less.

`doit(**hints)`

Either removes the brackets or enables complex computations in its arguments.

**Examples**

```python
>>> from sympy.physics.secondquant import NO, Fd, F
>>> from textwrap import fill
>>> from sympy import symbols, Dummy
>>> p, q = symbols('p, q', cls=Dummy)
>>> print(fill(str(NO(Fd(p)*F(q)).doit())))
KroneckerDelta(_a, _p)*KroneckerDelta(_a, _q)*CreateFermion(_a)*AnnihilateFermion(_a) + KroneckerDelta(_a, _p)*KroneckerDelta(_i, _q)*CreateFermion(_a)*AnnihilateFermion(_i) - KroneckerDelta(_a, _q)*KroneckerDelta(_i, _p)*AnnihilateFermion(_a)*CreateFermion(_i) - KroneckerDelta(_i, _p)*KroneckerDelta(_i, _q)*AnnihilateFermion(_i)*CreateFermion(_i)
```

`get_subNO(i)`

Returns a `NO()` without FermionicOperator at index i.
Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.secondquant import F, NO
>>> p, q, r = symbols('p, q, r')

>>> NO(F(p)*F(q)*F(r)).get_subNO(1)
NO(AnnihilateFermion(p)*AnnihilateFermion(r))
```

property has_q_annihilators

Return 0 if the rightmost argument of the first argument is a not a q_annihilator, else 1 if it is above fermi or -1 if it is below fermi.

Examples

```python
>>> a = symbols('a', above_fermi=True)
>>> i = symbols('i', below_fermi=True)
>>> NO(Fd(a)*Fd(i)).has_q_annihilators
-1
>>> NO(F(i)*F(a)).has_q_annihilators
1
>>> NO(Fd(a)*F(i)).has_q_annihilators
0
```

property has_q_creators

Return 0 if the leftmost argument of the first argument is a not a q_creator, else 1 if it is above fermi or -1 if it is below fermi.

Examples

```python
>>> a = symbols('a', above_fermi=True)
>>> i = symbols('i', below_fermi=True)
>>> NO(Fd(a)*Fd(i)).has_q_creators
1
>>> NO(F(i)*F(a)).has_q_creators
-1
>>> NO(Fd(i)*F(a)).has_q_creators
0
```

iter_q_annihilators()

Iterates over the annihilation operators.
Examples

```python
>>> from sympy import symbols
>>> i, j = symbols('i j', below_fermi=True)
>>> a, b = symbols('a b', above_fermi=True)
>>> from sympy.physics.secondquant import NO, F, Fd
>>> no = NO(Fd(a) * F(i) * F(b) * Fd(j))

>>> no.iter_q_creators()
<generator object... at 0x...>

>>> list(no.iter_q_creators())
[0, 1]

>>> list(no.iter_q_annihilators())
[3, 2]
```

```python
iter_q_creators() Iterates over the creation operators.
```

Examples

```python
>>> from sympy import symbols
>>> i, j = symbols('i j', below_fermi=True)
>>> a, b = symbols('a b', above_fermi=True)
>>> from sympy.physics.secondquant import NO, F, Fd
>>> no = NO(Fd(a) * F(i) * F(b) * Fd(j))

>>> no.iter_q_creators()
<generator object... at 0x...>

>>> list(no.iter_q_creators())
[0, 1]

>>> list(no.iter_q_annihilators())
[3, 2]
```

class sympy.physics.secondquant.PermutationOperator(i,j)

Represents the index permutation operator P(ij).

```
P(ij)*f(i)*g(j) = f(i)*g(j) - f(j)*g(i)
```

get_permuted(expr)

Returns -expr with permuted indices.

Explanation

```python
>>> from sympy import symbols, Function
>>> from sympy.physics.secondquant import PermutationOperator
>>> p, q = symbols('p,q')
>>> f = Function('f')
>>> PermutationOperator(p,q).get_permuted(f(p,q))
-f(q, p)
```
class sympy.physics.secondquant.VarBosonicBasis(n_max)
A single state, variable particle number basis set.

Examples

```python
>>> from sympy.physics.secondquant import VarBosonicBasis
>>> b = VarBosonicBasis(5)
>>> b
[FockState((0,)), FockState((1,)), FockState((2,)), FockState((3,)), FockState((4,))]
```

index(state)
Returns the index of state in basis.

Examples

```python
>>> from sympy.physics.secondquant import VarBosonicBasis
>>> b = VarBosonicBasis(3)
>>> state = b.state(1)
>>> b
[FockState((0,)), FockState((1,)), FockState((2,))]
>>> state
FockStateBosonKet((1,))
>>> b.index(state)
1
```

state(i)
The state of a single basis.

Examples

```python
>>> from sympy.physics.secondquant import VarBosonicBasis
>>> b = VarBosonicBasis(5)
>>> b.state(3)
FockStateBosonKet((3,))
```

sympy.physics.secondquant.apply_operators(e)
Take a SymPy expression with operators and states and apply the operators.
Examples

```python
>>> from sympy.physics.secondquant import apply_operators
>>> from sympy import sympify
>>> apply_operators(sympify(3) + 4)
7
```

`sympy.physics.secondquant.contraction(a, b)`

Calculates contraction of Fermionic operators a and b.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.secondquant import F, Fd, contraction
>>> p, q = symbols('p,q')
>>> a, b = symbols('a,b', above_fermi=True)
>>> i, j = symbols('i,j', below_fermi=True)
```

A contraction is non-zero only if a quasi-creator is to the right of a quasi-annihilator:

```python
>>> contraction(F(a), Fd(b))
KroneckerDelta(a, b)
>>> contraction(Fd(i), F(j))
KroneckerDelta(i, j)
```

For general indices a non-zero result restricts the indices to below/above the fermi surface:

```python
>>> contraction(Fd(p), F(q))
KroneckerDelta(_i, q)*KroneckerDelta(p, q)
>>> contraction(F(p), Fd(q))
KroneckerDelta(_a, q)*KroneckerDelta(p, q)
```

Two creators or two annihilators always vanishes:

```python
>>> contraction(F(p), F(q))
0
>>> contraction(Fd(p), Fd(q))
0
```

`sympy.physics.secondquant.evaluate_deltas(e)`

We evaluate KroneckerDelta symbols in the expression assuming Einstein summation.
**Explanation**

If one index is repeated it is summed over and in effect substituted with the other one. If both indices are repeated we substitute according to what is the preferred index. This is determined by KroneckerDelta.preferred_index and KroneckerDelta.killable_index.

In case there are no possible substitutions or if a substitution would imply a loss of information, nothing is done.

In case an index appears in more than one KroneckerDelta, the resulting substitution depends on the order of the factors. Since the ordering is platform dependent, the literal expression resulting from this function may be hard to predict.

**Examples**

We assume the following:

```python
>>> from sympy import symbols, Function, Dummy, KroneckerDelta
>>> from sympy.physics.secondquant import evaluate_deltas
>>> i, j = symbols('i j', below_fermi=True, cls=Dummy)
>>> a, b = symbols('a b', above_fermi=True, cls=Dummy)
>>> p, q = symbols('p q', cls=Dummy)
>>> f = Function('f')
>>> t = Function('t')
```

The order of preference for these indices according to KroneckerDelta is (a, b, i, j, p, q).

**Trivial cases:**

```python
>>> evaluate_deltas(KroneckerDelta(i,j)*f(i)) # d_ij f(i) -> f(j)  
f(j)
>>> evaluate_deltas(KroneckerDelta(i,j)*f(j)) # d_ij f(j) -> f(i)  
f(i)
>>> evaluate_deltas(KroneckerDelta(i,p)*f(p)) # d_ip f(p) -> f(i)  
f(i)
>>> evaluate_deltas(KroneckerDelta(q,p)*f(p)) # d_qp f(p) -> f(q)  
f(q)
>>> evaluate_deltas(KroneckerDelta(q,p)*f(q)) # d_qp f(q) -> f(p)  
f(p)
```

**More interesting cases:**

```python
>>> evaluate_deltas(KroneckerDelta(i,p)*t(a,i)*f(p,q))  
f(_i) * t(_a, _i) * f(_p, _q)
```  

Finally, here are some cases where nothing is done, because that would imply a loss of information:

```python
>>> evaluate_deltas(KroneckerDelta(i,p)*f(q))  
f(_q) * KroneckerDelta(_i, _p)
```
sympy.physics.secondquant.matrix_rep(op, basis)
Find the representation of an operator in a basis.

Examples

```python
>>> from sympy.physics.secondquant import VarBosonicBasis, B, matrix_rep
>>> b = VarBosonicBasis(5)
>>> o = B(0)
>>> matrix_rep(o, b)
Matrix([[0, 1, 0, 0, 0],
       [0, 0, sqrt(2), 0, 0],
       [0, 0, 0, sqrt(3), 0],
       [0, 0, 0, 0, 2],
       [0, 0, 0, 0, 0]])
```

sympy.physics.secondquant.simplify_index_permutations(expr, permutation_operators)
Performs simplification by introducing PermutationOperators where appropriate.

Explanation

Schematically:

\[ [abij] - [abji] - [baij] + [baji] \rightarrow P(ab)*P(ij)*[abij] \]

permutation_operators is a list of PermutationOperators to consider.

If permutation_operators=[P(ab),P(ij)] we will try to introduce the permutation operators P(ij) and P(ab) in the expression. If there are other possible simplifications, we ignore them.

```python
>>> from sympy import symbols, Function
>>> from sympy.physics.secondquant import simplify_index_permutations
>>> from sympy.physics.secondquant import PermutationOperator
>>> p, q, r, s = symbols('p,q,r,s')
>>> f = Function('f')
>>> g = Function('g')

>>> expr = f(p)*g(q) - f(q)*g(p); expr
f(p)*g(q) - f(q)*g(p)
>>> simplify_index_permutations(expr, [PermutationOperator(p, q)])
f(p)*g(q)*PermutationOperator(p, q)
```

```python
>>> PermutList = [PermutationOperator(p, q), PermutationOperator(r, s)]
>>> expr = f(p, r)*g(q, s) - f(q, r)*g(p, s) + f(q, s)*g(p, r) - f(p, s)*g(q, r)
>>> simplify_index_permutations(expr, PermutList)
f(p, r)*g(q, s)*PermutationOperator(p, q)*PermutationOperator(r, s)
```
sympy.physics.secondquant.substitute_dummies(expr, new_indices=False, pretty_indices={})

Collect terms by substitution of dummy variables.

**Explanation**

This routine allows simplification of Add expressions containing terms which differ only due to dummy variables.

The idea is to substitute all dummy variables consistently depending on the structure of the term. For each term, we obtain a sequence of all dummy variables, where the order is determined by the index range, what factors the index belongs to and its position in each factor. See _get_ordered_dummies() for more information about the sorting of dummies. The index sequence is then substituted consistently in each term.

**Examples**

```python
>>> from sympy import symbols, Function, Dummy
>>> from sympy.physics.secondquant import substitute_dummies
>>> a,b,c,d = symbols('a b c d', above_fermi=True, cls=Dummy)
>>> i,j = symbols('i j', below_fermi=True, cls=Dummy)
>>> f = Function('f')

>>> expr = f(a,b) + f(c,d); expr
f(_a, _b) + f(_c, _d)

Since a, b, c and d are equivalent summation indices, the expression can be simplified to a single term (for which the dummy indices are still summed over)

```python
>>> substitute_dummies(expr)
2*f(_a, _b)
```

Controlling output:

By default the dummy symbols that are already present in the expression will be reused in a different permutation. However, if new_indices=True, new dummies will be generated and inserted. The keyword ‘pretty_indices’ can be used to control this generation of new symbols.

By default the new dummies will be generated on the form i_1, i_2, a_1, etc. If you supply a dictionary with key:value pairs in the form:

```python
    { index_group: string_of_letters }
```

The letters will be used as labels for the new dummy symbols. The index_groups must be one of ‘above’, ‘below’ or ‘general’.

```python
>>> expr = f(a,b,i,j)
>>> my_dummies = { 'above': 'st', 'below': 'uv' }
>>> substitute_dummies(expr, new_indices=True, pretty_indices=my_dummies)
f(_s, _t, _u, _v)
```

If we run out of letters, or if there is no keyword for some index_group the default dummy generator will be used as a fallback:
```python
>>> p, q = symbols('p q', cls=Dummy)  # general indices
>>> expr = f(p, q)
>>> substitute_dummies(expr, new_indices=True, pretty_indices=my_dummies)
f(_p_0, _p_1)
```

`sympy.physics.secondquant.wicks(e, **kw_args)`

Returns the normal ordered equivalent of an expression using Wicks Theorem.

**Examples**

```python
>>> from sympy import symbols, Dummy
>>> from sympy.physics.secondquant import wicks, F, Fd
>>> p, q, r = symbols('p, q, r')
>>> wicks(Fd(p) * F(q))
KroneckerDelta(_i, q) * KroneckerDelta(p, q) +
  NO(CreateFermion(p) * AnnihilateFermion(q))
```

By default, the expression is expanded:

```python
>>> wicks(F(p) * (F(q) + F(r)))
NO(AnnihilateFermion(p) * AnnihilateFermion(q)) +
  _NO(AnnihilateFermion(p) * AnnihilateFermion(r))
```

With the keyword `keep_only_fully_contracted=True`, only fully contracted terms are returned.

**By request, the result can be simplified in the following order:**
- KroneckerDelta functions are evaluated
- Dummy variables are substituted consistently across terms

```python
>>> p, q, r = symbols('p q r', cls=Dummy)
>>> wicks(Fd(p) * (F(q) + F(r)), keep_only_fully_contracted=True)
KroneckerDelta(_i, _q) * KroneckerDelta(_p, _q) +
  KroneckerDelta(_i, _r) * KroneckerDelta(_p, _r)
```

**Wigner Symbols**

Wigner, Clebsch-Gordan, Racah, and Gaunt coefficients

Collection of functions for calculating Wigner 3j, 6j, 9j, Clebsch-Gordan, Racah as well as Gaunt coefficients exactly, all evaluating to a rational number times the square root of a rational number [Rasch03].

Please see the description of the individual functions for further details and examples.
SymPy Documentation, Release 1.12.1

- Oscar Gerardo Lazo Arjona (2017-06-18): added Wigner D matrices
- Phil Adam LeMaitre (2022-09-19): added real Gaunt coefficient

Copyright (C) 2008 Jens Rasch <jyr2000@gmail.com>

sympy.physics.wigner.clebsch_gordan(j_1, j_2, j_3, m_1, m_2, m_3)
Calculates the Clebsch-Gordan coefficient. \( \langle j_1 m_1 j_2 m_2 | j_3 m_3 \rangle \).
The reference for this function is [Edmonds74].

Parameters

- \( j_1, j_2, j_3, m_1, m_2, m_3 \) :
  Integer or half integer.

Returns

Rational number times the square root of a rational number.

Examples

```python
>>> from sympy import S
>>> from sympy.physics.wigner import clebsch_gordan
>>> clebsch_gordan(S(3)/2, S(1)/2, 2, S(3)/2, S(1)/2, 2)
1
>>> clebsch_gordan(S(3)/2, S(1)/2, 1, S(3)/2, -S(1)/2, 1)
sqrt(3)/2
>>> clebsch_gordan(S(3)/2, S(1)/2, 1, -S(1)/2, S(1)/2, 0)
-sqrt(2)/2
```

Notes

The Clebsch-Gordan coefficient will be evaluated via its relation to Wigner 3j symbols:

\[
\langle j_1 m_1 j_2 m_2 | j_3 m_3 \rangle = (-1)^{j_1 - j_2 + m_3} \sqrt{2j_3 + 1} \text{Wigner3j}(j_1, j_2, j_3, m_1, m_2, -m_3)
\]

See also the documentation on Wigner 3j symbols which exhibit much higher symmetry relations than the Clebsch-Gordan coefficient.
Authors

- Jens Rasch (2009-03-24): initial version

sympy.physics.wigner.dot_rot_grad_Ynm(j, p, l, m, theta, phi)

Returns dot product of rotational gradients of spherical harmonics.

Explanation

This function returns the right hand side of the following expression:

$$\tilde{R}^p_j \cdot \tilde{R}^m_l = (-1)^{m+p} \sum_{k=|l-j|}^{l+j} Y^{m+p}_k \cdot \alpha_{l,m,j,p,k} \cdot \frac{1}{2} (k^2 - j^2 - l^2 + k - j - l)$$

Arguments

j, p, l, m .... indices in spherical harmonics (expressions or integers) theta, phi .... angle arguments in spherical harmonics

Example

```python
>>> from sympy import symbols
>>> from sympy.physics.wigner import dot_rot_grad_Ynm
>>> theta, phi = symbols("theta phi")
>>> dot_rot_grad_Ynm(3, 2, 2, 0, theta, phi).doit()
3*sqrt(55)*Ynm(5, 2, theta, phi)/(11*sqrt(pi))
```

sympy.physics.wigner.gaunt(l_1, l_2, l_3, m_1, m_2, m_3, prec=None)

Calculate the Gaunt coefficient.

Parameters

l_1, l_2, l_3, m_1, m_2, m_3 :

Integer.

prec - precision, default: ``None``.

Providing a precision can drastically speed up the calculation.

Returns

Rational number times the square root of a rational number
(if prec=None), or real number if a precision is given.
**Explanation**

The Gaunt coefficient is defined as the integral over three spherical harmonics:

\[
\text{Gaunt}(l_1, l_2, l_3, m_1, m_2, m_3) = \int Y_{l_1, m_1}(\Omega)Y_{l_2, m_2}(\Omega)Y_{l_3, m_3}(\Omega) \, d\Omega \\
= \sqrt{\frac{(2l_1 + 1)(2l_2 + 1)(2l_3 + 1)}{4\pi}} W_{3j}(l_1, l_2, l_3, 0, 0) W_{3j}(l_1, l_2, l_3, m_1, m_2, m_3)
\]

**Examples**

```python
>>> from sympy.physics.wigner import gaunt
>>> gaunt(1,0,1,1,0,-1)
-1/(2*sqrt(pi))
>>> gaunt(1000,1000,1200,9,3,-12).n(64)
0.00689500421922113448...
```

It is an error to use non-integer values for \(l\) and \(m\):

```python
sage: gaunt(1.2,0,1.2,0,0,0)
Traceback (most recent call last):
...
ValueError: l values must be integer
sage: gaunt(1,0,1,1,0,-1.1)
Traceback (most recent call last):
...
ValueError: m values must be integer
```

**Notes**

The Gaunt coefficient obeys the following symmetry rules:

- invariant under any permutation of the columns

\[
Y(l_1, l_2, l_3, m_1, m_2, m_3) = Y(l_3, l_1, l_2, m_1, m_2, m_3) \\
= Y(l_2, l_3, l_1, m_2, m_3, m_1) \\
= Y(l_3, l_2, l_1, m_3, m_1, m_2) \\
= Y(l_1, l_3, l_2, m_1, m_3, m_2) \\
= Y(l_2, l_1, l_3, m_2, m_1, m_3)
\]

- invariant under space inflection, i.e.

\[
Y(l_1, l_2, l_3, m_1, m_2, m_3) = Y(l_1, l_2, l_3, -m_1, -m_2, -m_3)
\]

- symmetric with respect to the 72 Regge symmetries as inherited for the \(3j\) symbols [Regge58]

- zero for \(l_1, l_2, l_3\) not fulfilling triangle relation

- zero for violating any one of the conditions: \(l_1 \geq |m_1|, l_2 \geq |m_2|, l_3 \geq |m_3|\)

- non-zero only for an even sum of the \(l_i\), i.e. \(L = l_1 + l_2 + l_3 = 2n\) for \(n \in \mathbb{N}\)
Algorithms

This function uses the algorithm of [Liberatodebrito82] to calculate the value of the Gaunt coefficient exactly. Note that the formula contains alternating sums over large factorials and is therefore unsuitable for finite precision arithmetic and only useful for a computer algebra system [Rasch03].

Authors

Authors

sympy.physics.wigner.racah(aa, bb, cc, dd, ee, ff, prec=None)

Calculate the Racah symbol \( W(a, b, c; d, e, f) \).

Parameters

- \( a, \ldots, f \): Integer or half integer.
- \( \text{prec} \): Precision, default: None. Providing a precision can drastically speed up the calculation.

Returns

Rational number times the square root of a rational number (if \( \text{prec}=\text{None} \)), or real number if a precision is given.

Examples

```python
>>> from sympy.physics.wigner import racah
>>> racah(3, 3, 3, 3, 3, 3)
-1/14
```

Notes

The Racah symbol is related to the Wigner 6j symbol:

\[
\text{Wigner6j}(j_1, j_2, j_3, j_4, j_5, j_6) = (-1)^{j_1 + j_2 + j_3 + j_4 + j_5 + j_6} W(j_1, j_2, j_3, j_4, j_5, j_6)
\]

Please see the 6j symbol for its much richer symmetries and for additional properties.

Algorithm

This function uses the algorithm of [Edmonds74] to calculate the value of the 6j symbol exactly. Note that the formula contains alternating sums over large factorials and is therefore unsuitable for finite precision arithmetic and only useful for a computer algebra system [Rasch03].
real_gaunt(l_1, l_2, l_3, m_1, m_2, m_3, prec=None)

Calculate the real Gaunt coefficient.

Parameters

- **l_1, l_2, l_3, m_1, m_2, m_3**: Integer.
- **prec** - precision, default: `None`

Providing a precision can drastically speed up the calculation.

Returns

Rational number times the square root of a rational number.

Explanation

The real Gaunt coefficient is defined as the integral over three real spherical harmonics:

$$\text{RealGaunt}(l_1, l_2, l_3, m_1, m_2, m_3) = \int Z_{l_1}^{m_1}(\Omega)Z_{l_2}^{m_2}(\Omega)Z_{l_3}^{m_3}(\Omega) \, d\Omega$$

Alternatively, it can be defined in terms of the standard Gaunt coefficient by relating the real spherical harmonics to the standard spherical harmonics via a unitary transformation $U$, i.e. $Z_l^m(\Omega) = \sum_{m'} U_{m'm} Y_l^{m'}(\Omega)$ [Homeier96]. The real Gaunt coefficient is then defined as

$$\text{RealGaunt}(l_1, l_2, l_3, m_1, m_2, m_3) = \sum_{m_1', m_2', m_3'} U_{m_1'm_1} U_{m_2'm_2} U_{m_3'm_3} \text{Gaunt}(l_1, l_2, l_3, m_1', m_2', m_3')$$

The unitary matrix $U$ has components

$$U_{m'm} = \delta_{|m||m'|} \times (\delta_{m0}\delta_{m0} + \frac{1}{2} [\Theta(m)(\delta_m m + (-1)^m \delta_m - m) + i\Theta(-m)((-1)^m \delta_{m-m} - \delta_{m'-m} * (-1)^{m'-m})])$$

where $\delta_{ij}$ is the Kronecker delta symbol and $\Theta$ is a step function defined as

$$\Theta(x) = \begin{cases} \text{1 for } x > 0 \\ \text{0 for } x \leq 0 \end{cases}$$

Examples

```python
>>> from sympy.physics.wigner import real_gaunt
>>> real_gaunt(2,2,4,-1,-1,0)
-2/(7*sqrt(pi))
>>> real_gaunt(10,10,20,-9,-9,0).n(64)
-0.00002480019791932209313156167...
```
It is an error to use non-integer values for \(l\) and \(m\):

real_gaunt(2.8,0.5,1.3,0,0,0)  Traceback (most recent call last): ...
ValueError: l values must be integer
real_gaunt(2,2,4,0.7,1,-3.4)  Traceback (most recent call last):
...
ValueError: m values must be integer

Notes

The real Gaunt coefficient inherits from the standard Gaunt coefficient, the invariance under any permutation of the pairs \((l_i, m_i)\) and the requirement that the sum of the \(l_i\) be even to yield a non-zero value. It also obeys the following symmetry rules:

- zero for \(l_1, l_2, l_3\) not fulfilling the condition \(l_1 \in \{l_{\text{max}}, l_{\text{max}} - 2, \ldots, l_{\text{min}}\}\), where \(l_{\text{max}} = l_2 + l_3\),

\[
l_{\text{min}} = \begin{cases} \kappa(l_2, l_3, m_2, m_3) & \text{if } \kappa(l_2, l_3, m_2, m_3) + l_{\text{max}} \text{ is even} \\ \kappa(l_2, l_3, m_2, m_3) + 1 & \text{if } \kappa(l_2, l_3, m_2, m_3) + l_{\text{max}} \text{ is odd} \end{cases}
\]

and \(\kappa(l_2, l_3, m_2, m_3) = \max(|l_2 - l_3|, \min(|m_2 + m_3|, |m_2 - m_3|))\)

- zero for an odd number of negative \(m_i\)

Algorithms

This function uses the algorithms of [Homeier96] and [Rasch03] to calculate the value of the real Gaunt coefficient exactly. Note that the formula used in [Rasch03] contains alternating sums over large factorials and is therefore unsuitable for finite precision arithmetic and only useful for a computer algebra system [Rasch03]. However, this function can in principle use any algorithm that computes the Gaunt coefficient, so it is suitable for finite precision arithmetic in so far as the algorithm which computes the Gaunt coefficient is.

```python
sympy.physics.wigner.wigner_3j(j_1, j_2, j_3, m_1, m_2, m_3)
```

Calculate the Wigner 3j symbol Wigner3j\((j_1, j_2, j_3, m_1, m_2, m_3)\).

Parameters

- \(j_1, j_2, j_3, m_1, m_2, m_3\):
  Integer or half integer.

Returns

Rational number times the square root of a rational number.

Examples

```python
>>> from sympy.physics.wigner import wigner_3j
>>> wigner_3j(2, 6, 4, 0, 0, 0)
sqrt(715)/143
>>> wigner_3j(2, 6, 4, 0, 0, 1)
0
```

It is an error to have arguments that are not integer or half integer values:
sage: wigner_3j(2.1, 6, 4, 0, 0, 0)
Traceback (most recent call last):
...
ValueError: j values must be integer or half integer
sage: wigner_3j(2, 6, 4, 1, 0, -1.1)
Traceback (most recent call last):
...
ValueError: m values must be integer or half integer

Notes

The Wigner 3j symbol obeys the following symmetry rules:

• invariant under any permutation of the columns (with the exception of a sign change where $J := j_1 + j_2 + j_3$):

\[
\text{Wigner3j}(j_1, j_2, j_3, m_1, m_2, m_3) = \text{Wigner3j}(j_3, j_1, j_2, m_3, m_1, m_2)
= \text{Wigner3j}(j_2, j_3, j_1, m_2, m_3, m_1)
= (-1)^J \text{Wigner3j}(j_3, j_2, j_1, m_3, m_2, m_1)
= (-1)^J \text{Wigner3j}(j_1, j_3, j_2, m_1, m_3, m_2)
= (-1)^J \text{Wigner3j}(j_2, j_1, j_3, m_2, m_1, m_3)
\]

• invariant under space inflection, i.e.

\[
\text{Wigner3j}(j_1, j_2, j_3, m_1, m_2, m_3) = (-1)^J \text{Wigner3j}(j_1, j_2, j_3, -m_1, -m_2, -m_3)
\]

• symmetric with respect to the 72 additional symmetries based on the work by [Regge58]

• zero for $j_1, j_2, j_3$ not fulfilling triangle relation

• zero for $m_1 + m_2 + m_3 \neq 0$

• zero for violating any one of the conditions $j_1 \geq |m_1|, j_2 \geq |m_2|, j_3 \geq |m_3|$

Algorithm

This function uses the algorithm of [Edmonds74] to calculate the value of the 3j symbol exactly. Note that the formula contains alternating sums over large factorials and is therefore unsuitable for finite precision arithmetic and only useful for a computer algebra system [Rasch03].
SymPy Documentation, Release 1.12.1

Authors

- Jens Rasch (2009-03-24): initial version

\texttt{sympy.physics.wigner.wigner\_6j}(j_1, j_2, j_3, j_4, j_5, j_6, \text{prec}=\text{None})

Calculate the Wigner 6j symbol \(W(j_1, j_2, j_3, j_4, j_5, j_6).\)

**Parameters**

- \(j_1, \ldots, j_6:\) Integer or half integer.
- \text{prec}: Precision, default: \text{None}. Providing a precision can drastically speed up the calculation.

**Returns**

Rational number times the square root of a rational number (if \text{prec}=\text{None}), or real number if a precision is given.

**Examples**

```python
>>> from sympy.physics.wigner import wigner_6j
>>> wigner_6j(3, 3, 3, 3, 3)
-1/14
>>> wigner_6j(5, 5, 5, 5, 5)
1/52
```

It is an error to have arguments that are not integer or half integer values or do not fulfill the triangle relation:

```python
sage: wigner_6j(2.5, 2.5, 2.5, 2.5, 2.5, 2.5)
Traceback (most recent call last):
...
ValueError: j values must be integer or half integer and fulfill the \(_\triangle \)triangle relation
```

**Notes**

The Wigner 6j symbol is related to the Racah symbol but exhibits more symmetries as detailed below.

\[
Wigner6j(j_1, j_2, j_3, j_4, j_5, j_6) = (-1)^{j_1+j_2+j_4+j_6} W(j_1, j_2, j_5, j_4, j_3, j_6)
\]

The Wigner 6j symbol obeys the following symmetry rules:
• Wigner 6j symbols are left invariant under any permutation of the columns:
  \[ \text{Wigner6j}(j_1, j_2, j_3, j_4, j_5, j_6) = \text{Wigner6j}(j_3, j_1, j_2, j_6, j_4, j_5) = \text{Wigner6j}(j_2, j_3, j_1, j_5, j_6, j_4) = \text{Wigner6j}(j_1, j_3, j_2, j_4, j_6, j_5) = \text{Wigner6j}(j_2, j_1, j_3, j_5, j_4, j_6) \]

• They are invariant under the exchange of the upper and lower arguments in each of any two columns, i.e.
  \[ \text{Wigner6j}(j_1, j_2, j_3, j_4, j_5, j_6) = \text{Wigner6j}(j_1, j_5, j_6, j_4, j_2, j_3) = \text{Wigner6j}(j_4, j_2, j_6, j_1, j_5, j_3) = \text{Wigner6j}(j_4, j_5, j_3, j_1, j_2, j_6) \]

• additional 6 symmetries [Regge59] giving rise to 144 symmetries in total
• only non-zero if any triple of j’s fulfill a triangle relation

Algorithm

This function uses the algorithm of [Edmonds74] to calculate the value of the 6j symbol exactly. Note that the formula contains alternating sums over large factorials and is therefore unsuitable for finite precision arithmetic and only useful for a computer algebra system [Rasch03].

`sympy.physics.wigner.wigner_9j(j_1, j_2, j_3, j_4, j_5, j_6, j_7, j_8, j_9, prec=None)`

Calculate the Wigner 9j symbol Wigner9j(j_1, j_2, j_3, j_4, j_5, j_6, j_7, j_8, j_9).

Parameters

  \( j_1, \ldots, j_9 \):
  
  Integer or half integer.

  \( \text{prec} \):
  
  Precision, default None. Providing a precision can drastically speed up the calculation.

Returns

  Rational number times the square root of a rational number
  (if prec=None), or real number if a precision is given.

Examples

```python
>>> from sympy.physics.wigner import wigner_9j
>>> wigner_9j(1,1,1, 1,1, 1,1,0, prec=64) # ==1/18
0.055555555...

>>> wigner_9j(1/2,1/2,0, 1/2,3/2,1, 0,1,1, prec=64) # ==1/6
0.16666666...
```

It is an error to have arguments that are not integer or half integer values or do not fulfill the triangle relation:
Algorithm

This function uses the algorithm of [Edmonds74] to calculate the value of the 3j symbol exactly. Note that the formula contains alternating sums over large factorials and is therefore unsuitable for finite precision arithmetic and only useful for a computer algebra system [Rasch03].

```
sage: wigner_9j(0.5,0.5,0.5, 0.5,0.5,0.5, 0.5,0.5,0.5,prec=64)
Traceback (most recent call last):

```

Explanation

**J:**
An integer, half-integer, or SymPy symbol for the total angular momentum of the angular momentum space being rotated.

**alpha, beta, gamma - Real numbers representing the Euler.**
Angles of rotation about the so-called vertical, line of nodes, and figure axes. See [Edmonds74].

Examples

The simplest possible example:
```python
>>> from sympy.physics.wigner import wigner_d
>>> from sympy import Integer, symbols, pprint
>>> half = 1/Integer(2)
>>> alpha, beta, gamma = symbols("alpha, beta, gamma", real=True)
>>> pprint(wigner_d(half, alpha, beta, gamma), use_unicode=True)
```
sympy.physics.wigner.wigner_d_small(J, beta)

Return the small Wigner d matrix for angular momentum J.

**Returns**
A matrix representing the corresponding Euler angle rotation (in the basis of eigenvectors of \( J_z \)).

\[
\exp \left( \frac{i\beta}{\hbar} J_y \right)
\]

The components are calculated using the general form [Edmonds74], equation 4.1.15.

**Explanation**

\( J \)
[An integer, half-integer, or SymPy symbol for the total angular momentum of the angular momentum space being rotated.]

\( \beta \)
[A real number representing the Euler angle of rotation about the so-called line of nodes. See [Edmonds74].]

**Examples**

```python
>>> from sympy import Integer, symbols, pi, pprint
>>> from sympy.physics.wigner import wigner_d_small
>>> half = 1/Integer(2)
>>> beta = symbols("beta", real=True)
>>> pprint(wigner_d_small(half, beta), use_unicode=True)
⎡ ⎛β⎞ ⎛β⎞⎤
⎢cos⎜─⎟ sin⎜─⎟⎥
⎢ ⎝2⎠ ⎝2⎠⎥
⎢ ⎥
⎢ ⎛β⎞ ⎛β⎞⎥
⎢-sin⎜─⎟ cos⎜─⎟⎥
⎣ ⎝2⎠ ⎝2⎠⎦
```
From table 4 in [Edmonds74]

```python
>>> pprint(wigner_d_small(2*half, beta), use_unicode=True)
[[cos(β/2), \sqrt{2} \cdot \sin(β/2) \cdot \cos(β/2), \sin(β/2)]
[-\sqrt{2} \cdot \sin(β/2) \cdot \cos(β/2), -\sin(β/2) + \cos(β/2), \sqrt{2} \cdot \sin(β/2) \cdot \cos(β/2)]
[\sin(β/2), -\sqrt{2} \cdot \sin(β/2) \cdot \cos(β/2), \cos(β/2)]]
```

```python
>>> pprint(wigner_d_small(half, beta).subs({beta:pi/2}), use_unicode=True)
[[\sqrt{2}/2, \sqrt{2}/2, -\sqrt{2}/2, \sqrt{2}/2]]
```

```python
>>> pprint(wigner_d_small(2*half, beta).subs({beta:pi/2}), use_unicode=True)
[[1/2, \sqrt{2}/2, 1/2, \sqrt{2}/2]
[-\sqrt{2}/2, 0, \sqrt{2}/2, -\sqrt{2}/2]
[1/2, 1/2, 1/2, 1/2]]
```

```python
>>> pprint(wigner_d_small(3*half, beta).subs({beta:pi/2}), use_unicode=True)
[[\sqrt{2}/4, \sqrt{6}/4, \sqrt{6}/4, \sqrt{2}/4]
[-\sqrt{6}/4, -\sqrt{2}/4, \sqrt{2}/4, -\sqrt{6}/4]
[4/4, 4/4, 4/4, 4/4]]
```

(continues on next page)
```python
>>> pprint(wigner_d_small(4*half, beta).subs({beta:pi/2})),
... use_unicode=True)
```

**Unit systems**

This module integrates unit systems into SymPy, allowing a user choose which system to use when doing their computations and providing utilities to display and convert units.

Units (like meters, pounds, seconds) and constants (like light years, Boltzmann’s constant) are all considered quantities. A `Quantity` object defines both units and physical constants (though its subclass `PhysicalConstant` may be preferred for physical constants).

The relations between quantities are defined by their dimensions and the scale factor to at least another quantity of the same dimension. These two types of relations are usually defined inside `UnitSystem` objects, except for properties valid in every unit system. For example, 1 kilometer is equal to 1000 meters in all unit systems and its dimension is length in all dimension systems. On the other hand, the speed of light is equal to 299792458 meters per second in SI units, while it is equal to 1 (unitless) in natural units. In both SI and natural units the dimension of the speed of light in velocity, but in the dimension system of natural units velocity is dimensionless because length and time are equivalent. Similarly, there are discrepancies in the dimensions and scale factors of electromagnetic quantities between SI unit system and CGS and gaussian unit systems, as the last two ones do not consider the current to be a fundamental dimension.

The advantage of this implementation over the one found in other libraries is that it handles relations between units differently in different unit systems, without restrictions to the assumption of relations between units and physical constants provided by the SI unit system.
Examples

The most important function in the units module is `convert_to`, it allows the given quantity to be rewritten as the product of powers of some target quantities. For example, to represent the speed of light in terms of meters and seconds:

```python
>>> from sympy.physics.units import speed_of_light, meter, second
>>> from sympy.physics.units import convert_to
>>> convert_to(speed_of_light, [meter, second])
299792458*meter/second
```

If it is not possible to represent the given quantity in the target units, the given quantity will be returned unchanged:

```python
>>> convert_to(speed_of_light, [meter])
speed_of_light
```

The relations between quantities depend on the unit systems. So, `convert_to` accepts an optional third parameter representing the unit system, which is SI by default. The conversion may return different results depending on the chosen unit system, for example, in the cgs_gauss unit system the current is not a fundamental dimension, rather it can be represented as a combination of length, time and mass:

```python
>>> from sympy.physics.units.systems.si import SI
>>> from sympy.physics.units.systems.cgs import cgs_gauss
>>> from sympy.physics.units import ampere, gram, second
>>> convert_to(ampere, [meter, gram, second], SI)
ampere
>>> convert_to(ampere, [meter, gram, second], cgs_gauss)
149896229*sqrt(gram)*meter**(3/2)/(50*second**2)
```

Quantities of the same dimension do not get simplified automatically, for example if you divide meters by kilometers, you will get an object representing the division between the two units. In order to simplify this kind of expressions, you can either call the `.simplify()` method or import the `quantity_simplify()` function, the last one also accepting a unit system as optional parameter:

```python
>>> from sympy.physics.units.util import quantity_simplify
>>> from sympy.physics.units import kilometer
>>> meter/kilometer
meter/kilometer
>>> (meter/kilometer).simplify()
1/1000
>>> quantity_simplify(meter/kilometer)
1/1000
```
More

Ideas about future developments can be found on the Github wiki.

Philosophy behind unit systems

Dimensions

Introduction

At the root of unit systems are dimension systems, whose structure mainly determines the one of unit systems. Our definition could seem rough but they are largely sufficient for our purposes.

A dimension will be defined as a property which is measurable and assigned to a specific phenomenon. In this sense dimensions are different from pure numbers because they carry some extra-sense, and for this reason two different dimensions cannot be added. For example time or length are dimensions, but also any other things which has some sense for us, like angle, number of particles (moles...) or information (bits...).

From this point of view the only truly dimensionless quantity are pure numbers. The idea of being dimensionless is very system-dependent, as can be seen from the \((c, \hbar, G)\), in which all units appears to be dimensionless in the usual common sense. This is unavoidable for computability of generic unit systems (but at the end we can tell the program what is dimensionless).

Dimensions can be composed together by taking their product or their ratio (to be defined below). For example the velocity is defined as length divided by time, or we can see the length as velocity multiplied by time, depending of what we see as the more fundamental: in general we can select a set of base dimensions from which we can describe all the others.

Group structure

After this short introduction whose aim was to introduce the dimensions from an intuitive perspective, we describe the mathematical structure. A dimension system with \(n\) independent dimensions \(\{d_i\}_{i=1,\ldots,n}\) is described by a multiplicative group \(G\):

- there an identity element 1 corresponding to pure numbers;
- the product \(D_3 = D_1 D_2\) of two elements \(D_1, D_2 \in G\) is also in \(G\);
- any element \(D \in G\) has an inverse \(D^{-1} \in G\).

We denote

\[
D^n = D \times \cdots \times D, \quad \text{n times}
\]

and by definition \(D^0 = 1\). The \(\{d_i\}_{i=1,\ldots,n}\) are called generators of the group since any element \(D \in G\) can be expressed as the product of powers of the generators:

\[
D = \prod_{i=1}^{n} d_i^{a_i}, \quad a_i \in \mathbb{Z}.
\]

The identity is given for \(a_i = 0, \forall i\), while we recover the generator \(d_i\) for \(a_i = 1, a_j = 0, \forall j \neq i\). This group has the following properties:
1. abelian, since the generator commutes, \([d_i, d_j] = 0\);

2. countable (infinite but discrete) since the elements are indexed by the powers of the generators\(^1\).

One can change the dimension basis \(\{d'_i\}_{i=1,...,n}\) by taking some combination of the old generators:

\[
d'_i = \prod_{j=1}^{n} d'^{P_{ij}}.
\]

**Linear space representation**

It is possible to use the linear space \(\mathbb{Z}^n\) as a representation of the group since the power coefficients \(a_i\) carry all the information one needs (we do not distinguish between the element of the group and its representation):

\[
(d_i)_j = \delta_{ij}, \quad D = \begin{pmatrix} a_1 \\ \vdots \\ a_n \end{pmatrix}.
\]

The change of basis to \(d'_i\) follows the usual rule of change of basis for linear space, the matrix being given by the coefficients \(P_{ij}\), which are simply the coefficients of the new vectors in term of the old basis:

\[
d'_i = P_{ij}d_j.
\]

We will use this last solution in our algorithm.

**An example**

In order to illustrate all this formalism, we end this section with a specific example, the MKS system (m, kg, s) with dimensions (L: length, M: mass, T: time). They are represented as (we will always sort the vectors in alphabetic order)

\[
L = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}, \quad M = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}, \quad T = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}.
\]

Other dimensions can be derived, for example velocity \(V\) or action \(A\)

\[
V = LT^{-1}, \quad A = ML^2T^{-2},
\]

\[
V = \begin{pmatrix} 1 \\ 0 \\ -1 \end{pmatrix}, \quad A = \begin{pmatrix} 2 \\ 1 \\ -2 \end{pmatrix}.
\]

We can change the basis to go to the natural system \((m, c, \hbar)\) with dimension (L: length, V: velocity, A: action)\(^2\). In this basis the generators are

\[
A = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}, \quad L = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}, \quad V = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}.
\]

\(^1\) In general we will consider only dimensions with a maximum coefficient, so we can only a truncation of the group; but this is not useful for the algorithm.

\(^2\) We anticipate a little by considering \(c\) and \(\hbar\) as units and not as physical constants.
whereas the mass and time are given by

\[ T = L V^{-1}, \quad M = A V^{-2}, \]

\[ T = \begin{pmatrix} 0 \\ 1 \\ -1 \end{pmatrix}, \quad M = \begin{pmatrix} 1 \\ 0 \\ -2 \end{pmatrix}. \]

Finally the inverse change of basis matrix \( P^{-1} \) is obtained by gluing the vectors expressed in
the old basis:

\[ P^{-1} = \begin{pmatrix} 2 & 1 & 1 \\ 1 & 0 & 0 \\ -2 & 0 & -1 \end{pmatrix}. \]

To find the change of basis matrix we just have to take the inverse

\[ P = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & -2 & -1 \end{pmatrix}. \]

**Quantities**

A quantity is defined by its name, dimension and factor to a canonical quantity of the same
dimension. The canonical quantities are an internal reference of the units module and should
not be relevant for end-users. Both units and physical constants are quantities.

**Units**

Units, such as meters, seconds and kilograms, are usually reference quantities chosen by men
to refer to other quantities.

After defining several units of different dimensions we can form a unit system, which is basi-
cally a dimension system with a notion of scale.

**Constants**

Physical constants are just quantities. They indicate that we used not to understand that two
dimensions are in fact the same. For example, we see a velocity for the light different from
1 because we do not think that time is the same as space (which is normal because of our
sense; but it is different at the fundamental level). For example, once there was the “heat
constant” which allowed to convert between joules and calories since people did not know
that heat was energy. As soon as they understood it they fixed this constant to 1 (this is a very
schematic story).

We can interpret the fact that now we fix the value of fundamental constants in the SI as
showing that they are units (and we use them to define the other usual units).
The need for a reference

It is not possible to define from scratch units and unit systems: one needs to define some references, and then build the rest over them. Said in another way, we need an origin for the scales of our units (i.e. a unit with factor 1), and to be sure that all units of a given dimension are defined consistently we need to use the same origin for all of them. This can happen if we want to use a derived unit as a base units in another system: we should not define it as having a scale 1, because, even if it is inconsistent inside the system, we could not convert to the first system since we have two different units (from our point of view) of same scale (which means they are equal for the computer).

We will say that the dimensions and scales defined outside systems are canonical, because we use them for all computations. On the other side the dimensions and scales obtained with reference to a system are called physical, because they ultimately carry a sense.

Let’s use a concrete (and important) example: the case of the mass units. We would like to define the gram as the origin. We would like to define the gram as the canonical origin for the mass, so we assign it a scale 1. Then we can define a system (e.g. in chemistry) that take it as a base unit. The MKS system prefers to use the kilogram; a naive choice would be to attribute it a scale if 1 since it is a base, but we see that we could not convert to the chemistry system because g and kg have both been given the same factor. So we need to define kg as 1000 g, and only then use it as a base in MKS. But as soon as we ask the question “what is the factor of kg in MKS?”, we get the answer 1, since it is a base unit.

Thus we will define all computations without referring to a system, and it is only at the end that we can plug the result into a system to give the context we are interested in.

Literature

More examples

In the following sections we give few examples of what can be done with this module.

Dimensional analysis

We will start from Newton’s second law

\[ ma = F \]

where \( m, a \) and \( F \) are the mass, the acceleration and the force respectively. Knowing the dimensions of \( m \) (\( M \)) and \( a \) (\( LT^{-2} \)), we will determine the dimension of \( F \); obviously we will find that it is a force: \( MLT^{-2} \).

From there we will use the expression of the gravitational force between the particle of mass \( m \) and the body of mass \( M \), at a distance \( r \)

\[ F = \frac{GmM}{r^2} \]

to determine the dimension of the Newton’s constant \( G \). The result should be \( L^3M^{-1}T^{-2} \).
>>> from sympy import symbols
>>> from sympy.physics.unitsystems import SI
>>> from sympy.physics.units import length, mass, acceleration, force
>>> from sympy.physics.units import gravitational_constant as G
>>> F = mass*acceleration

>>> F
Dimension(acceleration*mass)

>>> dimsys_SI.get_dimensional_dependencies(F)
{Dimension(length): 1, Dimension(mass, M): 1, Dimension(time): -2}

>>> dimsys_SI.get_dimensional_dependencies(force)
{Dimension(length): 1, Dimension(mass): 1, Dimension(time): -2}

Dimensions cannot compared directly, even if in the SI convention they are the same:

>>> F == force
False

Dimension system objects provide a way to test the equivalence of dimensions:

>>> dimsys_SI.equivalent_dims(F, force)
True

Note that one should first solve the equation, and then substitute with the dimensions.

Equation with quantities

Using Kepler’s third law

\[
\frac{T^2}{a^3} = \frac{4\pi^2}{GM}
\]

we can find the Venus orbital period using the known values for the other variables (taken from Wikipedia). The result should be 224.701 days.

>>> from sympy import solve, symbols, pi, Eq
>>> from sympy.physics.units import Quantity, length, mass
>>> from sympy.physics.units import day, gravitational_constant as G
>>> T = symbols("T")
>>> a = Quantity("venus_a")

Specify the dimension and scale in SI units:
Add the solar mass as quantity:

```python
>>> M = Quantity("solar_mass")
>>> SI.set_quantity_dimension(M, mass)
>>> SI.set_quantity_scale_factor(M, 1.9891e30*kilogram)
```

Now Kepler’s law:

```python
>>> eq = Eq(T**2 / a**3, 4*pi**2 / G / M)
>>> q = solve(eq, T)[1]
>>> q
2*pi*venus_a**(3/2)/(sqrt(gravitational_constant)*sqrt(solar_mass))
```

To convert to days, use the `convert_to` function (and possibly approximate the outcome result):

```python
>>> from sympy.physics.units import convert_to
>>> convert_to(q, day)
71.5112118495813*pi*day
>>> convert_to(q, day).n()
224.659097795948*day
```

We could also have the solar mass and the day as units coming from the astrophysical system, but we wanted to show how to create a unit that one needs.

We can see in this example that intermediate dimensions can be ill-defined, such as sqrt(G), but one should check that the final result - when all dimensions are combined - is well defined.

### Dimensions and dimension systems

Definition of physical dimensions.

Unit systems will be constructed on top of these dimensions.

Most of the examples in the doc use MKS system and are presented from the computer point of view: from a human point, adding length to time is not legal in MKS but it is in natural system; for a computer in natural system there is no time dimension (but a velocity dimension instead) - in the basis - so the question of adding time to length has no meaning.

```python
class sympy.physics.units.dimensions.Dimension(name, symbol=None)
```

This class represent the dimension of a physical quantities.

The `Dimension` constructor takes as parameters a name and an optional symbol.

For example, in classical mechanics we know that time is different from temperature and dimensions make this difference (but they do not provide any measure of these qualities.)
Dimensions can be composed using multiplication, division and exponentiation (by a number) to give new dimensions. Addition and subtraction is defined only when the two objects are the same dimension.

```
>>> velocity = length / time
>>> velocity
Dimension(length/time)
```

It is possible to use a dimension system object to get the dimensional dependencies of a dimension, for example the dimension system used by the SI units convention can be used:

```
>>> from sympy.physics.units.systems.si import dimsys_SI
>>> dimsyst_SI.get_dimensional_dependencies(velocity)
{Dimension(length, L): 1, Dimension(time, T): -1}
```

```
>>> length + length
Dimension(length)

>>> l2 = length**2
>>> l2
Dimension(length**2)
```

```
>>> dimsyst_SI.get_dimensional_dependencies(l2)
{Dimension(length, L): 2}
```

### has_integer_powers(dim_sys)

Check if the dimension object has only integer powers.

All the dimension powers should be integers, but rational powers may appear in intermediate steps. This method may be used to check that the final result is well-defined.

### class sympy.physics.units.dimensions.DimensionSystem

```
class sympy.physics.units.dimensions.DimensionSystem(base_dims, derived_dims=(),
          dimensional_dependencies={})
```

DimensionSystem represents a coherent set of dimensions.

The constructor takes three parameters:

- base dimensions;
- derived dimensions: these are defined in terms of the base dimensions (for example velocity is defined from the division of length by time);
- dependency of dimensions: how the derived dimensions depend on the base dimensions.

Optionally either the derived_dims or the dimensional_dependencies may be omitted.

### property can_transf_matrix

Useless method, kept for compatibility with previous versions.

DO NOT USE.
Return the canonical transformation matrix from the canonical to the base dimension basis.
It is the inverse of the matrix computed with inv_can_transf_matrix().

**property dim**
Useless method, kept for compatibility with previous versions.
DO NOT USE.
Give the dimension of the system.
That is return the number of dimensions forming the basis.

**dim_can_vector**(dim)
Useless method, kept for compatibility with previous versions.
DO NOT USE.
Dimensional representation in terms of the canonical base dimensions.

**dim_vector**(dim)
Useless method, kept for compatibility with previous versions.
DO NOT USE.
Vector representation in terms of the base dimensions.

**property inv_can_transf_matrix**
Useless method, kept for compatibility with previous versions.
DO NOT USE.
Compute the inverse transformation matrix from the base to the canonical dimension basis.
It corresponds to the matrix where columns are the vector of base dimensions in canonical basis.
This matrix will almost never be used because dimensions are always defined with respect to the canonical basis, so no work has to be done to get them in this basis. Nonetheless if this matrix is not square (or not invertible) it means that we have chosen a bad basis.

**property is_consistent**
Useless method, kept for compatibility with previous versions.
DO NOT USE.
Check if the system is well defined.

**is_dimensionless**(dimension)
Check if the dimension object really has a dimension.
A dimension should have at least one component with non-zero power.

**property list_can_dims**
Useless method, kept for compatibility with previous versions.
DO NOT USE.
List all canonical dimension names.

**print_dim_base**(dim)
Give the string expression of a dimension in term of the basis symbols.
Unit prefixes

Module defining unit prefix class and some constants.

Constant dict for SI and binary prefixes are defined as PREFIXES and BIN_PREFIXES.

class sympy.physics.units.prefixes.Prefix(name, abbrev, exponent, base=10, latex_repr=None)

This class represents prefixes, with their name, symbol and factor.

Prefixes are used to create derived units from a given unit. They should always be
capsulated into units.

The factor is constructed from a base (default is 10) to some power, and it gives the total
multiple or fraction. For example the kilometer km is constructed from the meter (factor 1)
and the kilo (10 to the power 3, i.e. 1000). The base can be changed to allow e.g.
binary prefixes.

A prefix multiplied by something will always return the product of this other object times
the factor, except if the other object:

• is a prefix and they can be combined into a new prefix;
• defines multiplication with prefixes (which is the case for the Unit class).

Units and unit systems

Unit system for physical quantities; include definition of constants.

class sympy.physics.units.unitsystem.UnitSystem(base_units, units=(), name='',
                                                  descr='', dimension_system=None,
                                                  derived_units: Dict[Dimension (page 1631), Quantity (page 1635)]={})

UnitSystem represents a coherent set of units.

A unit system is basically a dimension system with notions of scales. Many of the methods
are defined in the same way.

It is much better if all base units have a symbol.

property dim
    Give the dimension of the system.
    That is return the number of units forming the basis.

extend(base, units=(), name='', description='', dimension_system=None,
       derived_units: Dict[Dimension (page 1631), Quantity (page 1635)]={})

Extend the current system into a new one.

Take the base and normal units of the current system to merge them to the base
and normal units given in argument. If not provided, name and description are
overridden by empty strings.

get_units_non_prefixed() \rightarrow Set[Quantity (page 1635)]

Return the units of the system that do not have a prefix.

property is_consistent
    Check if the underlying dimension system is consistent.
Physical quantities

Physical quantities.

```python
class sympy.physics.units.quantities.Quantity(name, abbrev=None, latex_repr=None, pretty_unicode_repr=None, pretty_ascii_repr=None, mathml_presentation_repr=None, is_prefixed=False, **assumptions)
```

Physical quantity: can be a unit of measure, a constant or a generic quantity.

**property abbrev**
Symbol representing the unit name.

Prepend the abbreviation with the prefix symbol if it is defines.

**convert_to(other, unit_system='SI')**
Convert the quantity to another quantity of same dimensions.

**Examples**

```python
>>> from sympy.physics.units import speed_of_light, meter, second
>>> speed_of_light
speed_of_light
>>> speed_of_light.convert_to(meter/second)
299792458*meter/second

>>> from sympy.physics.units import liter
>>> liter.convert_to(meter**3)
liter**3/1000
```

**property free_symbols**
Return free symbols from quantity.

**property is_prefixed**
Whether or not the quantity is prefixed. Eg. `kilogram` is prefixed, but `gram` is not.

**property scale_factor**
Overall magnitude of the quantity as compared to the canonical units.

**set_global_relative_scale_factor(scale_factor, reference_quantity)**
Setting a scale factor that is valid across all unit system.
Conversion between quantities

Several methods to simplify expressions involving unit objects.

```
sympy.physics.units.util.convert_to(expr, target_units, unit_system='SI')
```

Convert `expr` to the same expression with all of its units and quantities represented as factors of `target_units`, whenever the dimension is compatible.

`target_units` may be a single unit/quantity, or a collection of units/quantities.

Examples

```
>>> from sympy.physics.units import speed_of_light, meter, gram, second, day
>>> from sympy.physics.units import mile, newton, kilogram, atomic_mass_constant
>>> from sympy.physics.units import kilometer, centimeter
>>> from sympy.physics.units import gravitational_constant, hbar
>>> from sympy.physics.units import convert_to

convert_to(mile, kilometer)
25146*kilometer/15625

convert_to(mile, kilometer).n()
1.609344*kilometer

convert_to(speed_of_light, meter/second)
299792458*meter/second

convert_to(day, second)
86400*second

3*newton
3*newton

convert_to(3*newton, kilogram*meter/second**2)
3*kilogram*meter/second**2

convert_to(atomic_mass_constant, gram)
1.660539060e-24*gram

Conversion to multiple units:

```
>>> convert_to(speed_of_light, [meter, second])
299792458*meter/second

>>> convert_to(3*newton, [centimeter, gram, second])
300000*centimeter*gram/second**2
```

Conversion to Planck units:

```
>>> convert_to(atomic_mass_constant, [gravitational_constant, speed_of_light, hbar]).n()
7.6296087839509e-20*hbar**0.5*speed_of_light**0.5/gravitational_constant**0.5
```
High energy physics

Abstract

Contains docstrings for methods in high energy physics.

Gamma matrices

Module to handle gamma matrices expressed as tensor objects.

Examples

```python
>>> from sympy.physics.hep.gamma_matrices import GammaMatrix as G,
...    LorentzIndex
>>> from sympy.tensor.tensor import tensor_indices
>>> i = tensor_indices('i', LorentzIndex)
>>> G(i)
GammaMatrix(i)
```

Note that there is already an instance of GammaMatrixHead in four dimensions: GammaMatrix, which is simply declare as

```python
>>> from sympy.physics.hep.gamma_matrices import GammaMatrix
>>> from sympy.tensor.tensor import tensor_indices
>>> i = tensor_indices('i', LorentzIndex)
>>> GammaMatrix(i)
GammaMatrix(i)
```

To access the metric tensor

```python
>>> LorentzIndex.metric
metric(LorentzIndex, LorentzIndex)
```

sympy.physics.hep.gamma_matrices.extract_type_tens(expression, component)

Extract from a TensExpr all tensors with `component`.

Returns two tensor expressions:

- the first contains all Tensor of having `component`.
- the second contains all remaining.

sympy.physics.hep.gamma_matrices.gamma_trace(t)

trace of a single line of gamma matrices
Examples

```python
>>> from sympy.physics.hep.gamma_matrices import GammaMatrix as G,
    gamma_trace, LorentzIndex
>>> from sympy.tensor.tensor import tensor_indices, tensor_heads

>>> p, q = tensor_heads('p, q', [LorentzIndex])
>>> i0,i1,i2,i3,i4,i5 = tensor_indices('i0:6', LorentzIndex)
>>> ps = p(i0)*G(-i0)
>>> qs = q(i0)*G(-i0)
>>> gamma_trace(G(i0)*G(i1))
4*metric(i0, i1)
>>> gamma_trace(ps*ps) - 4*p(i0)*p(-i0)
0
>>> gamma_trace(ps*qs + ps*ps) - 4*p(i0)*p(-i0) - 4*p(i0)*q(-i0)
0
```

`SymPy.physics.hep.gamma_matrices.kahane_simplify(expression)`

This function cancels contracted elements in a product of four dimensional gamma matrices, resulting in an expression equal to the given one, without the contracted gamma matrices.

**Parameters**

`expression` the tensor expression containing the gamma matrices to simplify.

**Notes**

If spinor indices are given, the matrices must be given in the order given in the product.

**Algorithm**

The idea behind the algorithm is to use some well-known identities, i.e., for contractions enclosing an even number of $\gamma$ matrices

$$\gamma^\mu\gamma_{a_1} \cdots \gamma_{a_{2N}} \gamma_\mu = 2(\gamma_{a_{2N}} \gamma_{a_1} \cdots \gamma_{a_{2N-1}} + \gamma_{a_{2N-1}} \cdots \gamma_{a_1} \gamma_{a_{2N}})$$

for an odd number of $\gamma$ matrices

$$\gamma^\mu\gamma_{a_1} \cdots \gamma_{a_{2N-1}} \gamma_\mu = -2\gamma_{a_{2N+1}} \gamma_{a_{2N}} \cdots \gamma_{a_1}$$

Instead of repeatedly applying these identities to cancel out all contracted indices, it is possible to recognize the links that would result from such an operation, the problem is thus reduced to a simple rearrangement of free gamma matrices.
Examples

When using, always remember that the original expression coefficient has to be handled separately

```python
from sympy.physics.hep.gamma_matrices import GammaMatrix as G,
LorentzIndex
from sympy.physics.hep.gamma_matrices import kahane_simplify
from sympy.tensor.tensor import tensor_indices
i0, i1, i2 = tensor_indices('i0:3', LorentzIndex)
ta = G(i0)*G(-i0)
kahane_simplify(ta)
Matrix([[4, 0, 0, 0],
[0, 4, 0, 0],
[0, 0, 4, 0],
[0, 0, 0, 4]])
tb = G(i0)*G(i1)*G(-i0)
kahane_simplify(tb)
-2*GammaMatrix(i1)
t = G(i0)*G(-i0)
kahane_simplify(t)
Matrix([[4, 0, 0, 0],
[0, 4, 0, 0],
[0, 0, 4, 0],
[0, 0, 0, 4]])
t = G(i0)*G(-i0)
kahane_simplify(t)
Matrix([[4, 0, 0, 0],
[0, 4, 0, 0],
[0, 0, 4, 0],
[0, 0, 0, 4]])
```

If there are no contractions, the same expression is returned

```python
tc = G(i0)*G(i1)
kahane_simplify(tc)
GammaMatrix(i0)*GammaMatrix(i1)
```

References

```python
sympy.physics.hep.gamma_matrices.simplify_gpgp(ex, sort=True)
simplify products \( G(i)*p(-i)*G(j)*p(-j) \) -> \( p(i)*p(-i) \)
Examples

```python
>>> from sympy.physics.hep.gamma_matrices import GammaMatrix as G,
    LorentzIndex, simplify_gpgp
>>> from sympy.tensor.tensor import tensor_indices, tensor_heads
    p, q = tensor_heads('p, q', [LorentzIndex])
>>> i0,i1,i2,i3,i4,i5 = tensor_indices('i0:i5', LorentzIndex)
>>> ps = p(i0)*G(-i0)
>>> qs = q(i0)*G(-i0)
>>> simplify_gpgp(ps*qs*qs)
GammaMatrix(-L_0)*p(L_0)*q(L_1)*q(-L_1)
```

The Physics Vector Module

Abstract

In this documentation the components of the sympy.physics.vector module have been discussed. `sympy.physics.vector` (page 1640) has been written to facilitate the operations pertaining to 3-dimensional vectors, as functions of time or otherwise, in `sympy.physics` (page 1578).

References for Physics/Vector

Guide to Vector

Vector & ReferenceFrame

In `sympy.physics.vector` (page 1640), vectors and reference frames are the “building blocks” of dynamic systems. This document will describe these mathematically and describe how to use them with this module’s code.

Vector

A vector is a geometric object that has a magnitude (or length) and a direction. Vectors in 3-space are often represented on paper as:
Vector Algebra

Vector algebra is the first topic to be discussed.
Two vectors are said to be equal if and only if (iff) they have the same magnitude and orientation.

Vector Operations

Multiple algebraic operations can be done with vectors: addition between vectors, scalar multiplication, and vector multiplication.
Vector addition as based on the parallelogram law.

Vector addition is also commutative:
\[
a + b = b + a
\]
\[
(a + b) + c = a + (b + c)
\]

Scalar multiplication is the product of a vector and a scalar; the result is a vector with the same orientation but whose magnitude is scaled by the scalar. Note that multiplication by -1 is equivalent to rotating the vector by 180 degrees about an arbitrary axis in the plane perpendicular to the vector.

A unit vector is simply a vector whose magnitude is equal to 1. Given any vector \( \mathbf{v} \) we can define a unit vector as:
\[
\hat{n}_\mathbf{v} = \frac{\mathbf{v}}{||\mathbf{v}||}
\]
Note that every vector can be written as the product of a scalar and unit vector.
Three vector products are implemented in `sympy.physics.vector` (page 1640): the dot product, the cross product, and the outer product.

The dot product operation maps two vectors to a scalar. It is defined as:

\[ \mathbf{a} \cdot \mathbf{b} = \|\mathbf{a}\| \|\mathbf{b}\| \cos(\theta) \]

where \( \theta \) is the angle between \( \mathbf{a} \) and \( \mathbf{b} \).

The dot product of two unit vectors represent the magnitude of the common direction; for other vectors, it is the product of the magnitude of the common direction and the two vectors’ magnitudes. The dot product of two perpendicular is zero. The figure below shows some examples:

![Diagrams showing dot product calculations](image)

The dot product is commutative:

\[ \mathbf{a} \cdot \mathbf{b} = \mathbf{b} \cdot \mathbf{a} \]

The cross product vector multiplication operation of two vectors returns a vector:

\[ \mathbf{a} \times \mathbf{b} = \mathbf{c} \]

The vector \( \mathbf{c} \) has the following properties: it’s orientation is perpendicular to both \( \mathbf{a} \) and \( \mathbf{b} \), it’s magnitude is defined as \( \|\mathbf{c}\| = \|\mathbf{a}\| \|\mathbf{b}\| \sin(\theta) \) (where \( \theta \) is the angle between \( \mathbf{a} \) and \( \mathbf{b} \)), and has a sense defined by using the right hand rule between \( \|\mathbf{a}\| \|\mathbf{b}\| \). The figure below shows this:
The cross product has the following properties:

It is not commutative:

\[ \mathbf{a} \times \mathbf{b} \neq \mathbf{b} \times \mathbf{a} \]
\[ \mathbf{a} \times \mathbf{b} = -\mathbf{b} \times \mathbf{a} \]

and not associative:

\[ (\mathbf{a} \times \mathbf{b}) \times \mathbf{c} \neq \mathbf{a} \times (\mathbf{b} \times \mathbf{c}) \]

Two parallel vectors will have a zero cross product.

The outer product between two vectors will not be not be discussed here, but instead in the inertia section (that is where it is used). Other useful vector properties and relationships are:

\[ \alpha (\mathbf{a} + \mathbf{b}) = \alpha \mathbf{a} + \alpha \mathbf{b} \]
\[ \mathbf{a} \cdot (\mathbf{b} + \mathbf{c}) = \mathbf{a} \cdot \mathbf{b} + \mathbf{a} \cdot \mathbf{c} \]
\[ \mathbf{a} \times (\mathbf{b} + \mathbf{c}) = \mathbf{a} \times \mathbf{b} + \mathbf{a} \times \mathbf{b} \]
\[ (\mathbf{a} \times \mathbf{b}) \cdot \mathbf{c} \text{ gives the scalar triple product.} \]
\[ \mathbf{a} \times (\mathbf{b} \cdot \mathbf{c}) \text{ does not work, as you cannot cross a vector and a scalar.} \]
\[ (\mathbf{a} \times \mathbf{b}) \cdot \mathbf{c} = \mathbf{a} \cdot (\mathbf{b} \times \mathbf{c}) \]
\[ (\mathbf{a} \times \mathbf{b}) \cdot \mathbf{c} = (\mathbf{b} \times \mathbf{c}) \cdot \mathbf{a} = (\mathbf{c} \times \mathbf{a}) \cdot \mathbf{b} \]
\[ (\mathbf{a} \times \mathbf{b}) \times \mathbf{c} = \mathbf{b}(\mathbf{a} \cdot \mathbf{c}) - \mathbf{a}(\mathbf{b} \cdot \mathbf{c}) \]
\[ \mathbf{a} \times (\mathbf{b} \times \mathbf{c}) = \mathbf{b}(\mathbf{a} \cdot \mathbf{c}) - \mathbf{c}(\mathbf{a} \cdot \mathbf{b}) \]
Alternative Representation

If we have three non-coplanar unit vectors $\mathbf{n}_x, \mathbf{n}_y, \mathbf{n}_z$, we can represent any vector $\mathbf{a}$ as $\mathbf{a} = a_x \mathbf{n}_x + a_y \mathbf{n}_y + a_z \mathbf{n}_z$. In this situation $\mathbf{n}_x, \mathbf{n}_y, \mathbf{n}_z$ are referred to as a basis. $a_x, a_y, a_z$ are called the measure numbers. Usually the unit vectors are mutually perpendicular, in which case we can refer to them as an orthonormal basis, and they are usually right-handed.

To test equality between two vectors, now we can do the following. With vectors:

$$\mathbf{a} = a_x \mathbf{n}_x + a_y \mathbf{n}_y + a_z \mathbf{n}_z$$
$$\mathbf{b} = b_x \mathbf{n}_x + b_y \mathbf{n}_y + b_z \mathbf{n}_z$$

We can claim equality if: $a_x = b_x, a_y = b_y, a_z = b_z$.

Vector addition is then represented, for the same two vectors, as:

$$\mathbf{a} + \mathbf{b} = (a_x + b_x)\mathbf{n}_x + (a_y + b_y)\mathbf{n}_y + (a_z + b_z)\mathbf{n}_z$$

Multiplication operations are now defined as:

$$\mathbf{a} \cdot \mathbf{b} = a_x b_x + a_y b_y + a_z b_z$$
$$\mathbf{a} \times \mathbf{b} = \begin{vmatrix} \mathbf{n}_x & \mathbf{n}_y & \mathbf{n}_z \\ a_x & a_y & a_z \\ b_x & b_y & b_z \end{vmatrix}$$

$$(\mathbf{a} \times \mathbf{b}) \cdot \mathbf{c} = \begin{vmatrix} a_x & a_y & a_z \\ b_x & b_y & b_z \\ c_x & c_y & c_z \end{vmatrix}$$

To write a vector in a given basis, we can do the follow:

$$\mathbf{a} = (\mathbf{a} \cdot \mathbf{n}_x)\mathbf{n}_x + (\mathbf{a} \cdot \mathbf{n}_y)\mathbf{n}_y + (\mathbf{a} \cdot \mathbf{n}_z)\mathbf{n}_z$$

Examples

Some numeric examples of these operations follow:

$$\mathbf{a} = \mathbf{n}_x + 5\mathbf{n}_y$$
$$\mathbf{b} = \mathbf{n}_y + \alpha \mathbf{n}_z$$
$$\mathbf{a} + \mathbf{b} = \mathbf{n}_x + 6\mathbf{n}_y + \alpha \mathbf{n}_z$$
$$\mathbf{a} \cdot \mathbf{b} = 5$$
$$\mathbf{a} \cdot \mathbf{n}_y = 5$$
$$\mathbf{a} \cdot \mathbf{n}_z = 0$$
$$\mathbf{a} \times \mathbf{b} = 5\alpha \mathbf{n}_x - \alpha \mathbf{n}_y + \mathbf{n}_z$$
$$\mathbf{b} \times \mathbf{a} = -5\alpha \mathbf{n}_x + \alpha \mathbf{n}_y - \mathbf{n}_z$$
Vector Calculus

To deal with the calculus of vectors with moving object, we have to introduce the concept of a reference frame. A classic example is a train moving along its tracks, with you and a friend inside. If both you and your friend are sitting, the relative velocity between the two of you is zero. From an observer outside the train, you will both have velocity though.

We will now apply more rigor to this definition. A reference frame is a virtual “platform” which we choose to observe vector quantities from. If we have a reference frame \( N \), vector \( \mathbf{a} \) is said to be fixed in the frame \( N \) if none of its properties ever change when observed from \( N \). We will typically assign a fixed orthonormal basis vector set with each reference frame; \( N \) will have \( \hat{\mathbf{n}}_x, \hat{\mathbf{n}}_y, \hat{\mathbf{n}}_z \) as its basis vectors.

Derivatives of Vectors

A vector which is not fixed in a reference frame therefore has changing properties when observed from that frame. Calculus is the study of change, and in order to deal with the peculiarities of vectors fixed and not fixed in different reference frames, we need to be more explicit in our definitions.

In the above figure, we have vectors \( \mathbf{c}, \mathbf{d}, \mathbf{e}, \mathbf{f} \). If one were to take the derivative of \( \mathbf{e} \) with respect to \( \theta \):

\[
\frac{d\mathbf{e}}{d\theta}
\]

it is not clear what the derivative is. If you are observing from frame \( A \), it is clearly non-zero. If you are observing from frame \( B \), the derivative is zero. We will therefore introduce the
frame as part of the derivative notation:
\[
\frac{\mathbf{A} \mathbf{e}}{d\theta} \neq 0, \text{ the derivative of } \mathbf{e} \text{ with respect to } \theta \text{ in the reference frame } \mathbf{A}
\]
\[
\frac{\mathbf{B} \mathbf{e}}{d\theta} = 0, \text{ the derivative of } \mathbf{e} \text{ with respect to } \theta \text{ in the reference frame } \mathbf{B}
\]
\[
\frac{\mathbf{A} \mathbf{c}}{d\theta} = 0, \text{ the derivative of } \mathbf{c} \text{ with respect to } \theta \text{ in the reference frame } \mathbf{A}
\]
\[
\frac{\mathbf{B} \mathbf{c}}{d\theta} \neq 0, \text{ the derivative of } \mathbf{c} \text{ with respect to } \theta \text{ in the reference frame } \mathbf{B}
\]

Here are some additional properties of derivatives of vectors in specific frames:
\[
\frac{\mathbf{A}_d}{dt}(\mathbf{a} + \mathbf{b}) = \frac{\mathbf{A}_d \mathbf{a}}{dt} + \frac{\mathbf{A}_d \mathbf{b}}{dt}
\]
\[
\frac{\mathbf{A}_d}{dt}(\gamma \mathbf{a}) = \frac{d\gamma}{dt} \mathbf{a} + \gamma \frac{\mathbf{A}_d \mathbf{a}}{dt}
\]
\[
\frac{\mathbf{A}_d}{dt}(\mathbf{a} \times \mathbf{b}) = \frac{\mathbf{A}_d \mathbf{a}}{dt} \times \mathbf{b} + \mathbf{a} \times \frac{\mathbf{A}_d \mathbf{b}}{dt}
\]

**Relating Sets of Basis Vectors**

We need to now define the relationship between two different reference frames; or how to relate the basis vectors of one frame to another. We can do this using a direction cosine matrix (DCM). The direction cosine matrix relates the basis vectors of one frame to another, in the following fashion:

\[
\begin{bmatrix}
\hat{a}_x \\
\hat{a}_y \\
\hat{a}_z
\end{bmatrix} = [\mathbf{A} \mathbf{C} \mathbf{B}]
\begin{bmatrix}
\hat{b}_x \\
\hat{b}_y \\
\hat{b}_z
\end{bmatrix}
\]

When two frames (say, \( \mathbf{A} \) & \( \mathbf{B} \)) are initially aligned, then one frame has all of its basis vectors rotated around an axis which is aligned with a basis vector, we say the frames are related by a simple rotation. The figure below shows this:

The above rotation is a simple rotation about the Z axis by an angle \( \theta \). Note that after the rotation, the basis vectors \( \hat{a}_z \) and \( \hat{b}_z \) are still aligned.
This rotation can be characterized by the following direction cosine matrix:

\[ A^B_C = \begin{bmatrix}
\cos(\theta) & -\sin(\theta) & 0 \\
\sin(\theta) & \cos(\theta) & 0 \\
0 & 0 & 1
\end{bmatrix} \]

Simple rotations about the X and Y axes are defined by:

DCM for x-axis rotation:
\[ \begin{bmatrix} 1 & 0 & 0 \\
0 & \cos(\theta) & -\sin(\theta) \\
0 & \sin(\theta) & \cos(\theta) \end{bmatrix} \]

DCM for y-axis rotation:
\[ \begin{bmatrix} \cos(\theta) & 0 & \sin(\theta) \\
0 & 1 & 0 \\
-\sin(\theta) & 0 & \cos(\theta) \end{bmatrix} \]

Rotation in the positive direction here will be defined by using the right-hand rule.

The direction cosine matrix is also involved with the definition of the dot product between sets of basis vectors. If we have two reference frames with associated basis vectors, their direction cosine matrix can be defined as:

\[ \begin{bmatrix} C_{xx} & C_{xy} & C_{xz} \\
C_{yx} & C_{yy} & C_{yz} \\
C_{zx} & C_{zy} & C_{zz} \end{bmatrix} = \begin{bmatrix} \hat{a}_x \cdot \hat{b}_x & \hat{a}_x \cdot \hat{b}_y & \hat{a}_x \cdot \hat{b}_z \\
\hat{a}_y \cdot \hat{b}_x & \hat{a}_y \cdot \hat{b}_y & \hat{a}_y \cdot \hat{b}_z \\
\hat{a}_z \cdot \hat{b}_x & \hat{a}_z \cdot \hat{b}_y & \hat{a}_z \cdot \hat{b}_z \end{bmatrix} \]

Additionally, the direction cosine matrix is orthogonal, in that:

\[ A^B_C = (B^A_C)^{-1} = (B^A_C)^T \]

If we have reference frames \( A \) and \( B \), which in this example have undergone a simple z-axis rotation by an amount \( \theta \), we will have two sets of basis vectors. We can then define two vectors: \( \mathbf{a} = \hat{a}_x + \hat{a}_y + \hat{a}_z \) and \( \mathbf{b} = \hat{b}_x + \hat{b}_y + \hat{b}_z \). If we wish to express \( \mathbf{b} \) in the \( A \) frame, we do the following:

\[
\mathbf{b} = \mathbf{b}_x + \mathbf{b}_y + \mathbf{b}_z \\
\mathbf{b} = [\hat{a}_x \cdot (\hat{b}_x + \hat{b}_y + \hat{b}_z)] \hat{a}_x + [\hat{a}_y \cdot (\hat{b}_x + \hat{b}_y + \hat{b}_z)] \hat{a}_y + [\hat{a}_z \cdot (\hat{b}_x + \hat{b}_y + \hat{b}_z)] \hat{a}_z \\
\mathbf{b} = (\cos(\theta) - \sin(\theta)) \hat{a}_x + (\sin(\theta) + \cos(\theta)) \hat{a}_y + \hat{a}_z
\]

And if we wish to express \( \mathbf{a} \) in the \( B \) frame, we do:

\[
\mathbf{a} = \mathbf{a}_x + \mathbf{a}_y + \mathbf{a}_z \\
\mathbf{a} = [\hat{b}_x \cdot (\hat{a}_x + \hat{a}_y + \hat{a}_z)] \hat{b}_x + [\hat{b}_y \cdot (\hat{a}_x + \hat{a}_y + \hat{a}_z)] \hat{b}_y + [\hat{b}_z \cdot (\hat{a}_x + \hat{a}_y + \hat{a}_z)] \hat{b}_z \\
\mathbf{a} = (\cos(\theta) + \sin(\theta)) \hat{b}_x + (-\sin(\theta) + \cos(\theta)) \hat{b}_y + \hat{b}_z
\]

**Derivatives with Multiple Frames**

If we have reference frames \( A \) and \( B \) we will have two sets of basis vectors. We can then define two vectors: \( \mathbf{a} = a_x \hat{a}_x + a_y \hat{a}_y + a_z \hat{a}_z \) and \( \mathbf{b} = b_x \hat{b}_x + b_y \hat{b}_y + b_z \hat{b}_z \). If we want to take the derivative of \( \mathbf{b} \) in the reference frame \( A \), we must first express it in \( A \), and take the derivative of the measure numbers:

\[
\frac{\partial b}{\partial x} = \frac{d}{dx} (\mathbf{b} \cdot \hat{a}_x) \hat{a}_x + \frac{d}{dx} (\mathbf{b} \cdot \hat{a}_y) \hat{a}_y + \frac{d}{dx} (\mathbf{b} \cdot \hat{a}_z) \hat{a}_z
\]
Examples

An example of vector calculus:

In this example we have two bodies, each with an attached reference frame. We will say that $\theta$ and $x$ are functions of time. We wish to know the time derivative of vector $c$ in both the A and B frames.

First, we need to define $c$: $c = x\hat{b}_x + l\hat{b}_y$. This provides a definition in the B frame. We can now do the following:

\[
\frac{B}{dt} \frac{dc}{dt} = \frac{dx}{dt} \hat{b}_x + \frac{dl}{dt} \hat{b}_y
\]

To take the derivative in the A frame, we have to first relate the two frames:

\[
A^B C = \begin{bmatrix}
    \cos(\theta) & 0 & \sin(\theta) \\
    0 & 1 & 0 \\
    -\sin(\theta) & 0 & \cos(\theta)
\end{bmatrix}
\]
Now we can do the following:

\[ \frac{\mathbf{A} \cdot \mathbf{dC}}{dt} = \frac{d(c \cdot \mathbf{a}_x)}{dt} \mathbf{a}_x + \frac{d(c \cdot \mathbf{a}_y)}{dt} \mathbf{a}_y + \frac{d(c \cdot \mathbf{a}_z)}{dt} \mathbf{a}_z \]

\[ = \frac{d(\cos(\theta)x)}{dt} \mathbf{a}_x + \frac{d(l)}{dt} \mathbf{a}_y + \frac{d(-\sin(\theta)x)}{dt} \mathbf{a}_z \]

\[ = (-\dot{\theta} \sin(\theta)x + \cos(\theta)\dot{x})\mathbf{a}_x + (\dot{\theta} \cos(\theta)x + \sin(\theta)\dot{x})\mathbf{a}_z \]

Note that this is the time derivative of \( \mathbf{c} \) in \( \mathbf{A} \), and is expressed in the \( \mathbf{A} \) frame. We can express it in the \( \mathbf{B} \) frame however, and the expression will still be valid:

\[ \frac{\mathbf{A} \cdot \mathbf{dC}}{dt} = (-\dot{\theta} \sin(\theta)x + \cos(\theta)\dot{x})\mathbf{a}_x + (\dot{\theta} \cos(\theta)x + \sin(\theta)\dot{x})\mathbf{a}_z \]

\[ = \dot{\theta} \mathbf{a}_x - \dot{\theta} \mathbf{a}_x \]

Note the difference in expression complexity between the two forms. They are equivalent, but one is much simpler. This is an extremely important concept, as defining vectors in the more complex forms can vastly slow down formulation of the equations of motion and increase their length, sometimes to a point where they cannot be shown on screen.

### Using Vectors and Reference Frames

We have waited until after all of the relevant mathematical relationships have been defined for vectors and reference frames to introduce code. This is due to how vectors are formed. When starting any problem in `sympy.physics.vector` (page 1640), one of the first steps is defining a reference frame (remember to import `sympy.physics.vector` first):

```python
>>> from sympy.physics.vector import *
>>> N = ReferenceFrame('N')
```

Now we have created a reference frame, \( \mathbf{N} \). To have access to any basis vectors, first a reference frame needs to be created. Now that we have made and object representing \( \mathbf{N} \), we can access its basis vectors:

```python
>>> N.x
N.x
>>> N.y
N.y
>>> N.z
N.z
```

### Vector Algebra, in `physics.vector`

We can now do basic algebraic operations on these vectors:

```python
>>> N.x == N.x
True
>>> N.x == N.y
False
>>> N.x + N.y
N.x + N.y
>>> 2 * N.x + N.y
2*N.x + N.y
```
Remember, don’t add a scalar quantity to a vector \((N \cdot x + 5)\); this will raise an error. At this point, we’ll use SymPy’s Symbol in our vectors. Remember to refer to SymPy’s Gotchas and Pitfalls when dealing with symbols:

```python
>>> from sympy import Symbol, symbols
>>> x = Symbol('x')
>>> x * N.x
x*N.x
>>> x*(N.x + N.y)
x*N.x + x*N.y
```

In `sympy.physics.vector` multiple interfaces to vector multiplication have been implemented, at the operator level, method level, and function level. The vector dot product can work as follows:

```python
>>> N.x.dot(N.x)
1
>>> N.x.dot(N.y)
0
>>> dot(N.x, N.x)
1
>>> dot(N.x, N.y)
0
```

The “official” interface is the function interface; this is what will be used in all examples. This is to avoid confusion with the attribute and methods being next to each other, and in the case of the operator operation priority. The operators used in `sympy.physics.vector` for vector multiplication do not possess the correct order of operations; this can lead to errors. Care with parentheses is needed when using operators to represent vector multiplication.

The cross product is the other vector multiplication which will be discussed here. It offers similar interfaces to the dot product, and comes with the same warnings.

```python
>>> N.x.cross(N.x)
0
>>> N.x.cross(N.z)
- N.y
>>> cross(N.x, N.y)
N.z
>>> cross(N.x, (N.y + N.z))
- N.y + N.z
```

Two additional operations can be done with vectors: normalizing the vector to length 1, and getting its magnitude. These are done as follows:

```python
>>> (N.x + N.y).normalize()
sqrt(2)/2*N.x + sqrt(2)/2*N.y
>>> (N.x + N.y).magnitude()
sqrt(2)
```

Vectors are often expressed in a matrix form, especially for numerical purposes. Since the matrix form does not contain any information about the reference frame the vector is defined in, you must provide a reference frame to extract the measure numbers from the vector. There is a convenience function to do this:
Vector Calculus, in physics.vector

We have already introduced our first reference frame. We can take the derivative in that frame right now, if we desire:

```
>>> (x * N.x + 2 * x * N.y + 3 * x * N.z).diff(x, N)
N.x
```

SymPy has a `diff` function, but it does not currently work with `sympy.physics.vector` (page 1640) Vectors, so please use Vector's `diff` method. The reason for this is that when differentiating a Vector, the frame of reference must be specified in addition to what you are taking the derivative with respect to; SymPy's `diff` function doesn't fit this mold.

The more interesting case arise with multiple reference frames. If we introduce a second reference frame, A, we now have two frames. Note that at this point we can add components of N and A together, but cannot perform vector multiplication, as no relationship between the two frames has been defined.

```
>>> A = ReferenceFrame('A')
>>> A.x + N.x
N.x + A.x
```

If we want to do vector multiplication, first we have to define and orientation. The `orient` method of `ReferenceFrame` provides that functionality.

```
>>> A.orient(N, 'Axis', [x, N.y])
```

If we desire, we can view the DCM between these two frames at any time. This can be calculated with the `dcm` method. This code: N.dcm(A) gives the dcm $^A_N$.

This orients the A frame relative to the N frame by a simple rotation around the Y axis, by an amount x. Other, more complicated rotation types include Body rotations, Space rotations, quaternions, and arbitrary axis rotations. Body and space rotations are equivalent to doing 3 simple rotations in a row, each about a basis vector in the new frame. An example follows:

```
>>> N = ReferenceFrame('N')
>>> Bp = ReferenceFrame('Bp')
>>> Bpp = ReferenceFrame('Bpp')
>>> B = ReferenceFrame('B')
>>> q1,q2,q3 = symbols('q1 q2 q3')
>>> Bpp.orient(N, 'Axis', [q1, N.x])
>>> Bp.orient(Bpp, 'Axis', [q2, Bpp.y])
>>> B.orient(Bp, 'Axis', [q3, Bp.z])
>>> N.dcm(B)
Matrix([[-sin(q3)*cos(q2), sin(q2)*cos(q3), -cos(q2)],
       [cos(q2)*cos(q3), -sin(q2)*cos(q3), -sin(q2)],
       [sin(q3), cos(q3), 0]])
```
Space orientations are similar to body orientation, but applied from the frame to body. Body and space rotations can involve either two or three axes: ‘XYZ’ works, as does ‘YZX’, ‘ZXZ’, ‘XXY’, etc. What is key is that each simple rotation is about a different axis than the previous one; ‘ZZX’ does not completely orient a set of basis vectors in 3 space.

Sometimes it will be more convenient to create a new reference frame and orient relative to an existing one in one step. The orientnew method allows for this functionality, and essentially wraps the orient method. All of the things you can do in orient, you can do in orientnew.

```python
>>> C = N.orientnew('C', 'Axis', [q1, N.x])
```

Quaternions (or Euler Parameters) use 4 value to characterize the orientation of the frame. This and arbitrary axis rotations are described in the orient and orientnew method help, or in the references [Kane1983].

Finally, before starting multiframe calculus operations, we will introduce another sympy.physics.vector (page 1640) tool: dynamicsymbols. dynamicsymbols is a shortcut function to create undefined functions of time within SymPy. The derivative of such a ‘dynamicsymbol’ is shown below.

```python
>>> from sympy import diff
>>> q1, q2, q3 = dynamicsymbols('q1 q2 q3')
>>> diff(q1, Symbol('t'))
Derivative(q1(t), t)
```

The ‘dynamicsymbol’ printing is not very clear above; we will also introduce a few other tools here. We can use vprint instead of print for non-interactive sessions.

```python
>>> q1
q1(t)
>>> q1d = diff(q1, Symbol('t'))
>>> vprint(q1)
q1
>>> vprint(q1d)
q1'
```

For interactive sessions use init_vprinting. There also exist analogs for SymPy’s vprint, vpprint, and latex, vlatex.
A ‘dynamicsymbol’ should be used to represent any time varying quantity in `sympy.physics.vector` (page 1640), whether it is a coordinate, varying position, or force. The primary use of a ‘dynamicsymbol’ is for speeds and coordinates (of which there will be more discussion in the Kinematics Section of the documentation).

Now we will define the orientation of our new frames with a ‘dynamicsymbol’, and can take derivatives and time derivatives with ease. Some examples follow.

```python
>>> N = ReferenceFrame('N')
>>> B = N.orientnew('B', 'Axis', [q1, N.x])
>>> (B.y*q2 + B.z).diff(q2, N)
B.y
>>> (B.y*q2 + B.z).dt(N)
(-q1' + q2')*B.y + q2*q1'*B.z
```

Note that the output vectors are kept in the same frames that they were provided in. This remains true for vectors with components made of basis vectors from multiple frames:

```python
>>> (B.y*q2 + B.z + q2*N.x).diff(q2, N)
N.x + B.y
```

### How Vectors are Coded

What follows is a short description of how vectors are defined by the code in `sympy.physics.vector` (page 1640). It is provided for those who want to learn more about how this part of `sympy.physics.vector` (page 1640) works, and does not need to be read to use this module; don’t read it unless you want to learn how this module was implemented.

Every Vector’s main information is stored in the `args` attribute, which stores the three measure numbers for each basis vector in a frame, for every relevant frame. A vector does not exist in code until a ReferenceFrame is created. At this point, the x, y, and z attributes of the reference frame are immutable Vector’s which have measure numbers of [1,0,0], [0,1,0], and [0,0,1] associated with that ReferenceFrame. Once these vectors are accessible, new vectors can be created by doing algebraic operations with the basis vectors. A vector can have components from multiple frames though. That is why `args` is a list; it has as many elements in the list as there are unique ReferenceFrames in its components, i.e. if there are A and B frame basis vectors in our new vector, `args` is of length 2; if it has A, B, and C frame basis vector, `args` is of length three.

Each element in the `args` list is a 2-tuple; the first element is a SymPy Matrix (this is where the measure numbers for each set of basis vectors are stored) and the second element is a ReferenceFrame to associate those measure numbers with.

ReferenceFrame stores a few things. First, it stores the name you supply it on creation (name attribute). It also stores the direction cosine matrices, defined upon creation with the `orientnew` method, or calling the `orient` method after creation. The direction cosine matrices are represented by SymPy’s Matrix, and are part of a dictionary where the keys are the
ReferenceFrame and the value the Matrix; these are set bi-directionally; in that when you orient A to N you are setting A’s orientation dictionary to include N and its Matrix, but you are also setting N’s orientation dictionary to include A and its Matrix (that DCM being the transpose of the other).

**Vector: Kinematics**

This document will give some mathematical background to describing a system’s kinematics as well as how to represent the kinematics in `sympy.physics.vector` (page 1640).

**Introduction to Kinematics**

The first topic is rigid motion kinematics. A rigid body is an idealized representation of a physical object which has mass and rotational inertia. Rigid bodies are obviously not flexible. We can break down rigid body motion into translational motion, and rotational motion (when dealing with particles, we only have translational motion). Rotational motion can further be broken down into simple rotations and general rotations.

Translation of a rigid body is defined as a motion where the orientation of the body does not change during the motion; or during the motion any line segment would be parallel to itself at the start of the motion.

Simple rotations are rotations in which the orientation of the body may change, but there is always one line which remains parallel to itself at the start of the motion.

General rotations are rotations which there is not always one line parallel to itself at the start of the motion.

**Angular Velocity**

The angular velocity of a rigid body refers to the rate of change of its orientation. The angular velocity of a body is written down as: $\mathbf{N}_w^B$, or the angular velocity of $\mathbf{B}$ in $\mathbf{N}$, which is a vector. Note that here, the term rigid body was used, but reference frames can also have angular velocities. Further discussion of the distinction between a rigid body and a reference frame will occur later when describing the code representation.

Angular velocity is defined as being positive in the direction which causes the orientation angles to increase (for simple rotations, or series of simple rotations).
The angular velocity vector represents the time derivative of the orientation. As a time derivative vector quantity, like those covered in the Vector & ReferenceFrame documentation, this quantity (angular velocity) needs to be defined in a reference frame. That is what the \textbf{N} is in the above definition of angular velocity; the frame in which the angular velocity is defined in.

The angular velocity of \textbf{B} in \textbf{N} can also be defined by:

\[
N \omega^B = \left( \frac{N_d}{dt} \cdot \hat{b}_y \right) \hat{b}_x + \left( \frac{N_d}{dt} \cdot \hat{b}_x \right) \hat{b}_y + \left( \frac{N_d}{dt} \cdot \hat{b}_y \right) \hat{b}_z
\]

It is also common for a body’s angular velocity to be written as:

\[
N \omega^B = w_x \hat{b}_x + w_y \hat{b}_y + w_z \hat{b}_z
\]

There are a few additional important points relating to angular velocity. The first is the addition theorem for angular velocities, a way of relating the angular velocities of multiple bodies and frames. The theorem follows:

\[
N \omega^D = N \omega^A + A \omega^B + B \omega^C + C \omega^D
\]

This is also shown in the following example:
Note the signs used in the angular velocity definitions, which are related to how the displacement angle is defined in this case.

This theorem makes defining angular velocities of multibody systems much easier, as the angular velocity of a body in a chain needs to only be defined to the previous body in order to be fully defined (and the first body needs to be defined in the desired reference frame). The following figure shows an example of when using this theorem can make things easier.

Here we can easily write the angular velocity of the body \( D \) in the reference frame of the first body \( A \):

\[
A \omega^D = w_1 \hat{p}_1 + w_2 \hat{p}_2 + w_3 \hat{p}_3
\]
It is very important to remember to only use this with angular velocities; you cannot use this theorem with the velocities of points.

There is another theorem commonly used: the derivative theorem. It provides an alternative method (which can be easier) to calculate the time derivative of a vector in a reference frame:

\[
\frac{N_d\mathbf{v}}{dt} = \frac{B_d\mathbf{v}}{dt} + N \omega^B \times \mathbf{v}
\]

The vector \( \mathbf{v} \) can be any vector quantity: a position vector, a velocity vector, angular velocity vector, etc. Instead of taking the time derivative of the vector in \( N \), we take it in \( B \), where \( B \) can be any reference frame or body, usually one in which it is easy to take the derivative on \( \mathbf{v} \) in (\( \mathbf{v} \) is usually composed only of the basis vector set belonging to \( B \)). Then we add the cross product of the angular velocity of our newer frame, \( N \omega^B \) and our vector quantity \( \mathbf{v} \). Again, you can choose any alternative frame for this. Examples follow:

**Angular Acceleration**

Angular acceleration refers to the time rate of change of the angular velocity vector. Just as the angular velocity vector is for a body and is specified in a frame, the angular acceleration vector is for a body and is specified in a frame: \( N \omega^B \), or the angular acceleration of \( B \) in \( N \), which is a vector.

Calculating the angular acceleration is relatively straightforward:

\[
N_\alpha^B = \frac{N_d\omega^B}{dt}
\]

Note that this can be calculated with the derivative theorem, and when the angular velocity is defined in a body fixed frame, becomes quite simple:

\[
N_\alpha^B = \frac{B_d\omega^B}{dt} + N \omega^B \times \omega^B
\]

if \( \omega^B = w_x \mathbf{b}_x + w_y \mathbf{b}_y + w_z \mathbf{b}_z \)

then \( N_\alpha^B = \frac{B_d\omega^B}{dt} + \frac{\omega^B \times \omega^B}{dt} \)

this is 0 by definition

\[
N_\alpha^B = \frac{dw_x}{dt} \mathbf{b}_x + \frac{dw_y}{dt} \mathbf{b}_y + \frac{dw_z}{dt} \mathbf{b}_z
\]

\[
N_\alpha^B = w_x \mathbf{b}_x + w_y \mathbf{b}_y + w_z \mathbf{b}_z
\]

Again, this is only for the case in which the angular velocity of the body is defined in body fixed components.
Point Velocity & Acceleration

Consider a point, \( P \): we can define some characteristics of the point. First, we can define a position vector from some other point to \( P \). Second, we can define the velocity vector of \( P \) in a reference frame of our choice. Third, we can define the acceleration vector of \( P \) in a reference frame of our choice.

These three quantities are read as:

\[ \mathbf{r}^{OP}, \] the position vector from \( O \) to \( P \)

\[ \mathbf{Nv}^P, \] the velocity of \( P \) in the reference frame \( \mathbf{N} \)

\[ \mathbf{Na}^P, \] the acceleration of \( P \) in the reference frame \( \mathbf{N} \)

Note that the position vector does not have a frame associated with it; this is because there is no time derivative involved, unlike the velocity and acceleration vectors.

We can find these quantities for a simple example easily:

Let’s define: \( \mathbf{r}^{OP} = q_x \mathbf{n}_x + q_y \mathbf{n}_y \)

\[ \mathbf{Nv}^P = \frac{d\mathbf{r}^{OP}}{dt} \]

then we can calculate: \( \mathbf{Nv}^P = \dot{q}_x \mathbf{n}_x + \dot{q}_y \mathbf{n}_y \)

and: \( \mathbf{Na}^P = \frac{d\mathbf{Nv}^P}{dt} \)

\[ \mathbf{Na}^P = \ddot{q}_x \mathbf{n}_x + \ddot{q}_y \mathbf{n}_y \]

It is critical to understand in the above example that the point \( O \) is fixed in the reference frame \( \mathbf{N} \). There is no addition theorem for translational velocities; alternatives will be discussed later though. Also note that the position of every point might not always need to be defined to form the dynamic equations of motion. When you don’t want to define the position vector of a point, you can start by just defining the velocity vector. For the above example:

Let us instead define the velocity vector as: \( \mathbf{Nv}^P = u_x \mathbf{n}_x + u_y \mathbf{n}_y \)

then acceleration can be written as: \( \mathbf{Na}^P = \dot{u}_x \mathbf{n}_x + \dot{u}_y \mathbf{n}_y \)
There will often be cases when the velocity of a point is desired and a related point’s velocity is known. For the cases in which we have two points fixed on a rigid body, we use the 2-Point Theorem:

Let’s say we know the velocity of the point \( S \) and the angular velocity of the body \( B \), both defined in the reference frame \( N \). We can calculate the velocity and acceleration of the point \( P \) in \( N \) as follows:

\[
\begin{align*}
\mathbf{v}_P^N &= \mathbf{v}_S^N + \mathbf{\omega}_B^N \times \mathbf{r}_{SP}^N \\
\mathbf{a}_P^N &= \mathbf{a}_S^N + \mathbf{\omega}_B^N \times \mathbf{r}_{SP}^N + \mathbf{\alpha}_B^N \times (\mathbf{\omega}_B^N \times \mathbf{r}_{SP}^N)
\end{align*}
\]

When only one of the two points is fixed on a body, the 1 point theorem is used instead.
Here, the velocity of point $S$ is known in the frame $N$, the angular velocity of $B$ is known in $N$, and the velocity of the point $P$ is known in the frame associated with body $B$. We can then write the velocity and acceleration of $P$ in $N$ as:

$$
N\mathbf{v}^P = B\mathbf{v}^P + N\mathbf{v}^S + N\mathbf{B} \times \mathbf{r}^S_P
$$

$$
N\mathbf{a}^P = B\mathbf{a}^S + N\mathbf{a}^O + N\mathbf{B} \times \mathbf{r}^S_P + N\mathbf{B} \times (N\mathbf{B} \times \mathbf{r}^S_P) + 2N\mathbf{B} \times B\mathbf{v}^P
$$

Examples of applications of the 1 point and 2 point theorem follow.
This example has a disk translating and rotating in a plane. We can easily define the angular velocity of the body $B$ and velocity of the point $O$:

\[
\begin{align*}
\mathbf{N}_\omega^B &= u_3 \mathbf{n}_Z = u_3 \mathbf{b}_Z \\
\mathbf{N}_V^O &= u_1 \mathbf{n}_x + u_2 \mathbf{n}_y
\end{align*}
\]

and accelerations can be written as:

\[
\begin{align*}
\mathbf{N}_\alpha^B &= \dot{u}_3 \mathbf{n}_Z = \dot{u}_3 \mathbf{b}_Z \\
\mathbf{N}_a^O &= \dot{u}_1 \mathbf{n}_x + \dot{u}_2 \mathbf{n}_y
\end{align*}
\]

We can use the 2 point theorem to calculate the velocity and acceleration of point $P$ now.

\[
\begin{align*}
\mathbf{r}^{OP} &= \mathbf{R} \mathbf{b}_x \\
\mathbf{N}_V^P &= \mathbf{N}_V^O + \mathbf{N}_\omega^B \times \mathbf{r}^{OP} \\
\mathbf{N}_V^P &= u_1 \mathbf{n}_x + u_2 \mathbf{n}_y + u_3 \mathbf{b}_Z \times \mathbf{R} \mathbf{b}_x = u_1 \mathbf{n}_x + u_2 \mathbf{n}_y + u_3 \mathbf{R} \mathbf{b}_y \\
\mathbf{N}_a^P &= \mathbf{N}_a^O + \mathbf{N}_\alpha^B \times \mathbf{r}^{OP} + \mathbf{N}_\omega^B \times (\mathbf{N}_\omega^B \times \mathbf{r}^{OP}) \\
\mathbf{N}_a^P &= \dot{u}_1 \mathbf{n}_x + \dot{u}_2 \mathbf{n}_y + \dot{u}_3 \mathbf{b}_Z \times \mathbf{R} \mathbf{b}_x + u_3 \mathbf{b}_Z \times \mathbf{R} \mathbf{b}_y + \dot{u}_3 \mathbf{b}_Z \times \mathbf{R} \mathbf{b}_y \\
\mathbf{N}_a^P &= \dot{u}_1 \mathbf{n}_x + \dot{u}_2 \mathbf{n}_y + \mathbf{R} \dot{u}_3 \mathbf{b}_y - \mathbf{R} \dot{u}_3 \mathbf{b}_x
\end{align*}
\]
In this example we have a double pendulum. We can use the two point theorem twice here in order to find the velocity of points $Q$ and $P$; point $O$’s velocity is zero in $N$.

\[ \mathbf{r}^{OQ} = l \hat{\mathbf{b}}_x \]
\[ \mathbf{r}^{QP} = l \hat{\mathbf{c}}_x \]
\[ N \omega^B = u_1 \hat{\mathbf{b}}_z \]
\[ N \omega^C = u_2 \hat{\mathbf{c}}_z \]
\[ N \mathbf{v}^Q = N \mathbf{v}^O + N \omega^B \times \mathbf{r}^{OQ} \]
\[ N \mathbf{v}^P = N \mathbf{v}^Q + N \omega^C \times \mathbf{r}^{QP} \]
\[ N \mathbf{v}^Q = u_1 \hat{\mathbf{b}}_y \]
\[ N \mathbf{v}^P = u_1 \hat{\mathbf{b}}_y + u_2 \hat{\mathbf{c}}_z \times \hat{\mathbf{c}}_x \]
\[ N \mathbf{v}^Q = u_1 \hat{\mathbf{b}}_y + u_2 \hat{\mathbf{c}}_y \]

In this example we have a particle moving on a ring; the ring is supported by a rod which can rotate about the $\hat{\mathbf{n}}_x$ axis. First we use the two point theorem to find the velocity of the center point of the ring, $Q$, then use the 1 point theorem to find the velocity of the particle on the
A final topic in the description of velocities of points is that of rolling, or rather, rolling without slip. Two bodies are said to be rolling without slip if and only if the point of contact on each body has the same velocity in another frame. See the following figure:

This is commonly used to form the velocity of a point on one object rolling on another fixed object, such as in the following example:

**Kinematics in physics.vector**

It should be clear by now that the topic of kinematics here has been mostly describing the correct way to manipulate vectors into representing the velocities of points. Within *sympy.physics.vector* (page 1640) there are convenient methods for storing these velocities associated with frames and points. We'll now revisit the above examples and show how to represent them in sympy.

The topic of reference frame creation has already been covered. When a ReferenceFrame is created though, it automatically calculates the angular velocity of the frame using the time derivative of the DCM and the angular velocity definition.
Note that the angular velocity can be defined in an alternate way:

```
>>> B = ReferenceFrame('B')
>>> u1 = dynamicsymbols('u1')
>>> B.set_ang_vel(N, u1 * B.y)
>>> B.ang_vel_in(N)
u1*B.y
>>> N.ang_vel_in(B)
- u1*B.y
```

Both upon frame creation during orientnew and when calling set_ang_vel, the angular velocity is set in both frames involved, as seen above.

Here we have multiple bodies with angular velocities defined relative to each other. This is coded as:

```
>>> N = ReferenceFrame('N')
>>> A = ReferenceFrame('A')
>>> B = ReferenceFrame('B')
>>> C = ReferenceFrame('C')
>>> D = ReferenceFrame('D')
>>> u1, u2, u3 = dynamicsymbols('u1 u2 u3')
>>> A.set_ang_vel(N, 0)
>>> B.set_ang_vel(A, u1 * A.x)
>>> C.set_ang_vel(B, -u2 * B.z)
>>> D.set_ang_vel(C, u3 * C.y)
>>> D.ang_vel_in(N)
u1*A.x - u2*B.z + u3*C.y
```
In `sympy.physics.vector` the shortest path between two frames is used when finding the angular velocity. That would mean if we went back and set:

```python
>>> D.set_ang_vel(N, 0)
>>> D.ang_vel_in(N)
0
```

The path that was just defined is what is used. This can cause problems though, as now the angular velocity definitions are inconsistent. It is recommended that you avoid doing this.

Points are a translational analog to the rotational ReferenceFrame. Creating a Point can be done in two ways, like ReferenceFrame:

```python
>>> O = Point('O')
>>> P = O.locatenew('P', 3*N.x + N.y)
>>> P.pos_from(O)
3*N.x + N.y
>>> Q = Point('Q')
>>> Q.set_pos(P, N.z)
>>> Q.pos_from(P)
N.z
>>> Q.pos_from(O)
3*N.x + N.y + N.z
```

Similar to ReferenceFrame, the position vector between two points is found by the shortest path (number of intermediate points) between them. Unlike rotational motion, there is no addition theorem for the velocity of points. In order to have the velocity of a Point in a ReferenceFrame, you have to set the value.

```python
>>> O = Point('O')
>>> O.set_vel(N, u1*N.x)
>>> O.vel(N)
u1*N.x
```

For both translational and rotational accelerations, the value is computed by taking the time derivative of the appropriate velocity, unless the user sets it otherwise.

```python
>>> O.acc(N)
u1'*N.x
>>> O.set_acc(N, u2*u1*N.y)
>>> O.acc(N)
u1*u2*N.y
```

Next is a description of the 2 point and 1 point theorems, as used in sympy.
First is the translating, rotating disc.

```python
>>> N = ReferenceFrame('N')
>>> u1, u2, u3 = dynamicsymbols('u1 u2 u3')
>>> R = Symbol('R')
>>> B = ReferenceFrame('B')
>>> O = Point('O')
>>> O.set_vel(N, u1 * N.x + u2 * N.y)
>>> P = O.locatenew('P', R * B.x)
>>> B.set_ang_vel(N, u3 * B.z)
>>> P.v2pt_theory(O, N, B)
    u1*N.x + u2*N.y + R*u3*B.y
>>> P.a2pt_theory(O, N, B)
    u1'*N.x + u2'*N.y - R*u3**2*B.x + R*u3'*B.y
```

We will also cover implementation of the 1 point theorem.
This is the particle moving on a ring, again.

```python
>>> N = ReferenceFrame('N')
>>> u1, u2 = dynamicsymbols('u1 u2')
>>> q1, q2 = dynamicsymbols('q1 q2')
>>> l = Symbol('l')
>>> R = Symbol('R')
>>> C = N.orientnew('C', 'Axis', [q1, N.x])
>>> C.set_ang_vel(N, u1 * N.x)
>>> O = Point('O')
>>> O.set_vel(N, 0)
>>> Q = O.locatenew('Q', -l * C.z)
>>> P = Q.locatenew('P', R * (cos(q2) * C.x + sin(q2) * C.y))
>>> P.set_vel(C, R * u2 * (-sin(q2) * C.x + cos(q2) * C.y))
>>> Q.v2pt_theory(O, N, C)
- l*u1*C.y
>>> P.v1pt_theory(O, N, C)
- R*u2*sin(q2)*C.x + (R*u2*cos(q2) + l*u1)*C.y + R*u1*sin(q2)*C.z
```
This document will describe some of the more advanced functionality that this module offers but which is not part of the “official” interface. Here, some of the features that will be implemented in the future will also be covered, along with unanswered questions about proper functionality. Also, common problems will be discussed, along with some solutions.

**Inertia (Dyadics)**

A dyadic tensor is a second order tensor formed by the juxtaposition of a pair of vectors. There are various operations defined with respect to dyadics, which have been implemented in vector (page 1640) in the form of class `sympy.physics.vector.dyadic.Dyadic` (page 1696). To know more, refer to the `sympy.physics.vector.dyadic.Dyadic` (page 1696) and `sympy.physics.vector.vector.Vector` (page 1689) class APIs. Dyadics are used to define the inertia of bodies within `sympy.physics.mechanics` (page 1721). Inertia dyadics can be defined explicitly but the inertia function is typically much more convenient for the user:

```python
>>> from sympy.physics.mechanics import ReferenceFrame, inertia
>>> N = ReferenceFrame('N')

Supply a reference frame and the moments of inertia if the object is symmetrical:

```python
>>> inertia(N, 1, 2, 3)
(N.x|N.x) + 2*(N.y|N.y) + 3*(N.z|N.z)
```

Supply a reference frame along with the products and moments of inertia for a general object:

```python
>>> inertia(N, 1, 2, 3, 4, 5, 6)
(N.x|N.x) + 4*(N.x|N.y) + 6*(N.x|N.z) + 4*(N.y|N.x) + 2*(N.y|N.y) + 5*(N.y|N.z) + 6*(N.z|N.x) + 5*(N.z|N.y) + 3*(N.z|N.z)
```

Notice that the inertia function returns a dyadic with each component represented as two unit vectors separated by a |. Refer to the `sympy.physics.vector.dyadic.Dyadic` (page 1696) section for more information about dyadics.

Inertia is often expressed in a matrix, or tensor, form, especially for numerical purposes. Since the matrix form does not contain any information about the reference frame(s) the inertia dyadic is defined in, you must provide one or two reference frames to extract the measure numbers from the dyadic. There is a convenience function to do this:

```python
>>> inertia(N, 1, 2, 3, 4, 5, 6).to_matrix(N)
Matrix([[1, 4, 6],
        [4, 2, 5],
        [6, 5, 3]])
```
**Common Issues**

Here issues with numerically integrating code, choice of `dynamicsymbols` for coordinate and speed representation, printing, differentiating, and substitution will occur.

**Printing**

The default printing options are to use sorting for `Vector` and `Dyadic` measure numbers, and have unsorted output from the `vprint`, `vpprint`, and `vlatex` functions. If you are printing something large, please use one of those functions, as the sorting can increase printing time from seconds to minutes.

**Substitution**

Substitution into large expressions can be slow, and take a few minutes.

**Acceleration of Points**

At a minimum, points need to have their velocities defined, as the acceleration can be calculated by taking the time derivative of the velocity in the same frame. If the 1 point or 2 point theorems were used to compute the velocity, the time derivative of the velocity expression will most likely be more complex than if you were to use the acceleration level 1 point and 2 point theorems. Using the acceleration level methods can result in shorted expressions at this point, which will result in shorter expressions later (such as when forming Kane’s equations).

**Advanced Interfaces**

Here we will cover advanced options in: `ReferenceFrame`, `dynamicsymbols`, and some associated functionality.

**ReferenceFrame**

`ReferenceFrame` is shown as having a `.name` attribute and `.x`, `.y`, and `.z` attributes for accessing the basis vectors, as well as a fairly rigidly defined print output. If you wish to have a different set of indices defined, there is an option for this. This will also require a different interface for accessing the basis vectors.

```python
>>> from sympy.physics.vector import ReferenceFrame, vprint, vpprint, vlatex
>>> N = ReferenceFrame('N', indices=['i', 'j', 'k'])
>>> N['i']
N['i']
>>> N.x
N['i']
>>> vlatex(N.x)
'\mathbf{\hat{n}_{i}}'
```
Also, the latex output can have custom strings; rather than just indices though, the entirety of each basis vector can be specified. The custom latex strings can occur without custom indices, and also overwrites the latex string that would be used if there were custom indices.

```python
>>> from sympy.physics.vector import ReferenceFrame, vlatex
>>> N = ReferenceFrame('N', latexs=['n1', '\mathbf{n}_2', 'cat'])
>>> vlatex(N.x)
'n1'
>>> vlatex(N.y)
'\mathbf{n}_2'
>>> vlatex(N.z)
'cat'
```

dynamicsymbols

The dynamicsymbols function also has ‘hidden’ functionality; the variable which is associated with time can be changed, as well as the notation for printing derivatives.

```python
>>> from sympy import symbols
>>> from sympy.physics.vector import dynamicsymbols, vprint
>>> q1 = dynamicsymbols('q1')
>>> q1(t)
>>> dynamicsymbols._t = symbols('T')
>>> q2 = dynamicsymbols('q2')
>>> q2(T)
>>> q1
q1(t)
>>> q1d = dynamicsymbols('q1', 1)
>>> vprint(q1d)
q1'
>>> dynamicsymbols._str = 'd'
>>> vprint(q1d)
q1d
>>> dynamicsymbols._str = '\'
>>> dynamicsymbols._t = symbols('t')
```

Note that only dynamic symbols created after the change are different. The same is not true for the .str attribute; this affects the printing output only, so dynamic symbols created before or after will print the same way.

Also note that Vector’s .dt method uses the .t attribute of dynamicsymbols, along with a number of other important functions and methods. Don’t mix and match symbols representing time.
Scalar and Vector Field Functionality

Introduction

Vectors and Scalars

In physics, we deal with two kinds of quantities - scalars and vectors.

A scalar is an entity which only has a magnitude - no direction. Examples of scalar quantities include mass, electric charge, temperature, distance, etc.

A vector, on the other hand, is an entity that is characterized by a magnitude and a direction. Examples of vector quantities are displacement, velocity, magnetic field, etc.

A scalar can be depicted just by a number, for e.g. a temperature of 300 K. On the other hand, vectorial quantities like acceleration are usually denoted by a vector. Given a vector $\mathbf{V}$, the magnitude of the corresponding quantity can be calculated as the magnitude of the vector itself $||\mathbf{V}||$, while the direction would be specified by a unit vector in the direction of the original vector, $\hat{\mathbf{V}} = \frac{\mathbf{V}}{||\mathbf{V}||}$.

For example, consider a displacement of $(3\hat{i} + 4\hat{j} + 5\hat{k})$ m, where, as per standard convention, $\hat{i}, \hat{j}$ and $\hat{k}$ represent unit vectors in the X, Y and Z directions respectively. Therefore, it can be concluded that the distance traveled is $||3\hat{i} + 4\hat{j} + 5\hat{k}||$ m = $5\sqrt{2}$ m. The direction of travel is given by the unit vector $\frac{3}{5\sqrt{2}}\hat{i} + \frac{4}{5\sqrt{2}}\hat{j} + \frac{5}{5\sqrt{2}}\hat{k}$.

Fields

In general, a field is a vector or scalar quantity that can be specified everywhere in space as a function of position (Note that in general a field may also be dependent on time and other custom variables). In this module, we deal with 3-dimensional spaces only. Hence, a field is defined as a function of the $x$, $y$ and $z$ coordinates corresponding to a location in 3D space.

For example, temperate in 3 dimensional space (a temperature field) can be written as $T(x, y, z)$ - a scalar function of the position. An example of a scalar field in electromagnetism is the electric potential.

In a similar manner, a vector field can be defined as a vectorial function of the location $(x, y, z)$ of any point in space.

For instance, every point on the earth may be considered to be in the gravitational force field of the earth. We may specify the field by the magnitude and the direction of acceleration due to gravity (i.e. force per unit mass) $g(x, y, z)$ at every point in space.

To give an example from electromagnetism, consider an electric potential of form $2x^2y$, a scalar field in 3D space. The corresponding conservative electric field can be computed as the gradient of the electric potential function, and expressed as $4xy\hat{i} + 2xy\hat{j}$. The magnitude of this electric field can in turn be expressed as a scalar field of the form $\sqrt{4x^4 + 16x^2y^2}$. 

5.8. Topics 1671
Implementation of fields in sympy.physics.vector

In `sympy.physics.vector` (page 1640), every `ReferenceFrame` (page 1676) instance is assigned basis vectors corresponding to the $X$, $Y$ and $Z$ directions. These can be accessed using the attributes named $x$, $y$ and $z$ respectively. Hence, to define a vector $v$ of the form $3\hat{i} + 4\hat{j} + 5\hat{k}$ with respect to a given frame $\mathbf{R}$, you would do

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> R = ReferenceFrame('R')
>>> v = 3*R.x + 4*R.y + 5*R.z
```

Vector math and basic calculus operations with respect to vectors have already been elaborated upon in other sections of this module’s documentation.

On the other hand, base scalars (or coordinate variables) are implemented as special SymPy `Symbol` (page 1028)s assigned to every frame, one for each direction from $X$, $Y$ and $Z$. For a frame $\mathbf{R}$, the $X$, $Y$ and $Z$ base scalar `Symbol` (page 1028)s can be accessed using the $\mathbf{R}[0]$, $\mathbf{R}[1]$ and $\mathbf{R}[2]$ expressions respectively.

Therefore, to generate the expression for the aforementioned electric potential field $2x^2y$, you would have to do

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> R = ReferenceFrame('R')
>>> electric_potential = 2*R[0]**2*R[1]
>>> electric_potential
2*R_x**2*R_y
```

In string representation, $R_x$ denotes the $X$ base scalar assigned to `ReferenceFrame` (page 1676) $\mathbf{R}$. Essentially, $R_x$ is the string representation of $\mathbf{R}[0]$.

Scalar fields can be treated just as any other SymPy expression, for any math/calculus functionality. Hence, to differentiate the above electric potential with respect to $x$ (i.e. $\mathbf{R}[0]$), you would have to use the `diff` (page 1094) function.

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> R = ReferenceFrame('R')
>>> electric_potential = 2*R[0]**2*R[1]
>>> from sympy import diff
>>> diff(electric_potential, R[0])
4*R_x*R_y
```

Like vectors (and vector fields), scalar fields can also be re-expressed in other frames of reference, apart from the one they were defined in - assuming that an orientation relationship exists between the concerned frames. This can be done using the `sympy.physics.vector.Vector.express` (page 1692) method, in a way similar to vectors - but with the variables parameter set to True.

```python
>>> from sympy.physics.vector import ReferenceFrame
dynamicsymbols, express
>>> q = dynamicsymbols('q')
>>> R1 = R.orientnew('R1', rot_type = 'Axis', amounts = [q, R.z])
>>> express(electric_potential, R1, variables=True)
2*(R1_x*sin(q(t)) + R1_y*cos(q(t)))*(R1_x*cos(q(t)) - R1_y*sin(q(t)))**2
```
Moreover, considering scalars can also be functions of time just as vectors, differentiation with respect to time is also possible. Depending on the Symbol\textsuperscript{1028}s present in the expression and the frame with respect to which the time differentiation is being done, the output will change/remain the same.

\begin{verbatim}
>>> from sympy.physics.vector import ReferenceFrame
>>> R = ReferenceFrame('R')
>>> electric_potential = 2*R[0]**2*R[1]
>>> q = dynamicsymbols('q')
>>> R1 = R.orientnew('R1', rot_type = 'Axis', amounts = [q, R.z])
>>> from sympy.physics.vector import time_derivative
>>> time_derivative(electric_potential, R)
0
>>> time_derivative(electric_potential, R1).simplify()
2*(R1_x*cos(q(t)) - R1_y*sin(q(t)))*(3*R1_x**2*cos(2*q(t))/2 - R1_x**2/2 - 3*R1_x*R1_y*sin(2*q(t)) - 3*R1_y**2*cos(2*q(t))/2 - R1_y**2/2)*Derivative(q(t), t)
\end{verbatim}

Field operators and other related functions

Here we describe some basic field-related functionality implemented in sympy.physics.vector

Curl

A curl is a mathematical operator that describes an infinitesimal rotation of a vector in 3D space. The direction is determined by the right-hand rule (along the axis of rotation), and the magnitude is given by the magnitude of rotation.

In the 3D Cartesian system, the curl of a 3D vector \( \mathbf{F} \), denoted by \( \nabla \times \mathbf{F} \) is given by -

\[
\nabla \times \mathbf{F} = \left( \frac{\partial F_z}{\partial y} - \frac{\partial F_y}{\partial z} \right) \mathbf{i} + \left( \frac{\partial F_z}{\partial x} - \frac{\partial F_x}{\partial z} \right) \mathbf{j} + \left( \frac{\partial F_y}{\partial x} - \frac{\partial F_x}{\partial y} \right) \mathbf{k}
\]

where \( F_x \) denotes the \( X \) component of vector \( \mathbf{F} \).

To compute the curl of a vector field in \texttt{sympy.physics.vector} (page 1640), you would do

\begin{verbatim}
>>> from sympy.physics.vector import ReferenceFrame
>>> R = ReferenceFrame('R')
>>> from sympy.physics.vector import curl
>>> field = R[0]*R[1]*R[2]*R.x
>>> curl(field, R)
R_x*R_y*R.y - R_x*R_z*R.z
\end{verbatim}
**Divergence**

Divergence is a vector operator that measures the magnitude of a vector field’s source or sink at a given point, in terms of a signed scalar.

The divergence operator always returns a scalar after operating on a vector.

In the 3D Cartesian system, the divergence of a 3D vector \( \mathbf{F} \), denoted by \( \nabla \cdot \mathbf{F} \) is given by -
\[
\nabla \cdot \mathbf{F} = \frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} + \frac{\partial W}{\partial z}
\]

where \( U, V \) and \( W \) denote the \( X, Y \) and \( Z \) components of \( \mathbf{F} \) respectively.

To compute the divergence of a vector field in `sympy.physics.vector` (page 1640), you would do

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> R = ReferenceFrame('R')
>>> from sympy.physics.vector import divergence
>>> field = R[0]*R[1]*R[2] * (R.x+R.y+R.z)
>>> divergence(field, R)
R_x*R_y + R_x*R_z + R_y*R_z
```

**Gradient**

Consider a scalar field \( f(x, y, z) \) in 3D space. The gradient of this field is defined as the vector of the 3 partial derivatives of \( f \) with respect to \( x, y \) and \( z \) in the \( X, Y \) and \( Z \) directions respectively.

In the 3D Cartesian system, the gradient of a scalar field \( f \), denoted by \( \nabla f \) is given by -
\[
\nabla f = \frac{\partial f}{\partial x} \mathbf{i} + \frac{\partial f}{\partial y} \mathbf{j} + \frac{\partial f}{\partial z} \mathbf{k}
\]

To compute the gradient of a scalar field in `sympy.physics.vector` (page 1640), you would do

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> R = ReferenceFrame('R')
>>> from sympy.physics.vector import gradient
>>> scalar_field = R[0]*R[1]*R[2]
>>> gradient(scalar_field, R)
R_y*R_z*R.x + R_x*R_z*R.y + R_x*R_y*R.z
```

**Conservative and Solenoidal fields**

In vector calculus, a conservative field is a field that is the gradient of some scalar field. Conservative fields have the property that their line integral over any path depends only on the end-points, and is independent of the path between them. A conservative vector field is also said to be ‘irrotational’, since the curl of a conservative field is always zero.

In physics, conservative fields represent forces in physical systems where energy is conserved.

To check if a vector field is conservative in `sympy.physics.vector` (page 1640), use the `sympy.physics.vector.fieldfunctions.is_conservative` (page 1720) function.
A solenoidal field, on the other hand, is a vector field whose divergence is zero at all points in space.

To check if a vector field is solenoidal in `sympy.physics.vector` (page 1640), use the `sympy.physics.vector.fieldfunctions.is_solenoidal` function.

```python
>>> from sympy.physics.vector import ReferenceFrame, is_solenoidal
>>> R = ReferenceFrame('R')
>>> field = R[1]*R[2]*R.x + R[0]*R[2]*R.y + R[0]*R[1]*R.z
>>> is_solenoidal(field)
True
>>> divergence(field, R)
0
```

### Scalar potential functions

We have previously mentioned that every conservative field can be defined as the gradient of some scalar field. This scalar field is also called the 'scalar potential field' corresponding to the aforementioned conservative field.

The `sympy.physics.vector.fieldfunctions.scalar_potential` function in `sympy.physics.vector` (page 1640) calculates the scalar potential field corresponding to a given conservative vector field in 3D space - minus the extra constant of integration, of course.

Example of usage -

```python
>>> from sympy.physics.vector import ReferenceFrame, scalar_potential
>>> R = ReferenceFrame('R')
>>> conservative_field = 4*R[0]*R[1]*R[2]*R.x + 2*R[0]**2*R[2]*R.y +
-2*R[0]**2*R[1]*R.z
>>> scalar_potential(conservative_field, R)
2*R_x**2*R_y*R_z
```

Providing a non-conservative vector field as an argument to `sympy.physics.vector.fieldfunctions.scalar_potential` (page 1719) raises a `ValueError`.

The scalar potential difference, or simply 'potential difference', corresponding to a conservative vector field can be defined as the difference between the values of its scalar potential function at two points in space. This is useful in calculating a line integral with respect to a conservative function, since it depends only on the endpoints of the path.

This computation is performed as follows in `sympy.physics.vector` (page 1640).

```python
>>> from sympy.physics.vector import ReferenceFrame, Point
>>> from sympy.physics.vector import scalar_potential_difference
```

(continues on next page)
>>> R = ReferenceFrame('R')
>>> O = Point('O')
>>> P = O.locatenew('P', 1*R.x + 2*R.y + 3*R.z)
>>> vectfield = 4*R[0]*R[1]*R.x + 2*R[0]**2*R.y
>>> scalar_potential_difference(vectfield, R, O, P, O)
4

If provided with a scalar expression instead of a vector field, `sympy.physics.vector.fieldfunctions.scalar_potential_difference` (page 1719) returns the difference between the values of that scalar field at the two given points in space.

### Physics Vector API

#### Essential Classes

**class** sympy.physics.vector.frame.CoordinateSym(name, frame, index)

A coordinate symbol/base scalar associated wrt a Reference Frame.

Ideally, users should not instantiate this class. Instances of this class must only be accessed through the corresponding frame as `frame[index]`.

CoordinateSyms having the same frame and index parameters are equal (even though they may be instantiated separately).

**Parameters**
- **name**: string
  - The display name of the CoordinateSym
- **frame**: ReferenceFrame
  - The reference frame this base scalar belongs to
- **index**: 0, 1 or 2
  - The index of the dimension denoted by this coordinate variable

**Examples**

```python
>>> from sympy.physics.vector import ReferenceFrame, CoordinateSym
>>> A = ReferenceFrame('A')
>>> A[1]
A_y
>>> type(A[0])
<class 'sympy.physics.vector.frame.CoordinateSym'>
>>> a_y = CoordinateSym('a_y', A, 1)
>>> a_y == A[1]
True
```

**class** sympy.physics.vector.frame.ReferenceFrame(name, indices=None, latexs=None, variables=None)

A reference frame in classical mechanics.
ReferenceFrame is a class used to represent a reference frame in classical mechanics. It has a standard basis of three unit vectors in the frame’s x, y, and z directions.

It also can have a rotation relative to a parent frame; this rotation is defined by a direction cosine matrix relating this frame’s basis vectors to the parent frame’s basis vectors. It can also have an angular velocity vector, defined in another frame.

**ang_acc_in(otherframe)**

Returns the angular acceleration Vector of the ReferenceFrame.

Effectively returns the Vector:

\[ \mathbf{N}_{\alpha_B} \]

which represent the angular acceleration of B in N, where B is self, and N is other-frame.

**Parameters**

- **otherframe** : ReferenceFrame

  The ReferenceFrame which the angular acceleration is returned in.

**Examples**

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> N = ReferenceFrame('N')
>>> A = ReferenceFrame('A')
>>> V = 10 * N.x
>>> A.set_ang_acc(N, V)
>>> A.ang_acc_in(N)
10*N.x
```

**ang_vel_in(otherframe)**

Returns the angular velocity Vector of the ReferenceFrame.

Effectively returns the Vector:

\[ \omega_B \]

which represent the angular velocity of B in N, where B is self, and N is otherframe.

**Parameters**

- **otherframe** : ReferenceFrame

  The ReferenceFrame which the angular velocity is returned in.

**Examples**

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> N = ReferenceFrame('N')
>>> A = ReferenceFrame('A')
>>> V = 10 * N.x
>>> A.set_ang_vel(N, V)
>>> A.ang_vel_in(N)
10*N.x
```
**dcm(otherframe)**

Returns the direction cosine matrix of this reference frame relative to the provided reference frame.

The returned matrix can be used to express the orthogonal unit vectors of this frame in terms of the orthogonal unit vectors of **otherframe**.

**Parameters**

- **otherframe** : ReferenceFrame

  The reference frame which the direction cosine matrix of this frame is formed relative to.

**Examples**

The following example rotates the reference frame A relative to N by a simple rotation and then calculates the direction cosine matrix of N relative to A.

```python
>>> from sympy import symbols, sin, cos
>>> from sympy.physics.vector import ReferenceFrame
>>> q1 = symbols('q1')
>>> N = ReferenceFrame('N')
>>> A = ReferenceFrame('A')
>>> A.orient_axis(N, q1, N.x)
>>> N.dcm(A)
Matrix([1, 0, 0],
[0, cos(q1), -sin(q1)],
[0, sin(q1), cos(q1)])
```

The second row of the above direction cosine matrix represents the N.y unit vector in N expressed in A. Like so:

```python
>>> Nz = 0*A.x + cos(q1)*A.y - sin(q1)*A.z
```

Thus, expressing N.y in A should return the same result:

```python
>>> N.y.express(A)
cos(q1)*A.y - sin(q1)*A.z
```

**Notes**

It is important to know what form of the direction cosine matrix is returned. If B. 
**dcm(A)** is called, it means the “direction cosine matrix of B rotated relative to A”. 
This is the matrix **B**

$$
\begin{bmatrix}
\hat{b}_1 \\
\hat{b}_2 \\
\hat{b}_3
\end{bmatrix} = \begin{bmatrix}
\hat{a}_1 \\
\hat{a}_2 \\
\hat{a}_3
\end{bmatrix} B^A \quad \begin{bmatrix}
\hat{a}_1 \\
\hat{a}_2 \\
\hat{a}_3
\end{bmatrix}.
$$

**B**

$$
\begin{bmatrix}
\hat{b}_1 \\
\hat{b}_2 \\
\hat{b}_3
\end{bmatrix}
$$

is the matrix that expresses the B unit vectors in terms of the A unit vectors.
orient\(\text{(parent, rot\_type, amounts, rot\_order='')}\)

Sets the orientation of this reference frame relative to another (parent) reference frame.

**Note:** It is now recommended to use the .orient_axis, .orient_body_fixed, .orient_space_fixed, .orient_quaternion methods for the different rotation types.

**Parameters**

parent : ReferenceFrame

Reference frame that this reference frame will be rotated relative to.

rot\_type : str

The method used to generate the direction cosine matrix. Supported methods are:

- 'Axis': simple rotations about a single common axis
- 'DCM': for setting the direction cosine matrix directly
- 'Body': three successive rotations about new intermediate axes, also called “Euler and Tait-Bryan angles”
- 'Space': three successive rotations about the parent frames’ unit vectors
- 'Quaternion': rotations defined by four parameters which result in a singularity free direction cosine matrix

amounts:

Expressions defining the rotation angles or direction cosine matrix. These must match the rot\_type. See examples below for details. The input types are:

- 'Axis': 2-tuple (expr/sym/func, Vector)
- 'DCM': Matrix, shape(3,3)
- 'Body': 3-tuple of expressions, symbols, or functions
- 'Space': 3-tuple of expressions, symbols, or functions
- 'Quaternion': 4-tuple of expressions, symbols, or functions

rot\_order : str or int, optional

If applicable, the order of the successive of rotations. The string '123' and integer 123 are equivalent, for example. Required for 'Body' and 'Space'.

**Warns**

UserWarning

If the orientation creates a kinematic loop.

orient\_axis\(\text{(parent, axis, angle)}\)

Sets the orientation of this reference frame with respect to a parent reference frame by rotating through an angle about an axis fixed in the parent reference frame.
Parameters

**parent** : ReferenceFrame

Reference frame that this reference frame will be rotated relative to.

**axis** : Vector

Vector fixed in the parent frame about about which this frame is rotated. It need not be a unit vector and the rotation follows the right hand rule.

**angle** : sympifiable

Angle in radians by which it the frame is to be rotated.

**Warns**

**UserWarning**

If the orientation creates a kinematic loop.

**Examples**

Setup variables for the examples:

```python
>>> from sympy import symbols
>>> from sympy.physics.vector import ReferenceFrame
>>> q1 = symbols('q1')
>>> N = ReferenceFrame('N')
>>> B = ReferenceFrame('B')
>>> B.orient_axis(N, N.x, q1)
```

The `orient_axis()` method generates a direction cosine matrix and its transpose which defines the orientation of B relative to N and vice versa. Once orient is called, `dcm()` outputs the appropriate direction cosine matrix:

```python
>>> B.dcm(N)
Matrix([[1, 0, 0],
       [0, cos(q1), sin(q1)],
       [0, -sin(q1), cos(q1)]])
```

The following two lines show that the sense of the rotation can be defined by negating the vector direction or the angle. Both lines produce the same result.

```python
>>> B.orient_axis(N, -N.x, q1)
>>> B.orient_axis(N, N.x, -q1)
```

**orient_body_fixed()**

Rotates this reference frame relative to the parent reference frame by right hand rotating through three successive body fixed simple axis rotations. Each subsequent axis of rotation is about the “body fixed” unit vectors of a new intermediate reference
frame. This type of rotation is also referred to rotating through the Euler and Tait-Bryan Angles.

The computed angular velocity in this method is by default expressed in the child’s frame, so it is most preferable to use $u1 \ast \text{child.x} + u2 \ast \text{child.y} + u3 \ast \text{child.z}$ as generalized speeds.

**Parameters**

- **parent**: ReferenceFrame
  - Reference frame that this reference frame will be rotated relative to.
- **angles**: 3-tuple of sympifiable
  - Three angles in radians used for the successive rotations.
- **rotation_order**: 3 character string or 3 digit integer
  - Order of the rotations about each intermediate reference frames’ unit vectors. The Euler rotation about the X, Z’, X’’ axes can be specified by the strings 'XZX', '131', or the integer 131. There are 12 unique valid rotation orders (6 Euler and 6 Tait-Bryan): zxz, xyx, yzy, zyz, xzx, yxy, xyz, yzx, zxy, xzy, and yxz.

**Warns**

- **UserWarning**
  - If the orientation creates a kinematic loop.

**Examples**

Setup variables for the examples:

```python
>>> from sympy import symbols
>>> from sympy.physics.vector import ReferenceFrame
>>> q1, q2, q3 = symbols('q1, q2, q3')
>>> N = ReferenceFrame('N')
>>> B = ReferenceFrame('B')
>>> B1 = ReferenceFrame('B1')
>>> B2 = ReferenceFrame('B2')
>>> B3 = ReferenceFrame('B3')
```

For example, a classic Euler Angle rotation can be done by:

```python
>>> B.orient_body_fixed(N, (q1, q2, q3), 'XYX')
>>> B.dcm(N)
Matrix([[cos(q2), -sin(q2)*cos(q1)],
        [sin(q2)*sin(q3), -sin(q1)*sin(q3)*cos(q2) + cos(q1)*cos(q3)],
        [sin(q1)*cos(q3) + sin(q3)*cos(q1)*cos(q2)],
        [-sin(q3)*cos(q1), -sin(q1)*cos(q2)*cos(q3) - sin(q3)*cos(q1), -cos(q1)*cos(q2)*cos(q3)]])
```

This rotates reference frame B relative to reference frame N through q1 about N.x, then rotates B again through q2 about B.y, and finally through q3 about B.x. It is equivalent to three successive `orient_axis()` calls:
```python
>>> B1.orient_axis(N, N.x, q1)
>>> B2.orient_axis(B1, B1.y, q2)
>>> B3.orient_axis(B2, B2.x, q3)
>>> B3.dcm(N)
Matrix([cos(q2), sin(q1)*sin(q2), -sin(q2)*cos(q1)],
      [sin(q2)*sin(q3), -sin(q1)*sin(q3)*cos(q2) + cos(q1)*cos(q3), sin(q1)*cos(q3) + sin(q3)*cos(q1)*cos(q2)],
      [sin(q2)*cos(q3), -sin(q1)*cos(q2)*cos(q3) - sin(q3)*cos(q1), sin(q1)*sin(q3) + cos(q1)*cos(q2)*cos(q3)])
```

Acceptable rotation orders are of length 3, expressed in as a string 'XYZ' or '123' or integer 123. Rotations about an axis twice in a row are prohibited.

```python
>>> B.orient_body_fixed(N, (q1, q2, 0), 'ZXZ')
>>> B.orient_body_fixed(N, (q1, q2, 0), '121')
>>> B.orient_body_fixed(N, (q1, q2, q3), 123)
```

**orient_explicit**(parent, dcm)

Sets the orientation of this reference frame relative to a parent reference frame by explicitly setting the direction cosine matrix.

**Parameters**

- **parent** : ReferenceFrame
- **dcm** : Matrix, shape(3, 3)

**Warns**

- **UserWarning**
  
  If the orientation creates a kinematic loop.

**Examples**

Setup variables for the examples:

```python
>>> from sympy import symbols, Matrix, sin, cos
>>> from sympy.physics.vector import ReferenceFrame
>>> q1 = symbols('q1')
>>> A = ReferenceFrame('A')
>>> B = ReferenceFrame('B')
>>> N = ReferenceFrame('N')
```

A simple rotation of A relative to N about N.x is defined by the following direction cosine matrix:

```python
>>> dcm = Matrix([[1, 0, 0],
                 [0, cos(q1), -sin(q1)],
                 [0, sin(q1), cos(q1)]])
```
orient_explicit(N, dcm)

Matrix([1, 0, 0],
[0, cos(q1), sin(q1)],
[0, -sin(q1), cos(q1)])

This is equivalent to using orient_axis():

orient_axis(N, N.x, q1)

Matrix([1, 0, 0],
[0, cos(q1), sin(q1)],
[0, -sin(q1), cos(q1)])

Note carefully that N.dcm(B) (the transpose) would be passed into orient_explicit() for A.dcm(N) to match B.dcm(N):

orient_quaternion(parent, numbers)

Sets the orientation of this reference frame relative to a parent reference frame via an orientation quaternion. An orientation quaternion is defined as a finite rotation a unit vector, (lambda_x, lambda_y, lambda_z), by an angle theta. The orientation quaternion is described by four parameters:

- q0 = cos(theta/2)
- q1 = lambda_x*sin(theta/2)
- q2 = lambda_y*sin(theta/2)
- q3 = lambda_z*sin(theta/2)

See Quaternions and Spatial Rotation on Wikipedia for more information.

Parameters

- parent : ReferenceFrame
  Reference frame that this reference frame will be rotated relative to.

- numbers : 4-tuple of sympifiable
  The four quaternion scalar numbers as defined above: q0, q1, q2, q3.

Warns

- UserWarning
  If the orientation creates a kinematic loop.
Examples

Setup variables for the examples:

```python
>>> from sympy import symbols
>>> from sympy.physics.vector import ReferenceFrame
>>> q0, q1, q2, q3 = symbols('q0 q1 q2 q3')
>>> N = ReferenceFrame('N')
>>> B = ReferenceFrame('B')
```

Set the orientation:

```python
>>> B.orient_quaternion(N, (q0, q1, q2, q3))
>>> B.dcm(N)
Matrix([q0**2 + q1**2 - q2**2 - q3**2, 2*q0*q3 + 2*q1*q2, 2*q0*q2 + 2*q1*q3],
      [-2*q0*q2 + 2*q1*q3, q0**2 - q1**2 + q2**2 - q3**2, -2*q0*q1 + 2*q2*q3],
      [2*q0*q1 + 2*q2*q3, 2*q0*q2 + 2*q1*q3, q0**2 - q2**2 + q3**2])
```

orient_space_fixed(parent, angles, rotation_order)

Rotates this reference frame relative to the parent reference frame by right hand rotating through three successive space fixed simple axis rotations. Each subsequent axis of rotation is about the “space fixed” unit vectors of the parent reference frame.

The computed angular velocity in this method is by default expressed in the child’s frame, so it is most preferable to use \( u_1 \cdot \text{child.x} + u_2 \cdot \text{child.y} + u_3 \cdot \text{child.z} \) as generalized speeds.

**Parameters**

- **parent** : ReferenceFrame
  
  Reference frame that this reference frame will be rotated relative to.

- **angles** : 3-tuple of sympifiable
  
  Three angles in radians used for the successive rotations.

- **rotation_order** : 3 character string or 3 digit integer
  
  Order of the rotations about the parent reference frame’s unit vectors. The order can be specified by the strings ‘XZX’, ‘131’, or the integer 131. There are 12 unique valid rotation orders.

**Warns**

- **UserWarning**
  
  If the orientation creates a kinematic loop.
Examples

Setup variables for the examples:

```python
>>> from sympy import symbols
>>> from sympy.physics.vector import ReferenceFrame
>>> q1, q2, q3 = symbols('q1, q2, q3')
>>> N = ReferenceFrame('N')
>>> B = ReferenceFrame('B')
>>> B1 = ReferenceFrame('B1')
>>> B2 = ReferenceFrame('B2')
>>> B3 = ReferenceFrame('B3')
```

```python
>>> B.orient_space_fixed(N, (q1, q2, q3), '312')
>>> B.dcm(N)
Matrix()
[ sin(q1)*sin(q2)*sin(q3) + cos(q1)*cos(q3), sin(q1)*cos(q2),
  sin(q1)*sin(q3) + sin(q2)*cos(q1)*cos(q3), -sin(q2),
  sin(q3)*cos(q2), cos(q2)*cos(q3)]]
```

is equivalent to:

```python
>>> B1.orient_axis(N, N.z, q1)
>>> B2.orient_axis(B1, N.x, q2)
>>> B3.orient_axis(B2, N.y, q3)
```

```python
>>> B3.dcm(N).simplify()
Matrix()
[ sin(q1)*sin(q2)*sin(q3) + cos(q1)*cos(q3), sin(q1)*cos(q2),
  sin(q1)*sin(q3) + sin(q2)*cos(q1)*cos(q3), -sin(q2),
  sin(q3)*cos(q2), cos(q2)*cos(q3)]]
```

It is worth noting that space-fixed and body-fixed rotations are related by the order of the rotations, i.e. the reverse order of body fixed will give space fixed and vice versa.

```python
>>> B.orient_space_fixed(N, (q1, q2, q3), '231')
>>> B.dcm(N)
Matrix()
[ cos(q1)*cos(q2), sin(q1)*sin(q3) + sin(q2)*cos(q1)*cos(q3), -sin(q2),
  -sin(q1)*cos(q3) + sin(q2)*sin(q3)*cos(q1), cos(q1)*cos(q3),
  sin(q1)*cos(q2)*sin(q3) + cos(q1)*cos(q3)]]
```

```python
>>> B.orient_body_fixed(N, (q3, q2, q1), '132')
>>> B.dcm(N)
```

(continues on next page)
Matrix([cos(q1)*cos(q2), sin(q1)*sin(q3) + sin(q2)*cos(q1)*cos(q3), -
      sin(q1)*cos(q3) + sin(q2)*sin(q3)*cos(q1)],
     [-sin(q2), cos(q2)*cos(q3), sin(q3)*cos(q2)],
     [sin(q1)*cos(q2), sin(q1)*sin(q2)*cos(q3) - sin(q3)*cos(q1),
      sin(q1)*sin(q2)*sin(q3) + cos(q1)*cos(q3)])

orientnew(newname, rot_type, amounts, rot_order='", variables=None, indices=None, latexs=None)

Returns a new reference frame oriented with respect to this reference frame.

See ReferenceFrame.orient() for detailed examples of how to orient reference frames.

**Parameters**

- **newname**: str
  Name for the new reference frame.

- **rot_type**: str
  The method used to generate the direction cosine matrix. Supported methods are:
  - 'Axis': simple rotations about a single common axis
  - 'DCM': for setting the direction cosine matrix directly
  - 'Body': three successive rotations about new intermediate axes, also called "Euler and Tait-Bryan angles"
  - 'Space': three successive rotations about the parent frames’ unit vectors
  - 'Quaternion': rotations defined by four parameters which result in a singularity free direction cosine matrix

- **amounts**:
  Expressions defining the rotation angles or direction cosine matrix. These must match the rot_type. See examples below for details. The input types are:
  - 'Axis': 2-tuple (expr/sym/func, Vector)
  - 'DCM': Matrix, shape(3,3)
  - 'Body': 3-tuple of expressions, symbols, or functions
  - 'Space': 3-tuple of expressions, symbols, or functions
  - 'Quaternion': 4-tuple of expressions, symbols, or functions

- **rot_order**: str or int, optional
  If applicable, the order of the successive of rotations. The string '123' and integer 123 are equivalent, for example. Required for 'Body' and 'Space'.

- **indices**: tuple of str
Enables the reference frame's basis unit vectors to be accessed by Python's square bracket indexing notation using the provided three indice strings and alters the printing of the unit vectors to reflect this choice.

latexs: tuple of str

Alters the LaTeX printing of the reference frame's basis unit vectors to the provided three valid LaTeX strings.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.vector import ReferenceFrame, vlatex
>>> q0, q1, q2, q3 = symbols('q0 q1 q2 q3')
>>> N = ReferenceFrame('N')
```

Create a new reference frame A rotated relative to N through a simple rotation.

```python
>>> A = N.orientnew('A', 'Axis', (q0, N.x))
```

Create a new reference frame B rotated relative to N through body-fixed rotations.

```python
>>> B = N.orientnew('B', 'Body', (q1, q2, q3), '123')
```

Create a new reference frame C rotated relative to N through a simple rotation with unique indices and LaTeX printing.

```python
>>> C = N.orientnew('C', 'Axis', (q0, N.x), indices=('1', '2', '3'),
... latexs=(r'\hat{\mathbf{c}}_1', r'\hat{\mathbf{c}}_2', r'\hat{\mathbf{c}}_3'))
>>> C[1]
C['1']
>>> print(vlatex(C[1]))
\hat{\mathbf{c}}_1
```

partial_velocity(frame, *gen_speeds)

Returns the partial angular velocities of this frame in the given frame with respect to one or more provided generalized speeds.

Parameters

- **frame** : ReferenceFrame
  - The frame with which the angular velocity is defined in.
- **gen_speeds** : functions of time
  - The generalized speeds.

Returns

- **partial_velocities** : tuple of Vector
  - The partial angular velocity vectors corresponding to the provided generalized speeds.
Examples

```
>>> from sympy.physics.vector import ReferenceFrame, dynamicsymbols
>>> N = ReferenceFrame('N')
>>> A = ReferenceFrame('A')
>>> u1, u2 = dynamicsymbols('u1, u2')
>>> A.set_ang_vel(N, u1 * A.x + u2 * N.y)
>>> A.particle_velocity(N, u1)
A.x
>>> A.particle_velocity(N, u1, u2)
(A.x, N.y)
```

**set_ang_acc**(otherframe, value)

Define the angular acceleration Vector in a ReferenceFrame.

Defines the angular acceleration of this ReferenceFrame, in another. Angular acceleration can be defined with respect to multiple different ReferenceFrames. Care must be taken to not create loops which are inconsistent.

**Parameters**

otherframe : ReferenceFrame
A ReferenceFrame to define the angular acceleration in

value : Vector
The Vector representing angular acceleration

Examples

```
>>> from sympy.physics.vector import ReferenceFrame
>>> N = ReferenceFrame('N')
>>> A = ReferenceFrame('A')
>>> V = 10 * N.x
>>> A.set_ang_acc(N, V)
>>> A.ang_acc_in(N)
10*N.x
```

**set_ang_vel**(otherframe, value)

Define the angular velocity vector in a ReferenceFrame.

Defines the angular velocity of this ReferenceFrame, in another. Angular velocity can be defined with respect to multiple different ReferenceFrames. Care must be taken to not create loops which are inconsistent.

**Parameters**

otherframe : ReferenceFrame
A ReferenceFrame to define the angular velocity in

value : Vector
The Vector representing angular velocity
Examples

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> N = ReferenceFrame('N')
>>> A = ReferenceFrame('A')
>>> V = 10 * N.x
>>> A.set_ang_vel(N, V)
>>> A.ang_vel_in(N)
10*N.x
```

variable_map(otherframe)

Returns a dictionary which expresses the coordinate variables of this frame in terms of the variables of otherframe.

If Vector.simp is True, returns a simplified version of the mapped values. Else, returns them without simplification.

Simplification of the expressions may take time.

**Parameters**

otherframe: ReferenceFrame

The other frame to map the variables to

Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, dynamicsymbols
>>> A = ReferenceFrame('A')
>>> q = dynamicsymbols('q')
>>> B = A.orientnew('B', 'Axis', [q, A.z])
>>> A.variable_map(B)
{A_x: B_x*cos(q(t)) - B_y*sin(q(t)), A_y: B_x*sin(q(t)) + B_y*cos(q(t)), A_z: B_z}
```

property x

The basis Vector for the ReferenceFrame, in the x direction.

property y

The basis Vector for the ReferenceFrame, in the y direction.

property z

The basis Vector for the ReferenceFrame, in the z direction.

class sympy.physics.vector.vector.Vector(inlist)

The class used to define vectors.

It along with ReferenceFrame are the building blocks of describing a classical mechanics system in PyDy and sympy.physics.vector.
Attributes

simp (Boolean) Let certain methods use trigsimp on their outputs

angle_between(vec)
Returns the smallest angle between Vector ‘vec’ and self.

**Warning:** Python ignores the leading negative sign so that might give wrong results. -A.x.angle_between() would be treated as -(A.x.angle_between()), instead of (-A.x).angle_between().

Parameter

vec [Vector] The Vector between which angle is needed.

Examples

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> A = ReferenceFrame("A")
>>> v1 = A.x
>>> v2 = A.y
>>> v1.angle_between(v2)
pi/2

>>> v3 = A.x + A.y + A.z
>>> v1.angle_between(v3)
acos(sqrt(3)/3)
```

applyfunc(f)
Apply a function to each component of a vector.

cross(other)
The cross product operator for two Vectors.
Returns a Vector, expressed in the same ReferenceFrames as self.

**Parameters**

other : Vector
The Vector which we are crossing with
Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.vector import ReferenceFrame, cross
>>> q1 = symbols('q1')
>>> N = ReferenceFrame('N')
>>> cross(N.x, N.y)
N.z
>>> A = ReferenceFrame('A')
>>> A.orient_axis(N, q1, N.x)
>>> cross(A.x, N.y)
N.z
>>> cross(N.y, A.x)
- sin(q1)*A.y - cos(q1)*A.z
```

`diff(var, frame, var_in_dcm=True)`

Returns the partial derivative of the vector with respect to a variable in the provided reference frame.

Parameters

- **var**: Symbol
  What the partial derivative is taken with respect to.

- **frame**: ReferenceFrame
  The reference frame that the partial derivative is taken in.

- **var_in_dcm**: boolean
  If true, the differentiation algorithm assumes that the variable may be present in any of the direction cosine matrices that relate the frame to the frames of any component of the vector. But if it is known that the variable is not present in the direction cosine matrices, false can be set to skip full reexpression in the desired frame.

Examples

```python
>>> from sympy import Symbol
>>> from sympy.physics.vector import dynamicsymbols, ReferenceFrame
>>> from sympy.physics.vector import Vector
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> Vector.simp = True
>>> t = Symbol('t')
>>> q1 = dynamicsymbols('q1')
>>> N = ReferenceFrame('N')
>>> A = N.orientnew('A', 'Axis', [q1, N.y])
>>> A.x.diff(t, N)
- sin(q1)*q1'*N.x - cos(q1)*q1'*N.z
>>> A.x.diff(t, N).express(A)
- q1'*A.z
>>> B = ReferenceFrame('B')
>>> u1, u2 = dynamicsymbols('u1, u2')
```

(continues on next page)
>>> v = u1 * A.x + u2 * B.y
>>> v.diff(u2, N, var_in_dcm=False)
B.y
doit(**hints)
  Calls .doit() on each term in the Vector
dot(other)
  Dot product of two vectors.
  Returns a scalar, the dot product of the two Vectors

Parameters
  other : Vector
    The Vector which we are dotting with

Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, dot
>>> from sympy import symbols
>>> q1 = symbols('q1')
>>> N = ReferenceFrame('N')
>>> dot(N.x, N.x)
1
>>> dot(N.x, N.y)
0
>>> A = N.orientnew('A', 'Axis', [q1, N.x])
>>> dot(N.y, A.y)
cos(q1)
dt(otherframe)
  Returns a Vector which is the time derivative of the self Vector, taken in frame otherframe.
  Calls the global time_derivative method

Parameters
  otherframe : ReferenceFrame
    The frame to calculate the time derivative in

express(otherframe, variables=False)
  Returns a Vector equivalent to this one, expressed in otherframe. Uses the global express method.

Parameters
  otherframe : ReferenceFrame
    The frame for this Vector to be described in
  variables : boolean
    If True, the coordinate symbols(if present) in this Vector are re-expressed in terms otherframe
Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, dynamicsymbols
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> q1 = dynamicsymbols('q1')
>>> N = ReferenceFrame('N')
>>> A = N.orientnew('A', 'Axis', [q1, N.y])
>>> A.x.express(N)
cos(q1)*N.x - sin(q1)*N.z
```

`free_dynamicsymbols(reference_frame)`

Returns the free dynamic symbols (functions of time \( t \)) in the measure numbers of the vector expressed in the given reference frame.

**Parameters**

- `reference_frame`: ReferenceFrame
  
The frame with respect to which the free dynamic symbols of the given vector is to be determined.

**Returns**

- `set`
  
  Set of functions of time \( t \), e.g. `Function('f')(me.dynamicsymbols._t)`.

`free_symbols(reference_frame)`

Returns the free symbols in the measure numbers of the vector expressed in the given reference frame.

**Parameters**

- `reference_frame`: ReferenceFrame
  
The frame with respect to which the free symbols of the given vector is to be determined.

**Returns**

- `set of Symbol`
  
  set of symbols present in the measure numbers of `reference_frame`.

`property func`

Returns the class `Vector`.

`magnitude()`

Returns the magnitude (Euclidean norm) of self.

**Warning:** Python ignores the leading negative sign so that might give wrong results. `-A.x.magnitude()` would be treated as `-(A.x.magnitude())`, instead of `(-A.x).magnitude()`.

`normalize()`

Returns a Vector of magnitude 1, codirectional with self.
outer\( (other) \)  
Outer product between two Vectors.  
A rank increasing operation, which returns a Dyadic from two Vectors

**Parameters**  
other : Vector  
The Vector to take the outer product with

**Examples**

```python
>>> from sympy.physics.vector import ReferenceFrame, outer
>>> N = ReferenceFrame('N')
>>> outer(N.x, N.x)
(N.x|N.x)
```

separate()  
The constituents of this vector in different reference frames, as per its definition.

Returns a dict mapping each ReferenceFrame to the corresponding constituent Vector.

**Examples**

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> R1 = ReferenceFrame('R1')
>>> R2 = ReferenceFrame('R2')
>>> v = R1.x + R2.x
>>> v.separate() == {R1: R1.x, R2: R2.x}
True
```

simplify()  
Returns a simplified Vector.

subs\(*args, **kwargs\)  
Substitution on the Vector.

**Examples**

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> from sympy import Symbol
>>> N = ReferenceFrame('N')
>>> s = Symbol('s')
>>> a = N.x * s
>>> a.subs({s: 2})
2*N.x
```

to_matrix\( (reference\_frame) \)  
Returns the matrix form of the vector with respect to the given frame.
Parameters

reference_frame : ReferenceFrame

The reference frame that the rows of the matrix correspond to.

Returns

matrix : ImmutableMatrix, shape(3,1)

The matrix that gives the 1D vector.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.vector import ReferenceFrame
>>> a, b, c = symbols('a, b, c')
>>> N = ReferenceFrame('N')
>>> vector = a * N.x + b * N.y + c * N.z
>>> vector.to_matrix(N)
Matrix([[a], [b], [c]])
```

xreplace(rule)

Replace occurrences of objects within the measure numbers of the vector.

Parameters

rule : dict-like

Expresses a replacement rule.

Returns

Vector

Result of the replacement.

Examples

```python
>>> from sympy import symbols, pi
>>> from sympy.physics.vector import ReferenceFrame
>>> A = ReferenceFrame('A')
>>> x, y, z = symbols('x y z')
>>> ((1 + x*y) * A.x).xreplace({x: pi})
(pi*y + 1)*A.x
>>> ((1 + x*y) * A.x).xreplace({x: pi, y: 2})
(1 + 2*pi)*A.x
```

Replacements occur only if an entire node in the expression tree is matched:
class sympy.physics.vector.dyadic.Dyadic(inlist)
A Dyadic object.

A more powerful way to represent a rigid body’s inertia. While it is more complex, by choosing Dyadic components to be in body fixed basis vectors, the resulting matrix is equivalent to the inertia tensor.

applyfunc(f)
Apply a function to each component of a Dyadic.

cross(other)
For a cross product in the form: Dyadic x Vector.

Parameters
other : Vector

The Vector that we are crossing this Dyadic with

Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, outer, cross
>>> N = ReferenceFrame('N')
>>> d = outer(N.x, N.x)
>>> cross(d, N.y)
(N.x|N.z)
```

doit(**hints)
Calls .doit() on each term in the Dyadic

dot(other)
The inner product operator for a Dyadic and a Dyadic or Vector.

Parameters
other : Dyadic or Vector

The other Dyadic or Vector to take the inner product with
Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, outer
>>> N = ReferenceFrame('N')
>>> D1 = outer(N.x, N.y)
>>> D2 = outer(N.y, N.y)
>>> D1.dot(D2)
(N.x|N.y)
>>> D1.dot(N.y)
N.x
```

dt(frame)

Take the time derivative of this Dyadic in a frame.

This function calls the global time_derivative method

**Parameters**

- **frame** : ReferenceFrame
  
  The frame to take the time derivative in

Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, outer,
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> N = ReferenceFrame('N')
>>> q = dynamicsymbols('q')
>>> B = N.orientnew('B', 'Axis', [q, N.z])
>>> d = outer(N.x, N.x)
>>> d.dt(B)
- q'*(N.y|N.x) - q'*N.y
```

express(frame1, frame2=None)

Expressions this Dyadic in alternate frame(s)

The first frame is the list side expression, the second frame is the right side; if Dyadic is in form A.x|B.y, you can express it in two different frames. If no second frame is given, the Dyadic is expressed in only one frame.

Calls the global express function

**Parameters**

- **frame1** : ReferenceFrame
  
  The frame to express the left side of the Dyadic in

- **frame2** : ReferenceFrame
  
  If provided, the frame to express the right side of the Dyadic in
Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, outer,
    dynamicsymbols
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> N = ReferenceFrame('N')
>>> q = dynamicsymbols('q')
>>> B = N.orientnew('B', 'Axis', [q, N.z])
>>> d = outer(N.x, N.x)
>>> d.express(B, N)
\cos(q)*(B.x|N.x) - \sin(q)*(B.y|N.x)
```

property func

Returns the class Dyadic.

simplify()

Returns a simplified Dyadic.

subs(*args, **kwargs)

Substitution on the Dyadic.

Examples

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> from sympy import Symbol
>>> N = ReferenceFrame('N')
>>> s = Symbol('s')
>>> a = s*(N.x|N.x)
>>> a.subs({s: 2})
2*(N.x|N.x)
```

to_matrix(reference_frame, second_reference_frame=None)

Returns the matrix form of the dyadic with respect to one or two reference frames.

Parameters

- **reference_frame** : ReferenceFrame
  The reference frame that the rows and columns of the matrix correspond to. If a second reference frame is provided, this only corresponds to the rows of the matrix.

- **second_reference_frame** : ReferenceFrame, optional, default=None
  The reference frame that the columns of the matrix correspond to.

Returns

- **matrix** : ImmutableMatrix, shape(3,3)
  The matrix that gives the 2D tensor form.
Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.vector import ReferenceFrame, Vector
>>> Vector.simp = True
>>> from sympy.physics.mechanics import inertia
>>> Ixx, Iyy, Izz, Ixy, Iyz, Ixz = symbols('Ixx, Iyy, Izz, Ixy, Iyz, Ixz')
>>> N = ReferenceFrame('N')
>>> inertia_dyadic = inertia(N, Ixx, Iyy, Izz, Ixy, Iyz, Ixz)
>>> inertia_dyadic.to_matrix(N)
Matrix([[Ixx, Ixy, Ixz],
        [Ixy, Iyy, Iyz],
        [Ixz, Iyz, Izz]])
```

```python
>>> beta = symbols('beta')
>>> A = N.orientnew('A', 'Axis', (beta, N.x))
>>> inertia_dyadic.to_matrix(A)
Matrix([[(Ixx - Ixy*sin(beta)) + Ixz*cos(beta), Ixy*cos(beta) + Ixz*sin(beta), Ixz*cos(2*beta)/2 + Izz/2 + Iyz*sin(2*beta)/2 - Iyy*cos(2*beta)/2 + Iyy/2 - Izz*sin(2*beta)/2 + Izz/2],
        [Ixy*cos(beta) + Ixz*sin(beta), Iyy*cos(2*beta)/2 + Iyy/2 + Izz*cos(2*beta)/2 - Iyz*sin(2*beta) + Izz/2, -Iyy*sin(2*beta)/2 + Iyz*cos(2*beta) + Izz*sin(2*beta)/2],
        [-Ixy*sin(beta) + Ixz*cos(beta), -Iyy*sin(2*beta)/2 - Iyz*cos(2*beta) + Izz*sin(2*beta)/2, -Iyy*cos(2*beta)/2 + Iyy/2 - Izz*sin(2*beta)/2 + Izz/2]])
```

`xreplace(rule)`

Replace occurrences of objects within the measure numbers of the Dyadic.

**Parameters**

- `rule`: dict-like

  Expresses a replacement rule.

**Returns**

Dyadic

Result of the replacement.

Examples

```python
>>> from sympy import symbols, pi
>>> from sympy.physics.vector import ReferenceFrame, outer
>>> N = ReferenceFrame('N')
>>> D = outer(N.x, N.x)
>>> x, y, z = symbols('x y z')
>>> ((1 + x*y) * D).xreplace({x: pi})
(pi*y + 1)*(N.x|N.x)
>>> ((1 + x*y) * D).xreplace({x: pi, y: 2})
(1 + 2*pi)*(N.x|N.x)
```
Replacements occur only if an entire node in the expression tree is matched:

```python
>>> ((x*y + z) * D).xreplace({x*y: pi})
(z + pi)*(N.x|N.x)
```

```python
>>> ((x*y*z) * D).xreplace({x*y: pi})
x*y*z*(N.x|N.x)
```

### Kinematics (Docstrings)

`class sympy.physics.vector.point.Point(name)`

This object represents a point in a dynamic system.

It stores the: position, velocity, and acceleration of a point. The position is a vector defined as the vector distance from a parent point to this point.

**Parameters**

- `name`: string
  - The display name of the Point

**Examples**

```python
>>> from sympy.physics.vector import Point, ReferenceFrame, dynamicsymbols
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> N = ReferenceFrame('N')
>>> O = Point('O')
>>> P = Point('P')
>>> u1, u2, u3 = dynamicsymbols('u1 u2 u3')
>>> O.set_vel(N, u1 * N.x + u2 * N.y + u3 * N.z)
>>> O.acc(N)
```

```python
u1'*N.x + u2'*N.y + u3'*N.z
```

Symbols() can be used to create multiple Points in a single step, for example:

```python
>>> from sympy.physics.vector import Point, ReferenceFrame, dynamicsymbols
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> from sympy import symbols
>>> N = ReferenceFrame('N')
>>> u1, u2 = dynamicsymbols('u1 u2')
>>> A, B = symbols('A B', cls=Point)
>>> type(A)
<class 'sympy.physics.vector.point.Point'>
>>> A.set_vel(N, u1 * N.x + u2 * N.y)
>>> B.set_vel(N, u2 * N.x + u1 * N.y)
>>> A.acc(N) - B.acc(N)
```

```python
(u1' - u2')*N.x + (-u1' + u2')*N.y
```
a1pt_theory\( (\text{otherpoint}, \text{outframe}, \text{interframe}) \)

Sets the acceleration of this point with the 1-point theory.

The 1-point theory for point acceleration looks like this:

\[ ^N a^P = ^N a^O + ^N \alpha^B x r^OP + ^N \omega^B x (^N \omega^B x r^OP) + 2 ^N \omega^B x ^B v^P \]

where \( O \) is a point fixed in \( B \), \( P \) is a point moving in \( B \), and \( B \) is rotating in frame \( N \).

**Parameters**

- **otherpoint**: Point
  - The first point of the 1-point theory (\( O \))

- **outframe**: ReferenceFrame
  - The frame we want this point’s acceleration defined in (\( N \))

- **fixedframe**: ReferenceFrame
  - The intermediate frame in this calculation (\( B \))

**Examples**

```python
>>> from sympy.physics.vector import Point, ReferenceFrame
>>> from sympy.physics.vector import dynamicsymbols
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> q = dynamicsymbols('q')
>>> q2 = dynamicsymbols('q2')
>>> qd = dynamicsymbols('q', 1)
>>> q2d = dynamicsymbols('q2', 1)
>>> N = ReferenceFrame('N')
>>> B = ReferenceFrame('B')
>>> B.set_ang_vel(N, 5 * B.y)
>>> O = Point('O')
>>> P = O.locatenew('P', q * B.x)
>>> P.set_vel(B, qd * B.x + q2d * B.y)
>>> O.set_vel(N, 0)
>>> P.a1pt_theory(O, N, B)
(-25*q + q'')*B.x + q2''*B.y - 10*q'*B.z
```

a2pt_theory\( (\text{otherpoint}, \text{outframe}, \text{fixedframe}) \)

Sets the acceleration of this point with the 2-point theory.

The 2-point theory for point acceleration looks like this:

\[ ^N a^P = ^N a^O + ^N \alpha^B x r^OP + ^N \omega^B x (^N \omega^B x r^OP) \]

where \( O \) and \( P \) are both points fixed in frame \( B \), which is rotating in frame \( N \).

**Parameters**

- **otherpoint**: Point
  - The first point of the 2-point theory (\( O \))

- **outframe**: ReferenceFrame
  - The frame we want this point’s acceleration defined in (\( N \))
**fixedframe** : ReferenceFrame

The frame in which both points are fixed (B)

**Examples**

```python
>>> from sympy.physics.vector import Point, ReferenceFrame
>>> dynamicsymbols
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> q = dynamicsymbols('q')
>>> qd = dynamicsymbols('q', 1)
>>> N = ReferenceFrame('N')
>>> B = N.orientnew('B', 'Axis', [q, N.z])
>>> O = Point('O')
>>> P = O.locatenew('P', 10 * B.x)
>>> O.set_vel(N, 5 * N.x)
>>> P.a2pt_theory(O, N, B)
-10*q'*2*B.x + 10*q''*B.y
```

**acc(frame)**

The acceleration Vector of this Point in a ReferenceFrame.

**Parameters**

- **frame** : ReferenceFrame
  
The frame in which the returned acceleration vector will be defined in.

**Examples**

```python
>>> from sympy.physics.vector import Point, ReferenceFrame
>>> N = ReferenceFrame('N')
>>> p1 = Point('p1')
>>> p1.set_acc(N, 10 * N.x)
>>> p1.acc(N)
10*N.x
```

**locatenew(name, value)**

Creates a new point with a position defined from this point.

**Parameters**

- **name** : str
  
The name for the new point

- **value** : Vector
  
The position of the new point relative to this point
Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, Point
>>> N = ReferenceFrame('N')
>>> P1 = Point('P1')
>>> P2 = P1.locatenew('P2', 10 * N.x)
```

`partial_velocity(frame, *gen_speeds)`

Returns the partial velocities of the linear velocity vector of this point in the given frame with respect to one or more provided generalized speeds.

**Parameters**

- `frame`: ReferenceFrame
  The frame with which the velocity is defined in.
- `gen_speeds`: functions of time
  The generalized speeds.

**Returns**

- `partial_velocities`: tuple of Vector
  The partial velocity vectors corresponding to the provided generalized speeds.

Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, Point
>>> from sympy.physics.vector import dynamicsymbols
>>> N = ReferenceFrame('N')
>>> A = ReferenceFrame('A')
>>> p = Point('p')
>>> u1, u2 = dynamicsymbols('u1, u2')
>>> p.set_vel(N, u1 * N.x + u2 * A.y)
>>> p.partial_velocity(N, u1)
N.x
>>> p.partial_velocity(N, u1, u2)
(N.x, A.y)
```

`pos_from(otherpoint)`

Returns a Vector distance between this Point and the other Point.

**Parameters**

- `otherpoint`: Point
  The otherpoint we are locating this one relative to
Examples

```python
generate_output_for_examples
```

**set_acc(frame, value)**

Used to set the acceleration of this Point in a ReferenceFrame.

**Parameters**

- **frame** : ReferenceFrame
  
  The frame in which this point’s acceleration is defined

- **value** : Vector
  
  The vector value of this point’s acceleration in the frame

Examples

```python
generate_output_for_examples
```

**set_pos(otherpoint, value)**

Used to set the position of this point w.r.t. another point.

**Parameters**

- **otherpoint** : Point
  
  The other point which this point’s location is defined relative to

- **value** : Vector
  
  The vector which defines the location of this point

Examples

```python
generate_output_for_examples
```
**set_vel**(*frame*, *value*)

Sets the velocity Vector of this Point in a ReferenceFrame.

**Parameters**

- **frame**: ReferenceFrame
  - The frame in which this point’s velocity is defined
- **value**: Vector
  - The vector value of this point’s velocity in the frame

**Examples**

```python
>>> from sympy.physics.vector import Point, ReferenceFrame
>>> N = ReferenceFrame('N')
>>> p1 = Point('p1')
>>> p1.set_vel(N, 10 * N.x)
>>> p1.vel(N)
10*N.x
```

**vlpt_theory**(*otherpoint*, *outframe*, *interframe*)

Sets the velocity of this point with the 1-point theory.

The 1-point theory for point velocity looks like this:

\[ ^N v^P = ^B v^P + ^N v^O + ^N \omega^B x r^OP \]

where O is a point fixed in B, P is a point moving in B, and B is rotating in frame N.

**Parameters**

- **otherpoint**: Point
  - The first point of the 1-point theory (O)
- **outframe**: ReferenceFrame
  - The frame we want this point’s velocity defined in (N)
- **interframe**: ReferenceFrame
  - The intermediate frame in this calculation (B)

**Examples**

```python
>>> from sympy.physics.vector import Point, ReferenceFrame
>>> from sympy.physics.vector import dynamicsymbols
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> q = dynamicsymbols('q')
>>> q2 = dynamicsymbols('q2')
>>> qd = dynamicsymbols('q', 1)
>>> q2d = dynamicsymbols('q2', 1)
>>> N = ReferenceFrame('N')
>>> B = ReferenceFrame('B')
>>> B.set_ang_vel(N, 5 * B.y)
```
v2pt_theory(otherpoint, outframe, fixedframe)
Sets the velocity of this point with the 2-point theory.
The 2-point theory for point velocity looks like this:
\[ ^N \mathbf{v}^P = ^N \mathbf{v}^O + ^N \omega^B \times r^OP \]
where O and P are both points fixed in frame B, which is rotating in frame N.

Parameters
otherpoint : Point
    The first point of the 2-point theory (O)
outframe : ReferenceFrame
    The frame we want this point’s velocity defined in (N)
fixedframe : ReferenceFrame
    The frame in which both points are fixed (B)

Examples

>>> from sympy.physics.vector import Point, ReferenceFrame,
    dynamicsymbols
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> q = dynamicsymbols('q')
>>> qd = dynamicsymbols('q', 1)
>>> N = ReferenceFrame('N')
>>> B = N.orientnew('B', 'Axis', [q, N.z])
>>> O = Point('O')
>>> P = O.locatenew('P', 10 * B.x)
>>> P.set_vel(B, qd * B.x + q2d * B.y)
>>> P.v2pt_theory(O, N, B)
q'x + q2'B.y - 5*q'B.z

vel(frame)
The velocity Vector of this Point in the ReferenceFrame.

Parameters
frame : ReferenceFrame
    The frame in which the returned velocity vector will be defined in
Examples

```
>>> from sympy.physics.vector import Point, ReferenceFrame,
\     dynamicsymbols
>>> N = ReferenceFrame('N')
>>> p1 = Point('p1')
>>> p1.set_vel(N, 10 * N.x)
>>> p1.vel(N)
10*N.x
```

Velocities will be automatically calculated if possible, otherwise a ValueError will be returned. If it is possible to calculate multiple different velocities from the relative points, the points defined most directly relative to this point will be used. In the case of inconsistent relative positions of points, incorrect velocities may be returned. It is up to the user to define prior relative positions and velocities of points in a self-consistent way.

```
>>> p = Point('p')
>>> q = dynamicsymbols('q')
>>> p.set_vel(N, 10 * N.x)
>>> p2 = Point('p2')
>>> p2.set_pos(p, q*N.x)
>>> p2.vel(N)
(derivative(q(t), t) + 10)*N.x
```

kinematic_equations

`sympy.physics.vector.functions.get_motion_params(frame, **kwargs)`

Returns the three motion parameters - (acceleration, velocity, and position) as vectorial functions of time in the given frame.

If a higher order differential function is provided, the lower order functions are used as boundary conditions. For example, given the acceleration, the velocity and position parameters are taken as boundary conditions.

The values of time at which the boundary conditions are specified are taken from timevalue1 (for position boundary condition) and timevalue2 (for velocity boundary condition).

If any of the boundary conditions are not provided, they are taken to be zero by default (zero vectors, in case of vectorial inputs). If the boundary conditions are also functions of time, they are converted to constants by substituting the time values in the dynamicsymbols._t time Symbol.

This function can also be used for calculating rotational motion parameters. Have a look at the Parameters and Examples for more clarity.

**Parameters**

- `frame` : ReferenceFrame
  - The frame to express the motion parameters in
- `acceleration` : Vector
  - Acceleration of the object/frame as a function of time
velocity: Vector
Velocity as function of time or as boundary condition of velocity at
time = timevalue1

position: Vector
Velocity as function of time or as boundary condition of velocity at
time = timevalue1

timevalue1: sympyfiable
Value of time for position boundary condition

timevalue2: sympyfiable
Value of time for velocity boundary condition

Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, get_motion_params,
<dynamic_symbols
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> from sympy import symbols

R = ReferenceFrame('R')
>>> v1, v2, v3 = dynamicsymbols('v1 v2 v3')
>>> v = v1*R.x + v2*R.y + v3*R.z
>>> get_motion_params(R, position=v)
(v1''*R.x + v2''*R.y + v3''*R.z, v1'*R.x + v2'*R.y + v3'*R.z, v1*R.x +
v2*R.y + v3*R.z)
>>> a, b, c = symbols('a b c')
>>> v = a*R.x + b*R.y + c*R.z
>>> get_motion_params(R, velocity=v)
(0, a*R.x + b*R.y + c*R.z, a*t*R.x + b*t*R.y + c*t*R.z)
>>> parameters = get_motion_params(R, acceleration=v)

parameters[1]
a*t*R.x + b*t*R.y + c*t*R.z
>>> parameters[2]
a*t**2/2*R.x + b*t**2/2*R.y + c*t**2/2*R.z
```

sympy.physics.vector.functions.kinematic_equations(speeds, coords, rot_type, rot_order='')

Gives equations relating the qdot's to u's for a rotation type.

Supply rotation type and order as in orient. Speeds are assumed to be body-fixed; if we
are defining the orientation of B in A using by rot_type, the angular velocity of B in A is
assumed to be in the form: speed[0]*B.x + speed[1]*B.y + speed[2]*B.z

Parameters

- **speeds**: list of length 3
  The body fixed angular velocity measure numbers.

- **coords**: list of length 3 or 4
  The coordinates used to define the orientation of the two frames.

- **rot_type**: str
The type of rotation used to create the equations. Body, Space, or Quaternion only

**rot_order**: str or int

If applicable, the order of a series of rotations.

Examples

```python
>>> from sympy.physics.vector import dynamicsymbols
>>> from sympy.physics.vector import kinematic_equations, vprint
>>> u1, u2, u3 = dynamicsymbols('u1 u2 u3')
>>> q1, q2, q3 = dynamicsymbols('q1 q2 q3')
>>> vprint(kinematic_equations([u1,u2,u3], [q1,q2,q3], 'body', '313'),
...     order=None)
[-(u1*sin(q3) + u2*cos(q3))/sin(q2) + q1', -u1*cos(q3) + u2*sin(q3) + q2 →', (u1*sin(q3) + u2*cos(q3))*cos(q2)/sin(q2) - u3 + q3']
```

```python
sympy.physics.vector.functions.partial_velocity(vel_vecs, gen_speeds, frame)
```

Returns a list of partial velocities with respect to the provided generalized speeds in the given reference frame for each of the supplied velocity vectors.

The output is a list of lists. The outer list has a number of elements equal to the number of supplied velocity vectors. The inner lists are, for each velocity vector, the partial derivatives of that velocity vector with respect to the generalized speeds supplied.

**Parameters**

- **vel_vecs**: iterable
  An iterable of velocity vectors (angular or linear).

- **gen_speeds**: iterable
  An iterable of generalized speeds.

- **frame**: ReferenceFrame
  The reference frame that the partial derivatives are going to be taken in.

Examples

```python
>>> from sympy.physics.vector import Point, ReferenceFrame
>>> from sympy.physics.vector import dynamicsymbols
>>> from sympy.physics.vector import partial_velocity
>>> u = dynamicsymbols('u')
>>> N = ReferenceFrame('N')
>>> P = Point('P')
>>> P.set_vel(N, u * N.x)
>>> vel_vecs = [P.vel(N)]
>>> gen_speeds = [u]
>>> partial_velocity(vel_vecs, gen_speeds, N)
[[[N.x]]]
```
Printing (Docstrings)

```
init_vprinting(**kwargs)
```

Initializes time derivative printing for all SymPy objects, i.e. any functions of time will be displayed in a more compact notation. The main benefit of this is for printing of time derivatives; instead of displaying as `Derivative(f(t), t)`, it will display `f'`. This is only actually needed for when derivatives are present and are not in a physics.vector.Vector or physics.vector.Dyadic object. This function is a light wrapper to `init_printing()` (page 2192). Any keyword arguments for it are valid here.

Initializes pretty-printer depending on the environment.

**Parameters**

- **pretty_print**: bool, default=True
  - If True, use `pretty_print()` (page 2212) to stringify or the provided pretty printer; if False, use `sstrrepr()` (page 2253) to stringify or the provided string printer.

- **order**: string or None, default='lex'
  - There are a few different settings for this parameter: 'lex' (default), which is lexicographic order; 'grlex', which is graded lexicographic order; 'grevlex', which is reversed graded lexicographic order; 'old', which is used for compatibility reasons and for long expressions; None, which sets it to lex.

- **use_unicode**: bool or None, default=None
  - If True, use unicode characters; if False, do not use unicode characters; if None, make a guess based on the environment.

- **use_latex**: string, bool, or None, default=None
  - If True, use default LaTeX rendering in GUI interfaces (png and mathjax); if False, do not use LaTeX rendering; if None, make a guess based on the environment; if 'png', enable LaTeX rendering with an external LaTeX compiler, falling back to matplotlib if external compilation fails; if 'matplotlib', enable LaTeX rendering with matplotlib; if 'mathjax', enable LaTeX text generation, for example MathJax rendering in IPython notebook or text rendering in LaTeX documents; if 'svg', enable LaTeX rendering with an external latex compiler, no fallback

- **wrap_line**: bool
  - If True, lines will wrap at the end; if False, they will not wrap but continue as one line. This is only relevant if pretty_print is True.

- **num_columns**: int or None, default=None
  - If int, number of columns before wrapping is set to num_columns; if None, number of columns before wrapping is set to terminal width. This is only relevant if pretty_print is True.

- **no_global**: bool, default=False
  - If True, the settings become system wide; if False, use just for this console/session.

- **ip**: An interactive console
This can either be an instance of IPython, or a class that derives from code.InteractiveConsole.

**euler** : bool, optional, default=False

Loads the euler package in the LaTeX preamble for handwritten style fonts ([https://www.ctan.org/pkg/euler](https://www.ctan.org/pkg/euler)).

**forecolor** : string or None, optional, default=None

DVI setting for foreground color. None means that either 'Black', 'White', or 'Gray' will be selected based on a guess of the IPython terminal color setting. See notes.

**backcolor** : string, optional, default='Transparent'

DVI setting for background color. See notes.

**fontsize** : string or int, optional, default='10pt'

A font size to pass to the LaTeX documentclass function in the preamble. Note that the options are limited by the documentclass. Consider using scale instead.

**latex_mode** : string, optional, default='plain'

The mode used in the LaTeX printer. Can be one of: {'inline'|'plain'|'equation'|'equation*'}.

**print_builtin** : boolean, optional, default=True

If True then floats and integers will be printed. If False the printer will only print SymPy types.

**str_printer** : function, optional, default=None

A custom string printer function. This should mimic `sstrrepr()` (page 2253).

**pretty_printer** : function, optional, default=None

A custom pretty printer. This should mimic `pretty()` (page 2212).

**latex_printer** : function, optional, default=None

A custom LaTeX printer. This should mimic `latex()` (page 2245).

**scale** : float, optional, default=1.0

Scale the LaTeX output when using the 'png' or 'svg' backends. Useful for high dpi screens.

**settings** :

Any additional settings for the `latex` and `pretty` commands can be used to fine-tune the output.
Examples

```python
>>> from sympy import Function, symbols
t, x = symbols('t, x')
>>> omega = Function('omega')
>>> omega(x).diff()
Derivative(omega(x), x)
>>> omega(t).diff()
Derivative(omega(t), t)
```

Now use the string printer:

```python
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> omega(x).diff()
Derivative(omega(x), x)
>>> omega(t).diff()
omega'
```

**sympy.physics.vector.printing.vprint(expr, **settings)**

Function for printing of expressions generated in the sympy.physics vector package.

Extends SymPy’s StrPrinter, takes the same setting accepted by SymPy’s `sstr()` (page 2253), and is equivalent to `print(sstr(foo))`.

**Parameters**

- `expr` : valid SymPy object
  
  SymPy expression to print.

- `settings` : args
  
  Same as the settings accepted by SymPy’s `sstr()`.

**Examples**

```python
>>> from sympy.physics.vector import vprint, dynamicsymbols
>>> u1 = dynamicsymbols('u1')
>>> print(u1)
u1(t)
>>> vprint(u1)
u1
```

**sympy.physics.vector.printing.vpprint(expr, **settings)**

Function for pretty printing of expressions generated in the sympy.physics vector package.

Mainly used for expressions not inside a vector; the output of running scripts and generating equations of motion. Takes the same options as SymPy’s `pretty_print()` (page 2212); see that function for more information.

**Parameters**

- `expr` : valid SymPy object
  
  SymPy expression to pretty print
settings : args

    Same as those accepted by SymPy’s pretty_print.

sympy.physics.vector.printing.vlatex(expr, **settings)

    Function for printing latex representation of sympy.physics.vector objects.

    For latex representation of Vectors, Dyadics, and dynamicsymbols. Takes the same options
    as SymPy’s latex() (page 2245); see that function for more information;

    Parameters
    expr : valid SymPy object

        SymPy expression to represent in LaTeX form

    settings : args

        Same as latex()

Examples

>>> from sympy.physics.vector import vlatex, ReferenceFrame,
    dynamicsymbols
>>> N = ReferenceFrame('N')
>>> q1, q2 = dynamicsymbols('q1 q2')
>>> q1d, q2d = dynamicsymbols('q1 q2', 1)
>>> q1dd, q2dd = dynamicsymbols('q1 q2', 2)
>>> vlatex(N.x + N.y)
'\mathbf{\hat{n}_x} + \mathbf{\hat{n}_y}'
>>> vlatex(q1 + q2)
'q_{1} + q_{2}'
>>> vlatex(q1d)
'\dot{q}_{1}'
>>> vlatex(q1 * q2d)
'q_{1} \dot{q}_{2}'
>>> vlatex(q1dd * q1 / q1d)
'\frac{q_{1} \ddot{q}_{1}}{\dot{q}_{1}}'

Essential Functions (Docstrings)

sympy.physics.vector.dynamicsymbols(names, level=0, **assumptions)

    Uses symbols and Function for functions of time.

    Creates a SymPy UndefinedFunction, which is then initialized as a function of a variable,
    the default being Symbol('t').

    Parameters
    names : str

        Names of the dynamic symbols you want to create; works the same way as inputs to symbols

    level : int

        Level of differentiation of the returned function; d/dt once of t, twice of t, etc.
assumptions:

- **real**(bool)
  [This is used to set the dynamicsymbol as real,] by default is False.

- **positive**(bool)
  [This is used to set the dynamicsymbol as positive,] by default is False.

- **commutative**(bool)
  [This is used to set the commutative property of] a dynamicsymbol, by default is True.

- **integer**(bool)
  [This is used to set the dynamicsymbol as integer,] by default is False.

Examples

```python
>>> from sympy.physics.vector import dynamicsymbols
>>> from sympy import diff, Symbol

>>> q1 = dynamicsymbols('q1')
>>> q1
q1(t)

>>> q2 = dynamicsymbols('q2', real=True)
>>> q2.is_real
True

>>> q3 = dynamicsymbols('q3', positive=True)
>>> q3.is_positive
True

>>> q4, q5 = dynamicsymbols('q4,q5', commutative=False)

>>> bool(q4*q5 != q5*q4)
True

>>> q6 = dynamicsymbols('q6', integer=True)
>>> q6.is_integer
True

>>> diff(q1, Symbol('t'))
Derivative(q1(t), t)
```

**sympy.physics.vector.functions.dot(vec1, vec2)**

Dot product convenience wrapper for Vector.dot(): Dot product of two vectors.

Returns a scalar, the dot product of the two Vectors

**Parameters**

- **other**: Vector

  The Vector which we are dotting with
Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, dot
>>> from sympy import symbols
>>> q1 = symbols('q1')
>>> N = ReferenceFrame('N')
>>> dot(N.x, N.x)
1
>>> dot(N.x, N.y)
0
>>> A = N.orientnew('A', 'Axis', [q1, N.x])
>>> dot(N.y, A.y)
cos(q1)
```

sympy.physics.vector.functions.cross(vec1, vec2)

Cross product convenience wrapper for Vector.cross(): The cross product operator for two Vectors.

Returns a Vector, expressed in the same ReferenceFrames as self.

**Parameters**

other : Vector

The Vector which we are crossing with

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.vector import ReferenceFrame, cross
>>> q1 = symbols('q1')
>>> N = ReferenceFrame('N')
>>> cross(N.x, N.y)
N.z
>>> A = ReferenceFrame('A')
>>> A.orient_axis(N, q1, N.x)
>>> cross(A.x, N.y)
N.z
>>> cross(N.y, A.x)
-sin(q1)*A.y - cos(q1)*A.z
```

sympy.physics.vector.functions.outer(vec1, vec2)

Outer product convenience wrapper for Vector.outer(): Outer product between two Vectors.

A rank increasing operation, which returns a Dyadic from two Vectors.

**Parameters**

other : Vector

The Vector to take the outer product with
Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, outer
>>> N = ReferenceFrame('N')
>>> outer(N.x, N.x)
(N.x|N.x)
```

```python
sympy.physics.vector.functions.express(expr, frame, frame2=None, variables=False)
Global function for ‘express’ functionality.
Re-expresses a Vector, scalar(sympyfiable) or Dyadic in given frame.
Refer to the local methods of Vector and Dyadic for details. If ‘variables’ is True, then
the coordinate variables (CoordinateSym instances) of other frames present in the vec-
tor/scalar field or dyadic expression are also substituted in terms of the base scalars of
this frame.

Parameters
expr : Vector/Dyadic/scalar(sympyfiable)
The expression to re-express in ReferenceFrame ‘frame’
frame: ReferenceFrame
The reference frame to express expr in
frame2 : ReferenceFrame
The other frame required for re-expression(only for Dyadic expr)
variables : boolean
Specifies whether to substitute the coordinate variables present in
eq, in terms of those of frame

Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, outer,
... dynamicsymbols
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> N = ReferenceFrame('N')
>>> q = dynamicsymbols('q')
>>> B = N.orientnew('B', 'Axis', [q, N.z])
>>> d = outer(N.x, N.x)
>>> from sympy.physics.vector import express
>>> express(d, B, N)
>>> express(B.x, N, order=1)
cos(q)*B.x - sin(q)*B.y
B_x*cos(q) - B_y*sin(q)
```
Parameters

- **expr** : Vector/Dyadic/sympifyable
  The expression whose time derivative is to be calculated
- **frame** : ReferenceFrame
  The reference frame to calculate the time derivative in
- **order** : integer
  The order of the derivative to be calculated

Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, dynamicsymbols
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> from sympy import Symbol
>>> q1 = Symbol('q1')
>>> u1 = dynamicsymbols('u1')
>>> N = ReferenceFrame('N')
>>> A = N.orientnew('A', 'Axis', [q1, N.x])
>>> v = u1 * N.x
>>> A.set_ang_vel(N, 10*A.x)
>>> from sympy.physics.vector import time_derivative
>>> time_derivative(v, N)
u1'*N.x
>>> time_derivative(u1*A[0], N)
N_x*u1'
>>> B = N.orientnew('B', 'Axis', [u1, N.z])
>>> from sympy.physics.vector import outer
>>> d = outer(N.x, N.x)
>>> time_derivative(d, B)
- u1'*(N.y|N.x) - u1'*(N.x|N.y)
```

Docstrings for basic field functions

Field operation functions

These functions implement some basic operations pertaining to fields in general.

```python
sympy.physics.vector.fieldfunctions.curl(vect, frame)
```

Returns the curl of a vector field computed wrt the coordinate symbols of the given frame.

- **vect** : Vector
The vector operand

**frame**: ReferenceFrame

The reference frame to calculate the curl in

### Examples

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> from sympy.physics.vector import curl
>>> R = ReferenceFrame('R')
>>> v1 = R[1]*R[2]*R.x + R[0]*R[2]*R.y + R[0]*R[1]*R.z
>>> curl(v1, R)
0
>>> v2 = R[0]*R[1]*R[2]*R.x
>>> curl(v2, R)
R_x*R_y*R.y - R_x*R_z*R.z
```

**sympy.physics.vector.fieldfunctions.divergence**(vect, frame)

Returns the divergence of a vector field computed wrt the coordinate symbols of the given frame.

**Parameters**

- **vect**: Vector
  - The vector operand
- **frame**: ReferenceFrame
  - The reference frame to calculate the divergence in

### Examples

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> from sympy.physics.vector import divergence
>>> R = ReferenceFrame('R')
>>> v1 = R[0]*R[1]*R[2] * (R.x+R.y+R.z)
>>> divergence(v1, R)
R.x*R_y + R_x*R_z + R_y*R_z
>>> v2 = 2*R[1]*R[2]*R.y
>>> divergence(v2, R)
2*R_z
```

**sympy.physics.vector.fieldfunctions.gradient**(scalar, frame)

Returns the vector gradient of a scalar field computed wrt the coordinate symbols of the given frame.

**Parameters**

- **scalar**: sympifiable
  - The scalar field to take the gradient of
- **frame**: ReferenceFrame
  - The frame to calculate the gradient in
Examples

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> from sympy.physics.vector import gradient
>>> R = ReferenceFrame('R')
>>> s1 = R[0]*R[1]*R[2]
>>> gradient(s1, R)
R_y*R_z*R.x + R_x*R_z*R.y + R_x*R_y*R.z
>>> s2 = 5*R[0]**2*R[2]
>>> gradient(s2, R)
10*R_x*R_z*R.x + 5*R_x**2*R.z
```

`sympy.physics.vector.fieldfunctions.scalar_potential(field, frame)`

Returns the scalar potential function of a field in a given frame (without the added integration constant).

**Parameters**

- **field**: Vector
  
The vector field whose scalar potential function is to be calculated

- **frame**: ReferenceFrame
  
The frame to do the calculation in

Examples

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> from sympy.physics.vector import scalar_potential, gradient
>>> R = ReferenceFrame('R')
>>> scalar_potential(R.z, R) == R[2]
True
>>> scalar_field = 2*R[0]**2*R[1]*R[2]
>>> grad_field = gradient(scalar_field, R)
>>> scalar_potential(grad_field, R)
2*R_x**2*R_y*R_z
```

`sympy.physics.vector.fieldfunctions.scalar_potential_difference(field, frame, point1, point2, origin)`

Returns the scalar potential difference between two points in a certain frame, wrt a given field.

If a scalar field is provided, its values at the two points are considered. If a conservative vector field is provided, the values of its scalar potential function at the two points are used.

Returns (potential at position 2) - (potential at position 1)

**Parameters**

- **field**: Vector/sympyfiable
  
The field to calculate wrt

- **frame**: ReferenceFrame
  
The frame to do the calculations in
**point1**: Point

The initial Point in given frame

**position2**: Point

The second Point in the given frame

**origin**: Point

The Point to use as reference point for position vector calculation

---

### Examples

```python
>>> from sympy.physics.vector import ReferenceFrame, Point
>>> from sympy.physics.vector import scalar_potential_difference
>>> R = ReferenceFrame('R')
>>> O = Point('O')
>>> P = O.locatenew('P', R[0]*R.x + R[1]*R.y + R[2]*R.z)
>>> vectfield = 4*R[0]*R[1]*R.x + 2*R[0]**2*R.y
>>> scalar_potential_difference(vectfield, R, O, P, O)
2*R_x**2*R_y
```

Checking the type of vector field

**sympy.physics.vector.fieldfunctions.is_conservative(field)**

Checks if a field is conservative.

**Parameters**

- **field**: Vector

  The field to check for conservative property

**Examples**

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> from sympy.physics.vector import is_conservative
>>> R = ReferenceFrame('R')
>>> is_conservative(R[1]*R[2]*R.x + R[0]*R[2]*R.y + R[0]*R[1]*R.z)
True
>>> is_conservative(R[2] * R.y)
False
```

**sympy.physics.vector.fieldfunctions.is_solenoidal(field)**

Checks if a field is solenoidal.

**Parameters**

- **field**: Vector

  The field to check for solenoidal property
Examples

```python
>>> from sympy.physics.vector import ReferenceFrame
>>> from sympy.physics.vector import is_solenoidal
>>> R = ReferenceFrame('R')
True
>>> is_solenoidal(R[1] * R.y)
False
```

Classical Mechanics

Abstract

In this documentation many components of the physics/mechanics module will be discussed. `sympy.physics.mechanics` (page 1721) has been written to allow for creation of symbolic equations of motion for complicated multibody systems.

Vector

This module derives the vector-related abilities and related functionalities from `sympy.physics.vector` (page 1640). Please have a look at the documentation of `sympy.physics.vector` (page 1640) and its necessary API to understand the vector capabilities of `sympy.physics.mechanics` (page 1721).

Mechanics

In physics, mechanics describes conditions of rest (statics) or motion (dynamics). There are a few common steps to all mechanics problems. First, an idealized representation of a system is described. Next, we use physical laws to generate equations that define the system’s behavior. Then, we solve these equations, sometimes analytically but usually numerically. Finally, we extract information from these equations and solutions. The current scope of the module is multi-body dynamics: the motion of systems of multiple particles and/or rigid bodies. For example, this module could be used to understand the motion of a double pendulum, planets, robotic manipulators, bicycles, and any other system of rigid bodies that may fascinate us.

Often, the objective in multi-body dynamics is to obtain the trajectory of a system of rigid bodies through time. The challenge for this task is to first formulate the equations of motion of the system. Once they are formulated, they must be solved, that is, integrated forward in time. When digital computers came around, solving became the easy part of the problem. Now, we can tackle more complicated problems, which leaves the challenge of formulating the equations.

The term “equations of motion” is used to describe the application of Newton’s second law to multi-body systems. The form of the equations of motion depends on the method used to generate them. This package implements two of these methods: Kane’s method and Lagrange’s method. This module facilitates the formulation of equations of motion, which can then be solved (integrated) using generic ordinary differential equation (ODE) solvers.
The approach to a particular class of dynamics problems, that of forward dynamics, has the following steps:

1. describing the system’s geometry and configuration,
2. specifying the way the system can move, including constraints on its motion
3. describing the external forces and moments on the system,
4. combining the above information according to Newton’s second law ($F = ma$), and
5. organizing the resulting equations so that they can be integrated to obtain the system’s trajectory through time.

Together with the rest of SymPy, this module performs steps 4 and 5, provided that the user can perform 1 through 3 for the module. That is to say, the user must provide a complete representation of the free body diagrams that themselves represent the system, with which this code can provide equations of motion in a form amenable to numerical integration. Step 5 above amounts to arduous algebra for even fairly simple multi-body systems. Thus, it is desirable to use a symbolic math package, such as SymPy, to perform this step. It is for this reason that this module is a part of SymPy. Step 4 amounts to this specific module, `sympy.physics.mechanics`.

**Guide to Mechanics**

**Masses, Inertias, Particles and Rigid Bodies in Physics/Mechanics**

This document will describe how to represent masses and inertias in `sympy.physics.mechanics` (page 1721) and use of the RigidBody and Particle classes.

It is assumed that the reader is familiar with the basics of these topics, such as finding the center of mass for a system of particles, how to manipulate an inertia tensor, and the definition of a particle and rigid body. Any advanced dynamics text can provide a reference for these details.

**Mass**

The only requirement for a mass is that it needs to be a `sympify`-able expression. Keep in mind that masses can be time varying.

**Particle**

Particles are created with the class `Particle` in `sympy.physics.mechanics` (page 1721). A `Particle` object has an associated point and an associated mass which are the only two attributes of the object.

```python
>>> from sympy.physics.mechanics import Particle, Point
>>> from sympy import Symbol
>>> m = Symbol('m')
>>> po = Point('po')
>>> # create a particle container
>>> pa = Particle('pa', po, m)
```
The associated point contains the position, velocity and acceleration of the particle. *sympy.physics.mechanics* (page 1721) allows one to perform kinematic analysis of points separate from their association with masses.

**Inertia**

See the Inertia (Dyadics) section in ‘Advanced Topics’ part of *sympy.physics.vector* (page 1640) docs.

**Rigid Body**

Rigid bodies are created in a similar fashion as particles. The `RigidBody` class generates objects with four attributes: mass, center of mass, a reference frame, and an inertia tuple:

```python
>>> from sympy import Symbol
>>> from sympy.physics.mechanics import ReferenceFrame, Point, RigidBody
>>> m = Symbol('m')
>>> A = ReferenceFrame('A')
>>> P = Point('P')
>>> I = A.outer(A.x, A.x)
>>> # create a rigid body
>>> B = RigidBody('B', P, A, m, (I, P))
```

The mass is specified exactly as is in a particle. Similar to the Particle’s `.point`, the RigidBody’s center of mass, `.masscenter` must be specified. The reference frame is stored in an analogous fashion and holds information about the body’s orientation and angular velocity. Finally, the inertia for a rigid body needs to be specified about a point. In *sympy.physics.mechanics* (page 1721), you are allowed to specify any point for this. The most common is the center of mass, as shown in the above code. If a point is selected which is not the center of mass, ensure that the position between the point and the center of mass has been defined. The inertia is specified as a tuple of length two with the first entry being a Dyadic and the second entry being a Point of which the inertia dyadic is defined about.

**Dyadic**

In *sympy.physics.mechanics* (page 1721), dyadics are used to represent inertia ([Kane1985], [WikiDyadics], [WikiDyadicProducts]). A dyadic is a linear polynomial of component unit dyadics, similar to a vector being a linear polynomial of component unit vectors. A dyadic is the outer product between two vectors which returns a new quantity representing the juxtaposition of these two vectors. For example:

\[
\mathbf{a}_x \otimes \mathbf{a}_x = \mathbf{a}_x \mathbf{a}_x \\
\mathbf{a}_x \otimes \mathbf{a}_y = \mathbf{a}_x \mathbf{a}_y
\]

Where \(\mathbf{a}_x \mathbf{a}_x\) and \(\mathbf{a}_x \mathbf{a}_y\) are the outer products obtained by multiplying the left side as a column vector by the right side as a row vector. Note that the order is significant.
Some additional properties of a dyadic are:

\[
(xv) \otimes w = v \otimes (xw) = x(v \otimes w)
\]

\[
v \otimes (w + u) = v \otimes w + v \otimes u
\]

\[
(v + w) \otimes u = v \otimes u + w \otimes u
\]

A vector in a reference frame can be represented as \[\begin{bmatrix} a \\ b \\ c \end{bmatrix}\] or \[a \hat{\mathbf{i}} + b \hat{\mathbf{j}} + c \hat{\mathbf{k}}\]. Similarly, a dyadic can be represented in tensor form:

\[
\begin{bmatrix}
a_{11} & a_{12} & a_{13} \\
a_{21} & a_{22} & a_{23} \\
a_{31} & a_{32} & a_{33}
\end{bmatrix}
\]

or in dyadic form:

\[a_{11} \hat{\mathbf{a}}_x \hat{\mathbf{a}}_x + a_{12} \hat{\mathbf{a}}_x \hat{\mathbf{a}}_y + a_{13} \hat{\mathbf{a}}_x \hat{\mathbf{a}}_z + a_{21} \hat{\mathbf{a}}_y \hat{\mathbf{a}}_x + a_{22} \hat{\mathbf{a}}_y \hat{\mathbf{a}}_y + a_{23} \hat{\mathbf{a}}_y \hat{\mathbf{a}}_z + a_{31} \hat{\mathbf{a}}_z \hat{\mathbf{a}}_x + a_{32} \hat{\mathbf{a}}_z \hat{\mathbf{a}}_y + a_{33} \hat{\mathbf{a}}_z \hat{\mathbf{a}}_z\]

Just as with vectors, the later representation makes it possible to keep track of which frames the dyadic is defined with respect to. Also, the two components of each term in the dyadic need not be in the same frame. The following is valid:

\[\hat{\mathbf{a}}_x \otimes \hat{\mathbf{b}}_y = \hat{\mathbf{a}}_x \hat{\mathbf{b}}_y\]

Dyadics can also be crossed and dotted with vectors; again, order matters:

\[\hat{\mathbf{a}}_x \hat{\mathbf{a}}_x \cdot \hat{\mathbf{a}}_x = \hat{\mathbf{a}}_x\]

\[\hat{\mathbf{a}}_y \hat{\mathbf{a}}_x \cdot \hat{\mathbf{a}}_x = \hat{\mathbf{a}}_y\]

\[\hat{\mathbf{a}}_x \hat{\mathbf{a}}_y \cdot \hat{\mathbf{a}}_x = 0\]

\[\hat{\mathbf{a}}_x \cdot \hat{\mathbf{a}}_x \hat{\mathbf{a}}_x = \hat{\mathbf{a}}_x\]

\[\hat{\mathbf{a}}_x \cdot \hat{\mathbf{a}}_x \hat{\mathbf{a}}_y = \hat{\mathbf{a}}_y\]

\[\hat{\mathbf{a}}_x \cdot \hat{\mathbf{a}}_y \hat{\mathbf{a}}_x = 0\]

\[\hat{\mathbf{a}}_x \times \hat{\mathbf{a}}_y \hat{\mathbf{a}}_x = \hat{\mathbf{a}}_z \hat{\mathbf{a}}_x\]

\[\hat{\mathbf{a}}_x \times \hat{\mathbf{a}}_x \hat{\mathbf{a}}_x = 0\]

\[\hat{\mathbf{a}}_x \hat{\mathbf{a}}_x \times \hat{\mathbf{a}}_x = -\hat{\mathbf{a}}_y \hat{\mathbf{a}}_y\]

One can also take the time derivative of dyadics or express them in different frames, just like with vectors.

**Linear Momentum**

The linear momentum of a particle \(P\) is defined as:

\[L_P = mv\]

where \(m\) is the mass of the particle \(P\) and \(v\) is the velocity of the particle in the inertial frame.[Likins1973].

Similarly the linear momentum of a rigid body is defined as:

\[L_B = m\nu^*\]

where \(m\) is the mass of the rigid body, \(B\), and \(\nu^*\) is the velocity of the mass center of \(B\) in the inertial frame.
Angular Momentum

The angular momentum of a particle P about an arbitrary point O in an inertial frame N is defined as:

\[ N \mathbf{H}^{P/O} = \mathbf{r} \times m \mathbf{v} \]

where \( \mathbf{r} \) is a position vector from point O to the particle of mass \( m \) and \( \mathbf{v} \) is the velocity of the particle in the inertial frame.

Similarly the angular momentum of a rigid body B about a point O in an inertial frame N is defined as:

\[ N \mathbf{H}^{B/O} = N \mathbf{H}^{B/B^*} + N \mathbf{H}^{B^*/O} \]

where the angular momentum of the body about it’s mass center is:

\[ N \mathbf{H}^{B/B^*} = \mathbf{I}^* \cdot \omega \]

and the angular momentum of the mass center about O is:

\[ N \mathbf{H}^{B^*/O} = \mathbf{r}^* \times m \mathbf{v}^* \]

where \( \mathbf{I}^* \) is the central inertia dyadic of rigid body B, \( \omega \) is the inertial angular velocity of B, \( \mathbf{r}^* \) is a position vector from point O to the mass center of B, \( m \) is the mass of B and \( \mathbf{v}^* \) is the velocity of the mass center in the inertial frame.

Using momenta functions in Mechanics

The following example shows how to use the momenta functions in sympy.physics.mechanics (page 1721).

One begins by creating the requisite symbols to describe the system. Then the reference frame is created and the kinematics are done.

```python
>>> from sympy import symbols
>>> from sympy.physics.mechanics import dynamicsymbols, ReferenceFrame
>>> from sympy.physics.mechanics import RigidBody, Particle, Point, outer
>>> from sympy.physics.mechanics import linear_momentum, angular_momentum
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> m, M, l1 = symbols('m M l1')
>>> qld = dynamicsymbols('qld')
>>> N = ReferenceFrame('N')
>>> O = Point('O')
>>> O.set_vel(N, 0 * N.x)
>>> Ac = O.locatenew('Ac', l1 * N.x)
>>> P = Ac.locatenew('P', l1 * N.x)
>>> a = ReferenceFrame('a')
>>> a.set_ang_vel(N, qld * N.z)
>>> Ac.v2pt_theory(O, N, a)
ll1*qld*N.y
>>> P.v2pt_theory(O, N, a)
2*ll1*qld*N.y
```
Finally, the bodies that make up the system are created. In this case the system consists of a particle Pa and a RigidBody A.

```python
>>> Pa = Particle('Pa', P, m)
>>> I = outer(N.z, N.z)
>>> A = RigidBody('A', Ac, a, M, (I, Ac))
```

Then one can either choose to evaluate the momenta of individual components of the system or of the entire system itself.

```python
>>> linear_momentum(N, A)
M*l1*q1d*N.y
>>> angular_momentum(O, N, Pa)
4*l1**2*m*q1d*N.z
>>> linear_momentum(N, A, Pa)
(M*l1*q1d + 2*l1*m*q1d)*N.y
>>> angular_momentum(O, N, A, Pa)
(M*l1**2*q1d + 4*l1**2*m*q1d + q1d)*N.z
```

It should be noted that the user can determine either momenta in any frame in `sympy.physics.mechanics` (page 1721) as the user is allowed to specify the reference frame when calling the function. In other words the user is not limited to determining just inertial linear and angular momenta. Please refer to the docstrings on each function to learn more about how each function works precisely.

**Kinetic Energy**

The kinetic energy of a particle P is defined as

\[ T_P = \frac{1}{2}m\mathbf{v}^2 \]

where \( m \) is the mass of the particle P and \( \mathbf{v} \) is the velocity of the particle in the inertial frame.

Similarly the kinetic energy of a rigid body B is defined as

\[ T_B = T_t + T_r \]

where the translational kinetic energy is given by:

\[ T_t = \frac{1}{2}m\mathbf{v}^* \cdot \mathbf{v}^* \]

and the rotational kinetic energy is given by:

\[ T_r = \frac{1}{2}\omega \cdot \mathbf{I}^* \cdot \omega \]

where \( m \) is the mass of the rigid body, \( \mathbf{v}^* \) is the velocity of the mass center in the inertial frame, \( \omega \) is the inertial angular velocity of the body and \( \mathbf{I}^* \) is the central inertia dyadic.
Potential Energy

Potential energy is defined as the energy possessed by a body or system by virtue of its position or arrangement.

Since there are a variety of definitions for potential energy, this is not discussed further here. One can learn more about this in any elementary text book on dynamics.

Lagrangian

The Lagrangian of a body or a system of bodies is defined as:

\[ \mathcal{L} = T - V \]

where \( T \) and \( V \) are the kinetic and potential energies respectively.

Using energy functions in Mechanics

The following example shows how to use the energy functions in `sympy.physics.mechanics` (page 1721).

As was discussed above in the momenta functions, one first creates the system by going through an identical procedure.

```python
>>> from sympy import symbols
>>> from sympy.physics.mechanics import dynamicsymbols, ReferenceFrame, outer
>>> from sympy.physics.mechanics import RigidBody, Particle
>>> m, M, l1, g, h, H = symbols('m M l1 g h H')
>>> omega = dynamicsymbols('omega')
>>> N = ReferenceFrame('N')
>>> O = Point('O')
>>> O.set_vel(N, 0 * N.x)
>>> Ac = O.locatenew('Ac', l1 * N.x)
>>> P = Ac.locatenew('P', l1 * N.x)
>>> a = ReferenceFrame('a')
>>> a.set_ang_vel(N, omega * N.z)
>>> Pa = Particle('Pa', P, m)
>>> I = outer(N.z, N.z)
>>> A = RigidBody('A', Ac, a, M, (I, Ac))
```

The user can then determine the kinetic energy of any number of entities of the system:

```python
>>> kinetic_energy(N, Pa)
2*l1**2*m*omega**2
```
It should be noted that the user can determine either kinetic energy relative to any frame in `sympy.physics.mechanics` as the user is allowed to specify the reference frame when calling the function. In other words the user is not limited to determining just inertial kinetic energy.

For potential energies, the user must first specify the potential energy of every entity of the system using the `sympy.physics.mechanics.rigidbody.RigidBody.potential_energy` property. The potential energy of any number of entities comprising the system can then be determined:

```python
>>> Pa.potential_energy = m * g * h
>>> A.potential_energy = M * g * H
>>> potential_energy(A, Pa)
H*M*g + g*h*m
```

One can also determine the Lagrangian for this system:

```python
>>> from sympy.physics.mechanics import Lagrangian
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> Lagrangian(N, Pa, A)
-H*M*g + M*l1**2*omega**2/2 - g*h*m + 2*l1**2*m*omega**2 + omega**2/2
```

Please refer to the docstrings to learn more about each function.

**Kane’s Method in Physics/Mechanics**

`sympy.physics.mechanics` provides functionality for deriving equations of motion using Kane’s method [Kane1985]. This document will describe Kane’s method as used in this module, but not how the equations are actually derived.

**Structure of Equations**

In `sympy.physics.mechanics` we are assuming there are 5 basic sets of equations needed to describe a system. They are: holonomic constraints, non-holonomic constraints, kinematic differential equations, dynamic equations, and differentiated non-holonomic equations.

\[
\begin{align*}
    f_h(q, t) &= 0 \\
    k_{nh}(q, t)u + f_{nh}(q, t) &= 0 \\
    k_{kq}(q, t)\dot{q} + k_{ku}(q, t)u + f_k(q, t) &= 0 \\
    k_{d}(q, t)\ddot{u} + f_{d}(q, \dot{q}, u, t) &= 0 \\
    k_{dnh}(q, t)\ddot{u} + f_{dnh}(q, \dot{q}, u, t) &= 0
\end{align*}
\]

In `sympy.physics.mechanics` holonomic constraints are only used for the linearization process; it is assumed that they will be too complicated to solve for the dependent coordinate(s). If you are able to easily solve a holonomic constraint, you should consider
redefining your problem in terms of a smaller set of coordinates. Alternatively, the timedifferentiated holonomic constraints can be supplied.

Kane’s method forms two expressions, $F_r$ and $F^*_r$, whose sum is zero. In this module, these expressions are rearranged into the following form:

$$M(q, t)\dot{u} = f(q, \dot{q}, u, t)$$

For a non-holonomic system with $o$ total speeds and $m$ motion constraints, we will get $o - m$ equations. The mass-matrix/forcing equations are then augmented in the following fashion:

$$M(q, t) = \begin{bmatrix}
kd(q, t) \\
K_{dnh}(q, t)
\end{bmatrix}$$

$$(forcing)(q, \dot{q}, u, t) = \begin{bmatrix}
-f_d(q, \dot{q}, u, t) \\
-f_{dnh}(q, \dot{q}, u, t)
\end{bmatrix}$$

### Kane’s Method in Physics/Mechanics

The formulation of the equations of motion in sympy.physics.mechanics (page 1721) starts with creation of a KanesMethod object. Upon initialization of the KanesMethod object, an inertial reference frame needs to be supplied. along with some basic system information, such as coordinates and speeds

```python
>>> from sympy.physics.mechanics import *
>>> N = ReferenceFrame('N')
>>> q1, q2, u1, u2 = dynamicsymbols('q1 q2 u1 u2')
>>> q1d, q2d, u1d, u2d = dynamicsymbols('q1 q2 u1 u2', 1)
>>> KM = KanesMethod(N, [q1, q2], [u1, u2])
```

It is also important to supply the order of coordinates and speeds properly if there are dependent coordinates and speeds. They must be supplied after independent coordinates and speeds or as a keyword argument; this is shown later.

```python
>>> q1, q2, q3, q4 = dynamicsymbols('q1 q2 q3 q4')
>>> u1, u2, u3, u4 = dynamicsymbols('u1 u2 u3 u4')
>>> # Here we will assume q2 is dependent, and u2 and u3 are dependent
>>> # We need the constraint equations to enter them though
>>> KM = KanesMethod(N, [q1, q3, q4], [u1, u4])
```

Additionally, if there are auxiliary speeds, they need to be identified here. See the examples for more information on this. In this example u4 is the auxiliary speed.

```python
>>> KM = KanesMethod(N, [q1, q3, q4], [u1, u2, u3], u_auxiliary=[u4])
```

Kinematic differential equations must also be supplied; there are to be provided as a list of expressions which are each equal to zero. A trivial example follows:

```python
>>> kd = [q1d - u1, q2d - u2]
```

Turning on mechanics_printing() makes the expressions significantly shorter and is recommended. Alternatively, the mprint and mpprint commands can be used.

If there are non-holonomic constraints, dependent speeds need to be specified (and so do dependent coordinates, but they only come into play when linearizing the system). The constraints need to be supplied in a list of expressions which are equal to zero, trivial motion and configuration constraints are shown below:
SymPy Documentation, Release 1.12.1

>>> N = ReferenceFrame('N')
>>> q1, q2, q3, q4 = dynamicsymbols('q1 q2 q3 q4')
>>> q1d, q2d, q3d, q4d = dynamicsymbols('q1 q2 q3 q4', 1)
>>> u1, u2, u3, u4 = dynamicsymbols('u1 u2 u3 u4')
>>> # Here we will assume q2 is dependent, and u2 and u3 are dependent
>>> speed_cons = [u2 - u1, u3 - u1 - u4]
>>> coord_cons = [q2 - q1]
>>> q_ind = [q1, q3, q4]
>>> q_dep = [q2]
>>> u_ind = [u1, u4]
>>> u_dep = [u2, u3]
>>> kd = [q1d - u1, q2d - u2, q3d - u3, q4d - u4]
>>> KM = KanesMethod(N, q_ind, u_ind, kd,
...                 q_dependent=q_dep,
...                 configuration_constraints=coord_cons,
...                 u_dependent=u_dep,
...                 velocity_constraints=speed_cons)

A dictionary returning the solved \( \dot{q} \)'s can also be solved for:

>>> mechanics_printing(pretty_print=False)
>>> KM.kindiffdict()
{q1': u1, q2': u2, q3': u3, q4': u4}

The final step in forming the equations of motion is supplying a list of bodies and particles, and a list of 2-tuples of the form (Point, Vector) or (ReferenceFrame, Vector) to represent applied forces and torques.

>>> N = ReferenceFrame('N')
>>> q, u = dynamicsymbols('q u')
>>> qd, ud = dynamicsymbols('q u', 1)
>>> P = Point('P')
>>> P.set_vel(N, u * N.x)
>>> Pa = Particle('Pa', P, 5)
>>> BL = [Pa]
>>> FL = [(P, 7 * N.x)]
>>> KM = KanesMethod(N, [q], [u], [qd - u])
>>> (fr, frstar) = KM.kanes_equations(BL, FL)
>>> KM.mass_matrix
Matrix([[5]])
>>> KM.forcing
Matrix([[7]])

When there are motion constraints, the mass matrix is augmented by the \( k_{dnh}(q,t) \) matrix, and the forcing vector by the \( f_{dnh}(q,\dot{q},u,t) \) vector.

There are also the “full” mass matrix and “full” forcing vector terms, these include the kinematic differential equations; the mass matrix is of size \((n + o) \times (n + o)\), or square and the size of all coordinates and speeds.

>>> KM.mass_matrix_full
Matrix([[(1, 0),
         [0, 5]]])

(continues on next page)
Exploration of the provided examples is encouraged in order to gain more understanding of the KanesMethod object.

**Lagrange’s Method in Physics/Mechanics**

`sympy.physics.mechanics` (page 1721) provides functionality for deriving equations of motion using Lagrange’s method. This document will describe Lagrange’s method as used in this module, but not how the equations are actually derived.

**Structure of Equations**

In `sympy.physics.mechanics` (page 1721) we are assuming there are 3 basic sets of equations needed to describe a system; the constraint equations, the time differentiated constraint equations and the dynamic equations.

\[
\begin{align*}
    m_c(q,t)\ddot{q} + f_c(q,t) &= 0 \\
    m_{dc}(\dot{q},q,t)\dddot{q} + f_{dc}(\dot{q},q,t) &= 0 \\
    m_d(\dot{q},q,t)\dddot{q} + \nabla_c(q,t)\lambda + f_d(\dot{q},q,t) &= 0
\end{align*}
\]

In this module, the expressions formed by using Lagrange’s equations of the second kind are rearranged into the following form:

\[
M(q,t)x = f(q,\dot{q},t)
\]

where in the case of a system without constraints:

\[
x = \dot{q}
\]

For a constrained system with \( n \) generalized speeds and \( m \) constraints, we will get \( n - m \) equations. The mass-matrix/forcing equations are then augmented in the following fashion:

\[
x = \begin{bmatrix} \dot{q} \\ \lambda \end{bmatrix}
\]

\[
M(q,t) = \begin{bmatrix} m_d(q,t) & \nabla_c(q,t) \end{bmatrix}
\]

\[
F(\dot{q},q,t) = \begin{bmatrix} f_d(\dot{q},q,t) \end{bmatrix}
\]

**Lagrange’s Method in Physics/Mechanics**

The formulation of the equations of motion in `sympy.physics.mechanics` (page 1721) using Lagrange’s Method starts with the creation of generalized coordinates and a Lagrangian. The Lagrangian can either be created with the Lagrangian function or can be a user supplied function. In this case we will supply the Lagrangian.
To formulate the equations of motion we create a LagrangesMethod object. The Lagrangian and generalized coordinates need to be supplied upon initialization.

```python
>>> from sympy.physics.mechanics import *
>>> q1, q2 = dynamicsymbols('q1 q2')
>>> q1d, q2d = dynamicsymbols('q1 q2', 1)
>>> L = q1d**2 + q2d**2
```

With that the equations of motion can be formed.

```python
>>> mechanics_printing(pretty_print=False)
>>> LM = LagrangesMethod(L, [q1, q2])
```

It is possible to obtain the mass matrix and the forcing vector.

```python
>>> LM.mass_matrix
Matrix([ [2, 0], [0, 2]])
```

If there are any holonomic or non-holonomic constraints, they must be supplied as keyword arguments (hol_coneqs and nonhol_coneqs respectively) in a list of expressions which are equal to zero. Modifying the example above, the equations of motion can then be generated:

```python
>>> LM = LagrangesMethod(L, [q1, q2], hol_coneqs=[q1 - q2])
```

When the equations of motion are generated in this case, the Lagrange multipliers are introduced; they are represented by lam1 in this case. In general, there will be as many multipliers as there are constraint equations.

```
>>> LM.form_lagranges_equations()
Matrix([ [lam1 + 2*q1''], [-lam1 + 2*q2'']])
```

Also in the case of systems with constraints, the ‘full’ mass matrix is augmented by the $k_{qc}(q,t)$ matrix, and the forcing vector by the $f_{qc}(q,q,t)$ vector. The ‘full’ mass matrix is of size $(2n + o) \times (2n + o)$, i.e. it’s a square matrix.

```
>>> LM.mass_matrix_full
Matrix([ [1, 0, 0, 0, 0], [0, 1, 0, 0, 0], [0, 0, 2, 0, -1], [0, 0, 0, 1, 0], [0, 0, 0, 0, 1]])
```
If there are any non-conservative forces or moments acting on the system, they must also be supplied as keyword arguments in a list of 2-tuples of the form (Point, Vector) or (ReferenceFrame, Vector) where the Vector represents the non-conservative forces and torques. Along with this 2-tuple, the inertial frame must also be specified as a keyword argument. This is shown below by modifying the example above:

```python
>>> N = ReferenceFrame('N')
>>> P = Point('P')
>>> P.set_vel(N, q1d * N.x)
>>> FL = [(P, 7 * N.x)]
>>> LM = LagrangesMethod(L, [q1, q2], forcelist=FL, frame=N)
>>> LM.form_lagranges_equations()
Matrix([2*q1'' - 7],
[ 2*q2''])
```

Exploration of the provided examples is encouraged in order to gain more understanding of the LagrangesMethod object.

**Joints Framework in Physics/Mechanics**

`sympy.physics.mechanics` (page 1721) provides a joints framework. This system consists of two parts. The first are the joints (page 1818) themselves, which are used to create connections between bodies (page 1802). The second part is the JointsMethod (page 1849), which is used to form the equations of motion. Both of these parts are doing what we can call “book-keeping”: keeping track of the relationships between bodies (page 1802).
Joints in Physics/Mechanics

The general task of the joints (page 1818) is creating kinematic relationships between bodies (page 1802). A joint is generally described as shown in the image below.

As can be seen in this image, each joint needs several objects in order to define the relationships. First off it needs two bodies: the parent body (shown in green) and the child body (shown in blue). The transformation made by the joint is defined between the joint attachments of both bodies. A joint attachment of a body consists of a point and a body-fixed frame. In the parent body the point is called parent_point and the frame parent_interframe. For the child body these are called child_point and child_interframe. For most joints it is the case that when the generalized coordinates are zero, that there is no rotation or translation between the parent and child joint attachments. So the child_point is at the same location as the parent_point and the child_interframe is in the same orientation as the parent_interframe.

For describing the joint transformation the joint generally needs `dynamicsymbols()` (page 1713) for the generalized coordinates and speeds. Some joints like the PinJoint (page 1820), PrismaticJoint (page 1825) also require a joint_axis, which consists of the same components in the parent_interframe and child_interframe. This means that if for example the joint axis is defined in the parent_interframe as $2\hat{p}_x + 4\hat{p}_y + 3\hat{p}_z$, then this will also be $2\hat{c}_x + 4\hat{c}_y + 3\hat{c}_z$ in the child_interframe. Practically this means that in the case of the PinJoint (page 1820), also shown below, the joint_axis is the axis of rotation, with the generalized coordinate $q$ as the angle of rotation and the generalized speed $u$ as the angular velocity.
With the information listed above, the joint defines the following relationships. It first defines the kinematic differential equations, which relate the generalized coordinates to the generalized speeds. Next, it orients the parent and child body with respect to each other. After which it also defines their velocity relationships.

The code below shows the creation of a PinJoint (page 1820) as shown above with arbitrary linked position vectors. In this code the attachment points are set using vectors, which define the attachment point with respect to the body’s mass center. The intermediate frames are not set, so those are the same as the body’s frame.

```python
>>> from sympy.physics.mechanics import *
>>> mechanics_printing(pretty_print=False)
>>> q, u = dynamicsymbols('q, u')
>>> parent = Body('parent')
>>> child = Body('child')
>>> joint = PinJoint(...
...     'hinge', parent, child, coordinates=q, speeds=u,
...     parent_point=3 * parent.frame.x,
...     child_point=-3 * child.frame.x,
...     joint_axis=parent.frame.z)
>>> joint.kdes
Matrix([[u - q']])
>>> joint.parent_point.pos_from(parent.masscenter)
3*parent.frame.x
>>> joint.parent_interframe
parent_frame
>>> joint.joint_axis.express(child.frame)
```
child_frame.z

```python
>>> child.masscenter.pos_from(parent.masscenter)
3*parent_frame.x + 3*child_frame.x
```

```python
>>> child.masscenter.vel(parent.frame)
3*u*child_frame.y
```

### JointsMethod in Physics/Mechanics

After defining the entire system you can use the `JointsMethod` (page 1849) to parse the system and form the equations of motion. In this process the `JointsMethod` (page 1849) only does the “book-keeping” of the joints. It uses another method, like the `KanesMethod` (page 1810), as its backend for forming the equations of motion.

In the code below we form the equations of motion of the single `PinJoint` (page 1820) shown previously.

```python
>>> method = JointsMethod(parent, joint)
>>> method.form_eoms()
Matrix([[-(child_izz + 9*child_mass)*u']])
>>> type(method.method)  # The method working in the backend
<class 'sympy.physics.mechanics.kane.KanesMethod'>
```

### Symbolic Systems in Physics/Mechanics

The `SymbolicSystem` class in physics/mechanics is a location for the pertinent information of a multibody dynamic system. In its most basic form it contains the equations of motion for the dynamic system, however, it can also contain information regarding the loads that the system is subject to, the bodies that the system is comprised of and any additional equations the user feels is important for the system. The goal of this class is to provide a unified output format for the equations of motion that numerical analysis code can be designed around.

### SymbolicSystem Example Usage

This code will go over the manual input of the equations of motion for the simple pendulum that uses the Cartesian location of the mass as the generalized coordinates into `SymbolicSystem`.

The equations of motion are formed in the physics/mechanics/examples. In that spot the variables q1 and q2 are used in place of x and y and the reference frame is rotated 90 degrees.

```python
>>> from sympy import atan, symbols, Matrix
>>> from sympy.physics.mechanics import (dynamicsymbols, ReferenceFrame,
...                                        Particle, Point)
>>> import sympy.physics.mechanics.system as system
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
```

The first step will be to initialize all of the dynamic and constant symbols.
Next step is to define the equations of motion in multiple forms:

1. **Explicit form where the kinematics and dynamics are combined**
   \[ x' = F_1(x, t, r, p) \]

2. **Implicit form where the kinematics and dynamics are combined**
   \[ M_2(x, p)x' = F_2(x, t, r, p) \]

3. **Implicit form where the kinematics and dynamics are separate**
   \[ M_3(q, p)u' = F_3(q, u, t, r, p)q' = G(q, u, t, r, p) \]

where

- \( x \): states, e.g. \([q, u]\)
- \( t \): time
- \( r \): specified (exogenous) inputs
- \( p \): constants
- \( q \): generalized coordinates
- \( u \): generalized speeds
- \( F_1 \): right hand side of the combined equations in explicit form
- \( F_2 \): right hand side of the combined equations in implicit form
- \( F_3 \): right hand side of the dynamical equations in implicit form
- \( M_2 \): mass matrix of the combined equations in implicit form
- \( M_3 \): mass matrix of the dynamical equations in implicit form
- \( G \): right hand side of the kinematical differential equations

Now the reference frames, points and particles will be set up so this information can be passed into `system.SymbolicSystem` in the form of a bodies and loads iterable.
The equations of motion are in the form of a differential algebraic equation (DAE) and DAE solvers need to know which of the equations are the algebraic expressions. This information is passed into SymbolicSystem as a list specifying which rows are the algebraic equations. In this example it is a different row based on the chosen equations of motion format. The row index should always correspond to the mass matrix that is being input to the SymbolicSystem class but will always correspond to the row index of the combined dynamics and kinematics when being accessed from the SymbolicSystem class.

```
>>> alg_con = [2]
>>> alg_con_full = [4]
```

An iterable containing the states now needs to be created for the system. The SymbolicSystem class can determine which of the states are considered coordinates or speeds by passing in the indexes of the coordinates and speeds. If these indexes are not passed in the object will not be able to differentiate between coordinates and speeds.

```
>>> states = (x, y, u, v, lam)
>>> coord_idxs = (0, 1)
>>> speed_idxs = (2, 3)
```

Now the equations of motion instances can be created using the above mentioned equations of motion formats.

```
>>> symsystem1 = system.SymbolicSystem(states, comb_explicit_rhs, ...
... alg_con=alg_con_full, bodies=bodies, ...
... loads=loads)
>>> symsystem2 = system.SymbolicSystem(states, comb_implicit_rhs, ...
... mass_matrix=comb_implicit_mat, ...
... alg_con=alg_con_full, ...
... coord_idxs=coord_idxs)
>>> symsystem3 = system.SymbolicSystem(states, dyn_implicit_rhs, ...
... mass_matrix=dyn_implicit_mat, ...
... coordinate_derivatives=kin_explicit_, ...
... rhs, ...
... alg_con=alg_con, ...
... coord_idxs=coord_idxs, ...
... speed_idxs=speed_idxs)
```

Like coordinates and speeds, the bodies and loads attributes can only be accessed if they are specified during initialization of the SymbolicSystem class. Lastly here are some attributes accessible from the SymbolicSystem class.

```
>>> symsystem1.states
Matrix([[x],
        [y],
        [u],
        [v],
        [lambda]])
>>> symsystem2.coordinates
Matrix([[x],
        [y]])
>>> symsystem3.speeds
```

(continues on next page)
Matrix([u],
[v]))

>>> sysystem1.comb_explicit_rhs
Matrix([u],
[v],
[(-g*y + u**2 + v**2)*x/l**2],
[(-g*y + u**2 + v**2)*y/l**2],
[m*(-g*y + u**2 + v**2)/l**2])

>>> sysystem2.comb_implicit_rhs
Matrix([u],
v],
[0],
[0],
[-g*y + u**2 + v**2]])

>>> sysystem2.comb_implicit_mat
Matrix([1, 0, 0, 0, 0],
[0, 1, 0, 0, 0],
[0, 0, 1, 0, -x/m],
[0, 0, 0, 1, -y/m],
[0, 0, 0, 0, l**2/m])

>>> sysystem3.dyn_implicit_rhs
Matrix([0],
[0],
[-g*y + u**2 + v**2]])

>>> sysystem3.dyn_implicit_mat
Matrix([1, 0, -x/m],
[0, 1, -y/m],
[0, 0, l**2/m])

>>> sysystem3.kin_explicit_rhs
Matrix([u],
[v]])

>>> sysystem1.alg_con
[4]

>>> sysystem1.bodies
(Pa,)

>>> sysystem1.loads
((P, g*m*N.x),)
Linearization in Physics/Mechanics

`sympy.physics.mechanics` (page 1721) includes methods for linearizing the generated equations of motion (EOM) about an operating point (also known as the trim condition). Note that this operating point doesn’t have to be an equilibrium position, it just needs to satisfy the equations of motion.

Linearization is accomplished by taking the first order Taylor expansion of the EOM about the operating point. When there are no dependent coordinates or speeds this is simply the jacobian of the right hand side about $q$ and $u$. However, in the presence of constraints more care needs to be taken. The linearization methods provided here handle these constraints correctly.

Background

In `sympy.physics.mechanics` (page 1721) we assume all systems can be represented in the following general form:

\[
\begin{align*}
    f_c(q, t) &= 0_{l \times 1} \\
    f_v(q, u, t) &= 0_{m \times 1} \\
    f_a(q, \dot{q}, u, \dot{u}, t) &= 0_{m \times 1} \\
    f_0(q, \dot{q}, t) + f_1(q, u, t) &= 0_{n \times 1} \\
    f_2(q, u, \dot{u}, t) + f_3(q, \dot{q}, u, r, t) + f_4(q, \lambda, t) &= 0_{(o-m+k) \times 1}
\end{align*}
\]

where

\[
\begin{align*}
    q, \dot{q} &\in \mathbb{R}^n \\
    u, \dot{u} &\in \mathbb{R}^o \\
    r &\in \mathbb{R}^s \\
    \lambda &\in \mathbb{R}^k
\end{align*}
\]

In this form,

- $f_c$ represents the configuration constraint equations
- $f_v$ represents the velocity constraint equations
- $f_a$ represents the acceleration constraint equations
- $f_0$ and $f_1$ form the kinematic differential equations
- $f_2$, $f_3$, and $f_4$ form the dynamic differential equations
- $q$ and $\dot{q}$ are the generalized coordinates and their derivatives
- $u$ and $\dot{u}$ are the generalized speeds and their derivatives
- $r$ is the system inputs
- $\lambda$ is the Lagrange multipliers

This generalized form is held inside the Linearizer class, which performs the actual linearization. Both KanesMethod and LagrangesMethod objects have methods for forming the linearizer using the to_linearizer class method.
A Note on Dependent Coordinates and Speeds

If the system being linearized contains constraint equations, this results in not all generalized coordinates being independent (i.e. $q_1$ may depend on $q_2$). With $l$ configuration constraints, and $m$ velocity constraints, there are $l$ dependent coordinates and $m$ dependent speeds.

In general, you may pick any of the coordinates and speeds to be dependent, but in practice some choices may result in undesirable singularities. Methods for deciding which coordinates/speeds to make dependent is behind the scope of this guide. For more information, please see [Blajer1994].

Once the system is coerced into the generalized form, the linearized EOM can be solved for. The methods provided in `sympy.physics.mechanics` (page 1721) allow for two different forms of the linearized EOM:

**M, A, and B**

In this form, the forcing matrix is linearized into two separate matrices $A$ and $B$. This is the default form of the linearized EOM. The resulting equations are:

$$
M \begin{bmatrix}
\delta \dot{q} \\
\delta \dot{u} \\
\delta \lambda 
\end{bmatrix} = A \begin{bmatrix}
\delta q_i \\
\delta u_i 
\end{bmatrix} + B \begin{bmatrix}
\delta r 
\end{bmatrix}
$$

where

$$
M \in \mathbb{R}^{(n+o+k) \times (n+o+k)}
$$

$$
A \in \mathbb{R}^{(n+o+k) \times (n-l+o-m)}
$$

$$
B \in \mathbb{R}^{(n+o+k) \times s}
$$

Note that $q_i$ and $u_i$ are just the independent coordinates and speeds, while $q$ and $u$ contains both the independent and dependent coordinates and speeds.

**A and B**

In this form, the linearized EOM are brought into explicit first order form, in terms of just the independent coordinates and speeds. This form is often used in stability analysis or control theory. The resulting equations are:

$$
\begin{bmatrix}
\delta q_i \\
\delta u_i 
\end{bmatrix} = A \begin{bmatrix}
\delta q_i \\
\delta u_i 
\end{bmatrix} + B \begin{bmatrix}
\delta r 
\end{bmatrix}
$$

where

$$
A \in \mathbb{R}^{(n-l+o-m) \times (n-l+o-m)}
$$

$$
B \in \mathbb{R}^{(n-l+o-m) \times s}
$$

To use this form set `A_and_B=True` in the `linearize` class method.
Linearizing Kane’s Equations

After initializing the KanesMethod object and forming $F_r$ and $F^*_r$ using the kanes_equations class method, linearization can be accomplished in a couple ways. The different methods will be demonstrated with a simple pendulum system:

```python
from sympy import symbols, Matrix
from sympy.physics.mechanics import *

q1 = dynamicsymbols('q1')  # Angle of pendulum
u1 = dynamicsymbols('u1')  # Angular velocity
q1d = dynamicsymbols('q1', 1)
L, m, t, g = symbols('L, m, t, g')

# Compose world frame
N = ReferenceFrame('N')
pN = Point('N*')
pN.set_vel(N, 0)

# A.x is along the pendulum
A = N.orientnew('A', 'axis', [q1, N.z])
A.set_ang_vel(N, u1*N.z)

# Locate point P relative to the origin N*
P = pN.locatenew('P', L*A.x)
vel_P = P.v2pt_theory(pN, N, A)
pP = Particle('pP', P, m)

# Create Kinematic Differential Equations
kde = Matrix([q1d - u1])

# Input the force resultant at P
R = m*g*N.x

# Solve for eom with kanes method
KM = KanesMethod(N, q_ind=[q1], u_ind=[u1], kd_eqs=kde)
fr, frstar = KM.kanes_equations([pP], [(P, R)])
```

1. Using the Linearizer class directly:

A linearizer object can be created using the to_linearizer class method. This coerces the representation found in the KanesMethod object into the generalized form described above. As the independent and dependent coordinates and speeds are specified upon creation of the KanesMethod object, there is no need to specify them here.

```python
linearizer = KM.to_linearizer()
```

The linearized EOM can then be formed with the linearize method of the Linearizer object:

```python
M, A, B = linearizer.linearize()
```
Alternatively, the $A$ and $B$ form can be generated instead by specifying `A_and_B=True`:

```python
>>> A, B = linearizer.linearize(A_and_B=True)
>>> A
Matrix([[-g*cos(q1(t))/L, 0]])
>>> B
Matrix(0, 0, [])
```

An operating point can also be specified as a dictionary or an iterable of dictionaries. This will evaluate the linearized form at the specified point before returning the matrices:

```python
>>> op_point = {q1: 0, u1: 0}
>>> A_op, B_op = linearizer.linearize(A_and_B=True, op_point=op_point)
>>> A_op
Matrix([[-g/L, 0]])
```

Note that the same effect can be had by applying `msubs` to the matrices generated without the `op_point` kwarg:

```python
>>> assert msubs(A, op_point) == A_op
```

Sometimes the returned matrices may not be in the most simplified form. Simplification can be performed after the fact, or the `Linearizer` object can be made to perform simplification internally by setting the `simplify` kwarg to `True`.

### 2. Using the `linearize` class method:

The `linearize` method of the `KanesMethod` class is provided as a nice wrapper that calls `to_linearizer` internally, performs the linearization, and returns the result. Note that all the kwargs available in the `linearize` method described above are also available here:

```python
>>> A, B, inp_vec = KM.linearize(A_and_B=True, op_point=op_point, new_...method=True)
>>> A
Matrix([[0, 1], [-g/L, 0]])
```

The additional output `inp_vec` is a vector containing all found dynamicsymbols not included in the generalized coordinate or speed vectors. These are assumed to be inputs to the system,
forming the $r$ vector described in the background above. In this example there are no inputs, so the vector is empty:

```python
>>> inp_vec
Matrix(0, 0, [])
```

**What’s with the `new_method` kwarg?**

Previous releases of SymPy contained a linearization method for `KanesMethod` objects. This method is deprecated, and will be removed from future releases. Until then, you must set `new_method=True` in all calls to `KanesMethod.linearize`. After the old method is removed, this kwarg will no longer be needed.

**Linearizing Lagrange’s Equations**

Linearization of Lagrange’s equations proceeds much the same as that of Kane’s equations. As before, the process will be demonstrated with a simple pendulum system:

```python
>>> # Redefine A and P in terms of q1d, not u1
>>> A = N.orientnew('A', 'axis', [q1, N.z])
>>> A.set_ang_vel(N, q1d*N.z)
>>> P = pN.locatenew('P', L*A.x)
>>> vel_P = P.v2pt_theory(pN, N, A)
>>> pP = Particle('pP', P, m)

>>> # Solve for eom with Lagrange's method
>>> Lag = Lagrangian(N, pP)
>>> LM = LagrangesMethod(Lag, [q1], forcelist=[(P, R)], frame=N)
>>> lag_eqs = LM.form_lagranges_equations()
```

1. **Using the Linearizer class directly:**

A `Linearizer` object can be formed from a `LagrangesMethod` object using the `to_linearizer` class method. The only difference between this process and that of the `KanesMethod` class is that the `LagrangesMethod` object doesn’t already have its independent and dependent coordinates and speeds specified internally. These must be specified in the call to `to_linearizer`. In this example there are no dependent coordinates and speeds, but if there were they would be included in the `q_dep` and `qd_dep` kwargs:

```python
>>> linearizer = LM.to_linearizer(q_ind=[q1], qd_ind=[q1d])
```

Once in this form, everything is the same as it was before with the `KanesMethod` example:

```python
>>> A, B = linearizer.linearize(A_and_B=True, op_point=op_point)
>>> A
Matrix([[ 0, 1],
        [-g/L, 0]])
```
2. Using the `linearize` class method:

Similar to KanesMethod, the LagrangesMethod class also provides a `linearize` method as a nice wrapper that calls to `linearizer` internally, performs the linearization, and returns the result. As before, the only difference is that the independent and dependent coordinates and speeds must be specified in the call as well:

```python
>>> A, B, inp_vec = LM.linearize(q_ind=[q1], qd_ind=[q1d], A_and_B=True, op_point=op_point)
```

**Potential Issues**

While the `Linearizer` class should be able to linearize all systems, there are some potential issues that could occur. These are discussed below, along with some troubleshooting tips for solving them.

1. **Symbolic linearization with A_and_B=True is slow**

This could be due to a number of things, but the most likely one is that solving a large linear system symbolically is an expensive operation. Specifying an operating point will reduce the expression size and speed this up. If a purely symbolic solution is desired though (for application of many operating points at a later period, for example) a way to get around this is to evaluate with A_and_B=False, and then solve manually after applying the operating point:

```python
>>> M, A, B = linearizer.linearize()
>>> M_op = msubs(M, op_point)
>>> A_op = msubs(A, op_point)
>>> perm_mat = linearizer.perm_mat
>>> A_lin = perm_mat.T * M_op.LUsolve(A_op)
```

The fewer symbols in A and M before solving, the faster this solution will be. Thus, for large expressions, it may be to your benefit to delay conversion to the A and B form until most symbols are subbed in for their numeric values.
2. The linearized form has \texttt{nan}, \texttt{zoo}, or \texttt{oo} as matrix elements

There are two potential causes for this. The first (and the one you should check first) is that some choices of dependent coordinates will result in singularities at certain operating points. Coordinate partitioning in a systemic manner to avoid this is beyond the scope of this guide; see [Blajer1994] for more information.

The other potential cause for this is that the matrices may not have been in the most reduced form before the operating point was substituted in. A simple example of this behavior is:

```python
>>> from sympy import sin, tan
>>> expr = sin(q1)/tan(q1)
>>> op_point = {q1: 0}
>>> expr.subs(op_point)
nan
```

Note that if this expression was simplified before substitution, the correct value results:

```python
>>> expr.simplify().subs(op_point)
1
```

A good way of avoiding this hasn’t been found yet. For expressions of reasonable size, using \texttt{msubs} with \texttt{smart=True} will apply an algorithm that tries to avoid these conditions. For large expressions though this is extremely time consuming.

```python
>>> msubs(expr, op_point, smart=True)
1
```

Further Examples

The pendulum example used above was simple, but didn’t include any dependent coordinates or speeds. For a more thorough example, the same pendulum was linearized with dependent coordinates using both Kane’s and Lagrange’s methods:

Nonminimal Coordinates Pendulum

In this example we demonstrate the use of the functionality provided in \texttt{sympy.physics.mechanics} (page 1721) for deriving the equations of motion (EOM) for a pendulum with a nonminimal set of coordinates. As the pendulum is a one degree of freedom system, it can be described using one coordinate and one speed (the pendulum angle, and the angular velocity respectively). Choosing instead to describe the system using the \texttt{x} and \texttt{y} coordinates of the mass results in a need for constraints. The system is shown below:
The system will be modeled using both Kane’s and Lagrange’s methods, and the resulting EOM linearized. While this is a simple problem, it should illustrate the use of the linearization methods in the presence of constraints.

**Kane’s Method**

First we need to create the `dynamicsymbols` needed to describe the system as shown in the above diagram. In this case, the generalized coordinates \( q_1 \) and \( q_2 \) represent the mass \( x \) and \( y \) coordinates in the inertial \( N \) frame. Likewise, the generalized speeds \( u_1 \) and \( u_2 \) represent the velocities in these directions. We also create some symbols to represent the length and mass of the pendulum, as well as gravity and time.

```python
>>> from sympy.physics.mechanics import *
>>> from sympy import symbols, atan, Matrix, solve
>>> # Create generalized coordinates and speeds for this non-minimal realization
>>> # q1, q2 = N.x and N.y coordinates of pendulum
>>> # u1, u2 = N.x and N.y velocities of pendulum
>>> q1, q2 = dynamicsymbols('q1:3')
>>> q1d, q2d = dynamicsymbols('q1:3', level=1)
>>> u1, u2 = dynamicsymbols('u1:3')
>>> u1d, u2d = dynamicsymbols('u1:3', level=1)
>>> L, m, g, t = symbols('L, m, g, t')
```
Next, we create a world coordinate frame \( N \), and its origin point \( N^* \). The velocity of the origin is set to 0. A second coordinate frame \( A \) is oriented such that its x-axis is along the pendulum (as shown in the diagram above).

```python
>>> # Compose world frame
>>> N = ReferenceFrame('N')
>>> pN = Point('N*')
>>> pN.set_vel(N, 0)

>>> # A.x is along the pendulum
>>> theta1 = atan(q2/q1)
>>> A = N.orientnew('A', 'axis', [theta1, N.z])
```

Locating the pendulum mass is then as easy as specifying its location with in terms of its x and y coordinates in the world frame. A \texttt{Particle} object is then created to represent the mass at this location.

```python
>>> # Locate the pendulum mass
>>> P = pN.locatenew('P1', q1*N.x + q2*N.y)
>>> pP = Particle('pP', P, m)
```

The kinematic differential equations (KDEs) relate the derivatives of the generalized coordinates to the generalized speeds. In this case the speeds are the derivatives, so these are simple. A dictionary is also created to map \( \dot{q} \) to \( u \):

```python
>>> # Calculate the kinematic differential equations
>>> kde = Matrix([q1d - u1,
...                q2d - u2])
>>> dq_dict = solve(kde, [q1d, q2d])
```

The velocity of the mass is then the time derivative of the position from the origin \( N^* \):

```python
>>> # Set velocity of point P
>>> P.set_vel(N, P.pos_from(pN).dt(N).subs(dq_dict))
```

As this system has more coordinates than degrees of freedom, constraints are needed. The configuration constraints relate the coordinates to each other. In this case the constraint is that the distance from the origin to the mass is always the length \( L \) (the pendulum doesn’t get longer). Likewise, the velocity constraint is that the mass velocity in the \( A.x \) direction is always 0 (no radial velocity).

```python
>>> f_c = Matrix([P.pos_from(pN).magnitude() - L])
>>> f_v = Matrix([P.vel(N).express(A).dot(A.x)])
>>> f_v.simplify()
```

The force on the system is just gravity, at point \( P \).

```python
>>> # Input the force resultant at P
>>> R = m*g*N.x
```

With the problem setup, the equations of motion can be generated using the \texttt{KanesMethod} class. As there are constraints, dependent and independent coordinates need to be provided to the class. In this case we’ll use \( q_2 \) and \( u_2 \) as the independent coordinates and speeds:
Derive the equations of motion using the KanesMethod class.

```python
KM = KanesMethod(N, q_ind=[q2], u_ind=[u2], q_dependent=[q1],
...  u_dependent=[u1], configuration_constraints=f_c,
...  velocity_constraints=f_v, kd_eqs=kde)
```

```python
(fr, frstar) = KM.kanes_equations([pP], [(P, R)])
```

For linearization, operating points can be specified on the call, or be substituted in afterwards. In this case we’ll provide them in the call, supplied in a list. The `A_and_B=True` kwarg indicates to solve invert the $M$ matrix and solve for just the explicit linearized $A$ and $B$ matrices. The `simplify=True` kwarg indicates to simplify inside the linearize call, and return the presimplified matrices. The cost of doing this is small for simple systems, but for larger systems this can be a costly operation, and should be avoided.

```python
q_op = {q1: L, q2: 0}
u_op = {u1: 0, u2: 0}
ud_op = {u1d: 0, u2d: 0}
```

```python
A, B, inp_vec = KM.linearize(op_point=[q_op, u_op, ud_op], A_and_B=True,
...  new_method=True, simplify=True)
```

```python
A
Matrix([0, 1], [-g/L, 0])
```

```python
B
Matrix(0, 0, [])
```

The resulting $A$ matrix has dimensions 2 x 2, while the number of total states is $\text{len}(q) + \text{len}(u) = 2 + 2 = 4$. This is because for constrained systems the resulting $A$ and $B$ form has a partitioned state vector only containing the independent coordinates and speeds. Written out mathematically, the system linearized about this point would be written as:

\[
\begin{bmatrix}
q_2 \\
u_2
\end{bmatrix} =
\begin{bmatrix}
0 & 1 \\
-\frac{g}{L} & 0
\end{bmatrix}
\begin{bmatrix}
q_2 \\
u_2
\end{bmatrix}
\]

### Lagrange’s Method

The derivation using Lagrange’s method is very similar to the approach using Kane’s method described above. As before, we first create the dynamicsymbols needed to describe the system. In this case, the generalized coordinates $q_1$ and $q_2$ represent the mass $x$ and $y$ coordinates in the inertial $N$ frame. This results in the time derivatives $\dot{q}_1$ and $\dot{q}_2$ representing the velocities in these directions. We also create some symbols to represent the length and mass of the pendulum, as well as gravity and time.

```python
from sympy.physics.mechanics import *
from sympy import symbols, atan, Matrix
```

```python
q1, q2 = dynamicsymbols('q1:3')
q1d, q2d = dynamicsymbols('q1:3', level=1)
```

Next, we create a world coordinate frame $N$, and its origin point $N^*$. The velocity of the origin is set to 0. A second coordinate frame $A$ is oriented such that its $x$-axis is along the pendulum (as shown in the diagram above).

5.8. Topics

1749
Locating the pendulum mass is then as easy as specifying its location with in terms of its x and y coordinates in the world frame. A `Particle` object is then created to represent the mass at this location.

As this system has more coordinates than degrees of freedom, constraints are needed. In this case only a single holonomic constraints is needed: the distance from the origin to the mass is always the length $L$ (the pendulum doesn’t get longer).

The force on the system is just gravity, at point P.

With the problem setup, the Lagrangian can be calculated, and the equations of motion formed. Note that the call to `LagrangesMethod` includes the Lagrangian, the generalized coordinates, the constraints (specified by `hol_coneqs` or `nonhol_coneqs`), the list of (body, force) pairs, and the inertial frame. In contrast to the `KanesMethod` initializer, independent and dependent coordinates are not partitioned inside the `LagrangesMethod` object. Such a partition is supplied later.

Next, we compose the operating point dictionary, set in the hanging at rest position:

As there are constraints in the formulation, there will be corresponding Lagrange Multipliers. These may appear inside the linearized form as well, and thus should also be included inside the operating point dictionary. Fortunately, the `LagrangesMethod` class provides an easy way of solving for the multipliers at a given operating point using the `solve_multipliers` method.
With this solution, linearization can be completed. Note that in contrast to the `KanesMethod` approach, the `LagrangesMethod.linearize` method also requires the partitioning of the generalized coordinates and their time derivatives into independent and dependent vectors. This is the same as what was passed into the `KanesMethod` constructor above:

```python
>>> op_point.update(lam_op)
>>> # Perform the Linearization
>>> A, B, inp_vec = LM.linearize([q2], [q2d], [q1], [q1d],
...                            op_point=op_point, A_and_B=True)
>>> A
Matrix([[0, 1],
        [-g/L, 0]])
>>> B
Matrix(0, 0, [])
```

The resulting $A$ matrix has dimensions 2 x 2, while the number of total states is $2 \times \text{len}(q) = 4$. This is because for constrained systems the resulting $A$ and $B$ form has a partitioned state vector only containing the independent coordinates and their derivatives. Written out mathematically, the system linearized about this point would be written as:

$$
\begin{bmatrix}
\dot{q}_2 \\
\ddot{q}_2
\end{bmatrix} =
\begin{bmatrix}
0 & 1 \\
\frac{-g}{L} & 0
\end{bmatrix}
\begin{bmatrix}
q_2 \\
\dot{q}_2
\end{bmatrix}
$$

**Examples for Physics/Mechanics**

Here are some examples that illustrate how one typically uses this module. We have ordered the examples roughly according to increasing difficulty. If you have used this module to do something others might find useful or interesting, consider adding it here!

**A rolling disc**

The disc is assumed to be infinitely thin, in contact with the ground at only 1 point, and it is rolling without slip on the ground. See the image below.
We model the rolling disc in three different ways, to show more of the functionality of this module.

**A rolling disc, with Kane’s method**

Here the definition of the rolling disc’s kinematics is formed from the contact point up, removing the need to introduce generalized speeds. Only 3 configuration and three speed variables are need to describe this system, along with the disc’s mass and radius, and the local gravity (note that mass will drop out).

```python
from sympy import symbols, sin, cos, tan
from sympy.physics.mechanics import *
q1, q2, q3, u1, u2, u3 = dynamicsymbols('q1 q2 q3 u1 u2 u3')
q1d, q2d, q3d, u1d, u2d, u3d = dynamicsymbols('q1 q2 q3 u1 u2 u3', 1)
r, m, g = symbols('r m g')
mechanics_printing(pretty_print=False)
```

The kinematics are formed by a series of simple rotations. Each simple rotation creates a new frame, and the next rotation is defined by the new frame’s basis vectors. This example uses a 3-1-2 series of rotations, or Z, X, Y series of rotations. Angular velocity for this is defined using the second frame’s basis (the lean frame); it is for this reason that we defined intermediate frames, rather than using a body-three orientation.

```python
N = ReferenceFrame('N')
Y = N.orientnew('Y', 'Axis', [q1, N.z])
L = Y.orientnew('L', 'Axis', [q2, Y.x])
R = L.orientnew('R', 'Axis', [q3, L.y])
w_R_N_qd = R.ang_vel_in(N)
R.set_ang_vel(N, u1 * L.x + u2 * L.y + u3 * L.z)
```
This is the translational kinematics. We create a point with no velocity in N; this is the contact point between the disc and ground. Next we form the position vector from the contact point to the disc’s center of mass. Finally we form the velocity and acceleration of the disc.

```python
>>> C = Point('C')
>>> C.set_vel(N, 0)
>>> Dmc = C.locatenew('Dmc', r * L.z)
>>> Dmc.v2pt_theory(C, N, R)
r*u2*L.x - r*u1*L.y
```

This is a simple way to form the inertia dyadic. The inertia of the disc does not change within the lean frame as the disc rolls; this will make for simpler equations in the end.

```python
>>> I = inertia(L, m / 4 * r**2, m / 2 * r**2, m / 4 * r**2)
>>> mprint(I)
m*r**2/4*(L.x|L.x) + m*r**2/2*(L.y|L.y) + m*r**2/4*(L.z|L.z)
```

Kinematic differential equations; how the generalized coordinate time derivatives relate to generalized speeds.

```python
>>> kd = [dot(R.ang_vel_in(N) - w_R.N_qd, uv) for uv in L]
```

Creation of the force list; it is the gravitational force at the center of mass of the disc. Then we create the disc by assigning a Point to the center of mass attribute, a ReferenceFrame to the frame attribute, and mass and inertia. Then we form the body list.

```python
>>> ForceList = [(Dmc, - m * g * Y.z)]
>>> BodyD = RigidBody('BodyD', Dmc, R, m, (I, Dmc))
>>> BodyList = [BodyD]
```

Finally we form the equations of motion, using the same steps we did before. Specify inertial frame, supply generalized coordinates and speeds, supply kinematic differential equation dictionary, compute Fr from the force list and Fr* from the body list, compute the mass matrix and forcing terms, then solve for the u dots (time derivatives of the generalized speeds).

```python
>>> KM = KanesMethod(N, q_ind=[q1, q2, q3], u_ind=[u1, u2, u3], kd_eqs=kd)
>>> (fr, frstar) = KM.kanes_equations(BodyList, ForceList)
>>> MM = KM.mass_matrix
>>> forcing = KM.forcing
>>> rhs = MM.inv() * forcing
>>> kdd = KM.kindiffdict()
>>> rhs = rhs.subs(kdd)
>>> rhs.simplify()
>>> mprint(rhs)
Matrix([[(4*g*sin(q2) + 6*r*u2*u3 - r*u3**2*tan(q2))/(5*r)],
       [-2*u1*u3/3],
       [-2*u2 + u3*tan(q2)*u1]])
```
A rolling disc, with Kane’s method and constraint forces

We will now revisit the rolling disc example, except this time we are bringing the non-contributing (constraint) forces into evidence. See [Kane1985] for a more thorough explanation of this. Here, we will turn on the automatic simplification done when doing vector operations. It makes the outputs nicer for small problems, but can cause larger vector operations to hang.

```python
>>> from sympy import symbols, sin, cos, tan
>>> from sympy.physics.mechanics import *
>>> mechanics_printing(pretty_print=False)
>>> q1, q2, q3, u1, u2, u3 = dynamicsymbols('q1 q2 q3 u1 u2 u3')
>>> q1d, q2d, q3d, u1d, u2d, u3d = dynamicsymbols('q1 q2 q3 u1 u2 u3', 1)
>>> r, m, g = symbols('r m g')
```

These two lines introduce the extra quantities needed to find the constraint forces.

```python
>>> u4, u5, u6, f1, f2, f3 = dynamicsymbols('u4 u5 u6 f1 f2 f3')
```

Most of the main code is the same as before.

```python
>>> N = ReferenceFrame('N')
>>> Y = N.orientnew('Y', 'Axis', [q1, N.z])
>>> L = Y.orientnew('L', 'Axis', [q2, Y.x])
>>> R = L.orientnew('R', 'Axis', [q3, L.y])
>>> w_R_N_qd = R.ang_vel_in(N)
>>> R.set_ang_vel(N, u1 * L.x + u2 * L.y + u3 * L.z)
```

The definition of rolling without slip necessitates that the velocity of the contact point is zero; as part of bringing the constraint forces into evidence, we have to introduce speeds at this point, which will by definition always be zero. They are normal to the ground, along the path which the disc is rolling, and along the ground in a perpendicular direction.

```python
>>> C = Point('C')
>>> C.set_vel(N, u4 * L.x + u5 * cross(Y.z, L.x) + u6 * Y.z)
>>> Dmc = C.locatenew('Dmc', r * L.z)
>>> vel = Dmc.v2pt_theory(C, N, R)
>>> I = inertia(L, m / 4 * r**2, m / 2 * r**2, m / 4 * r**2)
>>> kd = [dot(R.ang_vel_in(N) - w_R_N_qd, uv) for uv in L]
```

Just as we previously introduced three speeds as part of this process, we also introduce three forces; they are in the same direction as the speeds, and represent the constraint forces in those directions.

```python
>>> ForceList = [(Dmc, - m * g * Y.z), (C, f1 * L.x + f2 * cross(Y.z, L.x) + u1 * f3 * Y.z)]
>>> BodyD = RigidBody('BodyD', Dmc, R, m, (I, Dmc))
>>> BodyList = [BodyD]
>>> KM = KanesMethod(N, q_ind=[q1, q2, q3], u_ind=[u1, u2, u3], kd_eqs=kd, ...
       u_auxiliary=[u4, u5, u6])
>>> (fr, frstar) = KM.kanes_equations(BodyList, ForceList)
>>> MM = KM.mass_matrix
>>> forcing = KM.forcing
```
\[\text{rhs} = \text{MM}.\text{inv()} \times \text{forcing}\]
\[\text{kdd} = \text{KM}.\text{kindiffdict()}
\[\text{rhs} = \text{rhs}.\text{subs(kdd)}
\[\text{rhs}.\text{simplify()}
\[\text{mprint(rhs)}
\begin{bmatrix}
(4g \sin(q2) + 6r u2 u3 - r u3^2 \tan(q2))/(5r)],
\[-2u1 u3/3],
\[-(2u2 + u3 \tan(q2)) u1]]
\end{bmatrix}
\]

from sympy import trigsimp, signsimp, collect, factor_terms

def simplify_auxiliary_eqs(w):
... return signsimp(trigsimp(collect(collect(factor_terms(w), f2), m*r)))

mprint(KM.auxiliary_eqs.applyfunc(simplify_auxiliary_eqs))
\begin{bmatrix}
-mr(u1 u3 + u2') + f1,
-mr u1 u2 u3/cos(q2) + m r cos(q2) u1' + f2,
-g m + m r(u1 u2 u3/cos(q2) + sin(q2) u1') + f3]
\end{bmatrix}

A rolling disc using Lagrange’s Method

Here the rolling disc is formed from the contact point up, removing the need to introduce
generalized speeds. Only 3 configuration and 3 speed variables are needed to describe this
system, along with the disc’s mass and radius, and the local gravity.

from sympy import symbols, cos, sin
from sympy.physics.mechanics import *
m Mechanics_printing(pretty_print=False)
q1, q2, q3 = dynamicsymbols('q1 q2 q3')
q1d, q2d, q3d = dynamicsymbols('q1 q2 q3', 1)
r, m, g = symbols('r m g')

The kinematics are formed by a series of simple rotations. Each simple rotation creates a new
frame, and the next rotation is defined by the new frame’s basis vectors. This example uses
a 3-1-2 series of rotations, or Z, X, Y series of rotations. Angular velocity for this is defined
using the second frame’s basis (the lean frame).

N = ReferenceFrame('N')
Y = N.orientnew('Y', 'Axis', [q1, N.z])
L = Y.orientnew('L', 'Axis', [q2, Y.x])
R = L.orientnew('R', 'Axis', [q3, L.y])

This is the translational kinematics. We create a point with no velocity in N; this is the contact
point between the disc and ground. Next we form the position vector from the contact point
to the disc’s center of mass. Finally we form the velocity and acceleration of the disc.

C = Point('C')
C.set_vel(N, 0)
Dmc = C.locatenew('Dmc', r * L.z)
Dmc.v2pt_theory(C, N, R)
r*(sin(q2)*q1' + q3')*L.x - r*q2'*L.y

Forming the inertia dyadic.

5.8. Topics 1755
We then set the potential energy and determine the Lagrangian of the rolling disc.

```python
>>> BodyD.potential_energy = - m * g * r * cos(q2)
>>> Lag = Lagrangian(N, BodyD)
```

Then the equations of motion are generated by initializing the LagrangesMethod object. Finally we solve for the generalized accelerations (q double dots) with the rhs method.

```python
>>> q = [q1, q2, q3]
>>> l = LagrangesMethod(Lag, q)
>>> le = l.form_lagranges_equations()
>>> le.simplify(); le
Matrix([m*r**2*(6*sin(q2)*q3'' + 5*sin(2*q2)*q1'*q2' + 6*cos(q2)*q2'*q3' + 5*cos(2*q2)*q1''/2 + 7*q1''/2)/4], [m*r*(4*g*sin(q2) - 5*r*sin(2*q2)*q1''/2 - 6*r*cos(q2)*q1'*q3' + 5*r*q2'')/4], [3*m*r**2*(sin(q2)*q1'' + cos(q2)*q1'*q2' + q3'')/2])

```

### A bicycle

The bicycle is an interesting system in that it has multiple rigid bodies, non-holonomic constraints, and a holonomic constraint. The linearized equations of motion are presented in [Meijaard2007]. This example will go through construction of the equations of motion in `sympy.physics.mechanics` (page 1721).

```python
>>> from sympy import *
>>> from sympy.physics.mechanics import *
>>> print('Calculation of Linearized Bicycle "A" Matrix, 
... 'with States: Roll, Steer, Roll Rate, Steer Rate')
Calculation of Linearized Bicycle "A" Matrix, with States: Roll, Steer, Roll Rate, Steer Rate
```

Note that this code has been crudely ported from Autolev, which is the reason for some of the unusual naming conventions. It was purposefully as similar as possible in order to aid initial porting & debugging. We set Vector.simp to False (in case it has been set True elsewhere), since it slows down the computations:
宣誓 Declaration of Coordinates & Speeds: A simple definition for qdots, \( q_d = u \), is used in this code. Speeds are: yaw frame ang. rate, roll frame ang. rate, rear wheel frame ang. rate (spinning motion), frame ang. rate (pitching motion), steering frame ang. rate, and front wheel ang. rate (spinning motion). Wheel positions are ignorable coordinates, so they are not introduced.

```python
>>> q1, q2, q3, q4, q5 = dynamicsymbols('q1 q2 q3 q4 q5')
>>> q1d, q2d, q4d, q5d = dynamicsymbols('q1 q2 q4 q5', 1)
```

Declaration of System’s Parameters: The below symbols should be fairly self-explanatory.

```python
>>> WRad, WRrad, htangle, forkoffset = symbols('WRad WRrad htangle _forkoffset')
>>> forklength, framelength, forkcg1 = symbols('forklength framelength forkcg1 _Iwr11')
>>> forkcg3, framecg1, framecg3, Iwr11 = symbols('forkcg3 framecg1 framecg3 _Iwr11')
>>> Iwr22, Iwf11, Iwf22, Iframe11 = symbols('Iwr22 Iwf11 Iwf22 Iframe11')
>>> Ifork22, Ifork33, Ifork31, g = symbols('Ifork22 Ifork33 Ifork31 g')
>>> mframe, mfork, mwf, mwr = symbols('mframe mfork mwf mwr')
```

Set up reference frames for the system: N - inertial Y - yaw R - roll WR - rear wheel, rotation angle is ignorable coordinate so not oriented Frame - bicycle frame TempFrame - statically rotated frame for easier reference inertia definition Fork - bicycle fork TempFork - statically rotated frame for easier reference inertia definition WF - front wheel, again posses an ignorable coordinate.

```python
>>> N = ReferenceFrame('N')
>>> Y = N.orientnew('Y', 'Axis', [q1, N.z])
>>> R = Y.orientnew('R', 'Axis', [q2, Y.x])
>>> Frame = R.orientnew('Frame', 'Axis', [q4 + htangle, R.y])
>>> WR = ReferenceFrame('WR')
>>> TempFrame = Frame.orientnew('TempFrame', 'Axis', [-htangle, Frame.y])
>>> Fork = Frame.orientnew('Fork', 'Axis', [q5, Frame.x])
>>> TempFork = Fork.orientnew('TempFork', 'Axis', [-htangle, Fork.y])
>>> WF = ReferenceFrame('WF')
```

Kinematics of the Bicycle: First block of code is forming the positions of the relevant points rear wheel contact -> rear wheel's center of mass -> frame’s center of mass + frame/fork connection -> fork’s center of mass + front wheel’s center of mass -> front wheel contact point.

```python
>>> WR_cont = Point('WR_cont')
>>> WR_mc = WR_cont.locatenew('WR_mc', WRrad * R.z)
>>> Steer = WR_mc.locatenew('Steer', framelength * Frame.z)
>>> Frame_mc = WR_mc.locatenew('Frame_mc', -framecg1 * Frame.x + framecg3 * 
```

(continues on next page)
Set the angular velocity of each frame: Angular accelerations end up being calculated automatically by differentiating the angular velocities when first needed.

```
>>> Y.set_ang_vel(N, u1 * Y.z)
>>> R.set_ang_vel(Y, u2 * R.x)
>>> Frame.set_ang_vel(R, u3 * Frame.y)
>>> Fork.set_ang_vel(Frame, u4 * Fork.x)
>>> WF.set_ang_vel(Fork, u6 * Fork.y)
```

Form the velocities of the points, using the 2-point theorem. Accelerations again are calculated automatically when first needed.

```
>>> WR_cont.set_vel(N, 0)
>>> WR_mc.v2pt_theory(WR_cont, N, WR)
>>> Steer.v2pt_theory(WR_mc, N, Frame)
>>> Frame_mc.v2pt_theory(WR_mc, N, Frame)
>>> Fork_mc.v2pt_theory(Steer, N, Fork)
>>> WF_mc.v2pt_theory(Steer, N, Fork)
```
Sets the inertias of each body. Uses the inertia frame to construct the inertia dyadics. Wheel inertias are only defined by principal moments of inertia, and are in fact constant in the frame and fork reference frames; it is for this reason that the orientations of the wheels does not need to be defined. The frame and fork inertias are defined in the 'Temp' frames which are fixed to the appropriate body frames; this is to allow easier input of the reference values of the benchmark paper. Note that due to slightly different orientations, the products of inertia need to have their signs flipped; this is done later when entering the numerical value.

>>> Frame_I = (inertia(TempFrame, Iframe11, Iframe22, Iframe33, 0, 0, ... Frame_I))
>>> Fork_I = (inertia(TempFork, Ifork11, Ifork22, Ifork33, 0, 0, Fork_I))
>>> WR_I = (inertia(Frame, Iwr11, Iwr22, Iwr11), WR_mc)
>>> WF_I = (inertia(Fork, Iwf11, Iwf22, Iwf11, WF_mc)

Declaration of the RigidBody containers.

>>> BodyFrame = RigidBody('BodyFrame', Frame_mc, Frame, mframe, Frame_I)
>>> BodyFork = RigidBody('BodyFork', Fork_mc, Fork, mfork, Fork_I)
>>> BodyWR = RigidBody('BodyWR', WR_mc, WR, mwr, WR_I)
>>> BodyWF = RigidBody('BodyWF', WF_mc, WF, mwf, WF_I)

>>> print('Before Forming the List of Nonholonomic Constraints. ')

Before Forming the List of Nonholonomic Constraints.

The kinematic differential equations; they are defined quite simply. Each entry in this list is equal to zero.
>>> \( \mathbf{\dot{kd}} = [q1d - u1, q2d - u2, q4d - u4, q5d - u5] \)

The nonholonomic constraints are the velocity of the front wheel contact point dotted into the X, Y, and Z directions; the yaw frame is used as it is “closer” to the front wheel (1 less DCM connecting them). These constraints force the velocity of the front wheel contact point to be 0 in the inertial frame; the X and Y direction constraints enforce a “no-slip” condition, and the Z direction constraint forces the front wheel contact point to not move away from the ground frame, essentially replicating the holonomic constraint which does not allow the frame pitch to change in an invalid fashion.

>>> conlist_speed = [dot(WF_cont.vel(N), Y.x),
                      ...                  dot(WF_cont.vel(N), Y.y),
                      ...                  dot(WF_cont.vel(N), Y.z)]

The holonomic constraint is that the position from the rear wheel contact point to the front wheel contact point when dotted into the normal-to-ground plane direction must be zero; effectively that the front and rear wheel contact points are always touching the ground plane. This is actually not part of the dynamic equations, but instead is necessary for the linearization process.

>>> conlist_coord = [dot(WF_cont.pos_from(WR_cont), Y.z)]

The force list; each body has the appropriate gravitational force applied at its center of mass.

>>> FL = [(Frame_mc, -mframe*g*Y.z),
        ...       (Fork_mc, -mfork*g*Y.z),
        ...       (WF_mc, -mwf*g*Y.z),
        ...       (WR_mc, -mwr*g*Y.z)]

>>> BL = [BodyFrame, BodyFork, BodyWR, BodyWF]

The N frame is the inertial frame, coordinates are supplied in the order of independent, dependent coordinates. The kinematic differential equations are also entered here. Here the independent speeds are specified, followed by the dependent speeds, along with the nonholonomic constraints. The dependent coordinate is also provided, with the holonomic constraint. Again, this is only comes into play in the linearization process, but is necessary for the linearization to correctly work.

>>> KM = KanesMethod(N, q_ind=[q1, q2, q5],
                    ...        q_dependent=[q4],
                    ...        configuration_constraints=conlist_coord,
                    ...        u_ind=[u2, u3, u5],
                    ...        u_dependent=[u1, u4, u6],
                    ...        velocity_constraints=conlist_speed,
                    ...        kd_eqs=kd)

>>> print('Before Forming Generalized Active and Inertia Forces, Fr and Fr*')
Before Forming Generalized Active and Inertia Forces, Fr and Fr*

>>> (fr, frstar) = KM.kanes_equations(BL, FL)

>>> print('Base Equations of Motion Computed')
Base Equations of Motion Computed

This is the start of entering in the numerical values from the benchmark paper to validate the eigenvalues of the linearized equations from this model to the reference eigenvalues. Look at the aforementioned paper for more information. Some of these are intermediate values, used to transform values from the paper into the coordinate systems used in this model.

>>> PaperRadRear = 0.3
>>> PaperRadFront = 0.35
>>> HTA = evalf.N(pi/2 - pi/10)
Here is the final assembly of the numerical values. The symbol ‘v’ is the forward speed of the bicycle (a concept which only makes sense in the upright, static equilibrium case?). These are in a dictionary which will later be substituted in. Again the sign on the product of inertia values is flipped here, due to different orientations of coordinate systems.

```python
>>> v = Symbol('v')
>>> val_dict = {
...     'WFrad': PaperRadFront,
...     'WRrad': PaperRadRear,
...     'htangle': HTA,
...     'forkoffset': rake,
...     'forklength': PaperForkL,
...     'frameLength': FrameLength,
...     'forkcg1': ForkCGPar,
...     'forkcg3': ForkCGNorm,
...     'framecg1': FrameCGNorm,
...     'framecg3': FrameCGPar,
...     'Iwr11': 0.0603,
...     'Iwr22': 0.12,
...     'Iwf11': 0.1405,
...     'Iwf22': 0.28,
...     'Ifork11': 0.05892,
...     'Ifork22': 0.06,
...     'Ifork33': 0.00708,
...     'Iframe11': 9.2,
...     'Iframe22': 11,
...}
```

(continues on next page)
Linearizes the forcing vector; the equations are set up as MM udot = forcing, where MM is the mass matrix, udot is the vector representing the time derivatives of the generalized speeds, and forcing is a vector which contains both external forcing terms and internal forcing terms, such as centripetal or Coriolis forces. This actually returns a matrix with as many rows as total coordinates and speeds, but only as many columns as independent coordinates and speeds. (Note that below this is commented out, as it takes a few minutes to run, which is not good when performing the doctests)

As mentioned above, the size of the linearized forcing terms is expanded to include both q’s and u’s, so the mass matrix must have this done as well. This will likely be changed to be part of the linearized process, for future reference.

Finally, we construct an “A” matrix for the form xdot = A x (x being the state vector, although in this case, the sizes are a little off). The following line extracts only the minimum entries
required for eigenvalue analysis, which correspond to rows and columns for lean, steer, lean
rate, and steer rate. (this is all commented out due to being dependent on the above code,
which is also commented out):

```python
# Amat = MM_full.inv() * forcing_lin
# A = Amat.extract([1,2,4,6],[1,2,3,5])
# print(A)
# print('v = 1')
# print(A.subs(v, 1).eigenvals())
# print('v = 2')
# print(A.subs(v, 2).eigenvals())
# print('v = 3')
# print(A.subs(v, 3).eigenvals())
# print('v = 4')
# print(A.subs(v, 4).eigenvals())
# print('v = 5')
# print(A.subs(v, 5).eigenvals())
```

Upon running the above code yourself, enabling the commented out lines, compare the com-
puted eigenvalues to those is the referenced paper. This concludes the bicycle example.

**Multi Degree of Freedom Holonomic System**

In this example we demonstrate the use of the functionality provided in `sympy.physics.
mechanics` (page 1721) for deriving the equations of motion (EOM) of a holonomic system
that includes both particles and rigid bodies with contributing forces and torques, some of
which are specified forces and torques. The system is shown below:
The system will be modeled using JointsMethod. First we need to create the dynamicsymbols needed to describe the system as shown in the above diagram. In this case, the generalized coordinates \( q_1 \) represent lateral distance of block from wall, \( q_2 \) represents angle of the compound pendulum from vertical, \( q_3 \) represents angle of the simple pendulum from the compound pendulum. The generalized speeds \( u_1 \) represents lateral speed of block, \( u_2 \) represents lateral speed of compound pendulum and \( u_3 \) represents angular speed of C relative to B.

We also create some symbols to represent the length and mass of the pendulum, as well as gravity and others.

```python
>>> from sympy import zeros, symbols
>>> from sympy.physics.mechanics import Body, PinJoint, PrismaticJoint,
    JointsMethod, inertia
>>> from sympy.physics.mechanics import dynamicsymbols
>>> q1, q2, q3, u1, u2, u3 = dynamicsymbols('q1, q2, q3, u1, u2, u3')
```
Next, we create the bodies and connect them using joints to establish the kinematics.

```python
>>> wall = Body('N')
>>> block = Body('A', mass=ma)
>>> IB = inertia(block.frame, 0, 0, IBzz)
>>> compound_pend = Body('B', mass=mb, central_inertia=IB)
>>> simple_pend = Body('C', mass=mc)
```

Now we can apply loads (forces and torques) to the bodies, gravity acts on all bodies, a linear spring and damper act on block and wall, a rotational linear spring acts on C relative to B specified torque T acts on compound_pend and block, specified force F acts on block.

```python
>>> F, T = dynamicsymbols('F, T')
>>> block.apply_force(F*block.x)
>>> block.apply_force(-k*q1*block.x, reaction_body=wall)
>>> block.apply_force(-c*u1*block.x, reaction_body=wall)
>>> compound_pend.apply_torque(T*compound_pend.z, reaction_body=block)
>>> simple_pend.apply_torque(-kT*q3*simple_pend.z, reaction_body=compound_pend)
>>> block.apply_force(-wall.y*block.mass*g)
>>> compound_pend.apply_force(-wall.y*compound_pend.mass*g)
>>> simple_pend.apply_force(-wall.y*simple_pend.mass*g)
```

With the problem setup, the equations of motion can be generated using the JointsMethod class with KanesMethod in backend.

```python
>>> method = JointsMethod(wall, slider, rev1, rev2)
>>> method.form_eoms()
```

(continues on next page)
\[\begin{align*}
&\sin(q_3(t))\cos(q_2(t)) - g*l*mc*\sin(q_2(t)) + l**2*mc*(u_2(t) + \\
&u_3(t))**2*\sin(q_3(t)) - l**2*mc*u_2(t)**2*\sin(q_3(t)) - mc*(l**2*\cos(q_3(t)) + \\

\sin(q_2(t)))*\sin(q_3(t)) + l**2*mc*(l**2*\cos(q_3(t)) + l**2)],
(continues on next page)
A four bar linkage

The four bar linkage is a common example used in mechanics, which can be formulated with only two holonomic constraints. This example will make use of joints functionality provided in `sympy.physics.mechanics` (page 1721). In summary we will use bodies and joints to define the open loop system. Next, we define the configuration constraints to close the loop. The `JointsMethod` will be used to do the “book-keeping” of the open-loop system. From this we will get the input used in combination with the constraints to manually setup the `KanesMethod` (page 1810) as the backend.

First we need to create the `dynamicsymbols()` (page 1713) needed to describe the system as shown in the above diagram. In this case, the generalized coordinates \( q_1, q_2 \) and \( q_3 \) represent the angles between the links. Likewise, the generalized speeds \( u_1, u_2 \) and \( u_3 \) represent the angular velocities between the links. We also create some `symbols()` (page 1030) to represent the lengths and density of the links.

```
>>> from sympy import symbols, Matrix, solve, simplify
>>> from sympy.physics.mechanics import *
>>> mechanics_printing(pretty_print=False)
>>> q1, q2, q3, u1, u2, u3 = dynamicsymbols('q1:4, u1:4')
>>> l1, l2, l3, l4, rho = symbols(['l1:5, rho'])
```

With all symbols defined, we can now define the bodies.

```
>>> N = ReferenceFrame('N')
>>> inertias = [inertia(N, 0, 0, rho * l ** 2 / 12) for l in (l1, l2, l3, l4)]
```
Next, we also define the first three joints.

```python
>>> joint1 = PinJoint('J1', link1, link2, coordinates=q1, speeds=u1,
...                   parent_point=l1/2 * link1.x,
...                   child_point=-l2/2 * link2.x, joint_axis=link1.z)
>>> joint2 = PinJoint('J2', link2, link3, coordinates=q2, speeds=u2,
...                   parent_point=l2/2 * link2.x,
...                   child_point=-l3/2 * link3.x, joint_axis=link2.z)
>>> joint3 = PinJoint('J3', link3, link4, coordinates=q3, speeds=u3,
...                   parent_point=l3/2 * link3.x,
...                   child_point=-l4/2 * link4.x, joint_axis=link3.z)
```

Now we can formulate the holonomic constraint that will close the kinematic loop.

```python
>>> loop = link4.masscenter.pos_from(link1.masscenter) + l1/2 * link1.x + l4/2 * link4.x
>>> fh = Matrix([[loop.dot(link1.x), loop.dot(link1.y)])
```

In order to generate the equations of motions, we will use the JointsMethod as our fronted. Before setting up the KanesMethod (page 1810) as its backend we need to calculate the velocity constraints.

```python
>>> method = JointsMethod(link1, joint1, joint2, joint3)
>>> t = dynamicsymbols._t
>>> qdots = solve(method.kdes, [q1.diff(t), q2.diff(t), q3.diff(t)])
>>> fhd = fh.diff(t).subs(qdots)
```

Now we can setup the KanesMethod (page 1810) as the backend and compute the equations of motion.

```python
>>> method._method = KanesMethod(
... method.frame, q_ind=[q1], u_ind=[u1], q_dependent=[q2, q3],
... u_dependent=[u2, u3], kd_eqs=method.kdes,
... configuration_constraints=fh, velocity_constraints=fhd,
... forcelist=method.loads, bodies=method.bodies)
>>> simplify(method._method._form_eoms())
Matrix([[l2*rho*(-2*l2**2*sin(q3)*u1' + 3*l2*l3*u1**2*sin(q2 + q3)*sin(q2) +
... 3*l2*l3*sin(q2)*cos(q2 + q3)*u1' - 3*l2*l3*sin(q3)*u1' +
... 3*l2*l4*u1**2*sin(q2 + q3)*sin(q2) + 3*l2*l4*sin(q2)*cos(q2 + q3)*u1' +
... 3*l3**2*u1**2*sin(q2)*sin(q3) + 6*l3**2*u1*u2*sin(q2)*sin(q3) +
... 3*l3**2*u2**2*sin(q2)*sin(q3) + 2*l3**2*sin(q2)*cos(q3)*u1' +
... 2*l3**2*sin(q2)*cos(q3)*u2' - l3**2*sin(q3)*cos(q2)*u1' -
... l3**2*sin(q3)*cos(q2)*u2' + 3*l3*l4*u1**2*sin(q2)*sin(q3) +
... 6*l3*l4*u1*u2*sin(q2)*sin(q3) + 3*l3*l4*u2**2*sin(q2)*sin(q3) +
... 3*l3*l4*sin(q2)*cos(q3)*u2' + l4**2*sin(q2)*u1' + l4**2*sin(q2)*u2' +
... l4**2*sin(q2)*u3'/(6*sin(q3))])])
```
Potential Issues/Advanced Topics/Future Features in Physics/Mechanics

This document will describe some of the more advanced functionality that this module offers but which is not part of the “official” interface. Here, some of the features that will be implemented in the future will also be covered, along with unanswered questions about proper functionality. Also, common problems will be discussed, along with some solutions.

Common Issues

Here issues with numerically integrating code, choice of dynamicsymbols for coordinate and speed representation, printing, differentiating, and substitution will occur.

Numerically Integrating Code

See Future Features: Code Output

Differentiating

Differentiation of very large expressions can take some time in SymPy; it is possible for large expressions to take minutes for the derivative to be evaluated. This will most commonly come up in linearization.

Choice of Coordinates and Speeds

The Kane object is set up with the assumption that the generalized speeds are not the same symbol as the time derivatives of the generalized coordinates. This isn’t to say that they can’t be the same, just that they have to have a different symbol. If you did this:

```python
>> KM.coords([q1, q2, q3])
>> KM.speeds([q1d, q2d, q3d])
```

Your code would not work. Currently, kinematic differential equations are required to be provided. It is at this point that we hope the user will discover they should not attempt the behavior shown in the code above.

This behavior might not be true for other methods of forming the equations of motion though.

Printing

The default printing options are to use sorting for Vector and Dyad measure numbers, and have unsorted output from the mprint, mprint, and mlatex functions. If you are printing something large, please use one of those functions, as the sorting can increase printing time from seconds to minutes.
Substitution

There are two common issues with substitution in mechanics:

- When subbing in expressions for dynamicsymbols, sympy’s normal subs will substitute in for derivatives of the dynamic symbol as well:

  ```python
  >>> from sympy.physics.mechanics import dynamicsymbols
  >>> x = dynamicsymbols('x')
  >>> expr = x.diff() + x
  >>> sub_dict = {x: 1}
  >>> expr.subs(sub_dict)
  Derivative(1, t) + 1
  ```

  In this case, x was replaced with 1 inside the Derivative as well, which is undesired.

- Substitution into large expressions can be slow.

  If your substitution is simple (direct replacement of expressions with other expressions, such as when evaluating at an operating point) it is recommended to use the provided msubs function, as it is significantly faster, and handles the derivative issue appropriately:

  ```python
  >>> from sympy.physics.mechanics import msubs
  >>> msubs(expr, sub_dict)
  Derivative(x(t), t) + 1
  ```

Linearization

Currently, the linearization methods don’t support cases where there are non-coordinate, non-speed dynamic symbols outside of the “dynamic equations”. It also does not support cases where time derivatives of these types of dynamic symbols show up. This means if you have kinematic differential equations which have a non-coordinate, non-speed dynamic symbol, it will not work. It also means if you have defined a system parameter (say a length or distance or mass) as a dynamic symbol, its time derivative is likely to show up in the dynamic equations, and this will prevent linearization.

Acceleration of Points

At a minimum, points need to have their velocities defined, as the acceleration can be calculated by taking the time derivative of the velocity in the same frame. If the 1 point or 2 point theorems were used to compute the velocity, the time derivative of the velocity expression will most likely be more complex than if you were to use the acceleration level 1 point and 2 point theorems. Using the acceleration level methods can result in shorted expressions at this point, which will result in shorter expressions later (such as when forming Kane’s equations).
Advanced Interfaces

Advanced Functionality

Remember that the Kane object supports bodies which have time-varying masses and inertias, although this functionality isn’t completely compatible with the linearization method.

Operators were discussed earlier as a potential way to do mathematical operations on Vector and Dyad objects. The majority of the code in this module is actually coded with them, as it can (subjectively) result in cleaner, shorter, more readable code. If using this interface in your code, remember to take care and use parentheses; the default order of operations in Python results in addition occurring before some of the vector products, so use parentheses liberally.

Future Features

This will cover the planned features to be added to this submodule.

Code Output

A function for generating code output for numerical integration is the highest priority feature to implement next. There are a number of considerations here.

Code output for C (using the GSL libraries), Fortran 90 (using LSODA), MATLAB, and SciPy is the goal. Things to be considered include: use of cse on large expressions for MATLAB and SciPy, which are interpretive. It is currently unclear whether compiled languages will benefit from common subexpression elimination, especially considering that it is a common part of compiler optimization, and there can be a significant time penalty when calling cse.

Care needs to be taken when constructing the strings for these expressions, as well as handling of input parameters, and other dynamic symbols. How to deal with output quantities when integrating also needs to be decided, with the potential for multiple options being considered.

References for Physics/Mechanics

Autolev Parser

Introduction

Autolev (now superseded by MotionGenesis) is a domain specific language used for symbolic multibody dynamics. The SymPy mechanics module now has enough power and functionality to be a fully featured symbolic dynamics module. This parser parses Autolev (version 4.1) code to SymPy code by making use of SymPy’s math libraries and the mechanics module.

The parser has been built using the ANTLR framework and its main purpose is to help former users of Autolev to get familiarized with multibody dynamics in SymPy.

The sections below shall discuss details of the parser like usage, gotchas, issues and future improvements. For a detailed comparison of Autolev and SymPy Mechanics you might want to look at the SymPy Mechanics for Autolev Users guide (page 1781).
Usage

We first start with an Autolev code file.

Let us take this example (Comments % have been included to show the Autolev responses):

```autolev
% double_pendulum.al
%-------------------
MOTIONVARIABLES' Q{2}', U{2}'
CONSTANTS L,M,G
NEWTONIAN N
FRAMES A,B
SIMPROT(N, A, 3, Q1)
% -> N_A = [COS(Q1), -SIN(Q1), 0; SIN(Q1), COS(Q1), 0; 0, 0, 1]
SIMPROT(N, B, 3, Q2)
% -> N_B = [COS(Q2), -SIN(Q2), 0; SIN(Q2), COS(Q2), 0; 0, 0, 1]
W_A_N>=U1*N3>
% -> W_A_N> = U1*N3>
W_B_N>=U2*N3>
% -> W_B_N> = U2*N3>
POINT O
PARTICLES P,R
P_O_P> = L*A1>
% -> P_O_P> = L*A1>
P_P_R> = L*B1>
% -> P_P_R> = L*B1>
V_O_N> = 0>
% -> V_O_N> = 0>
V2PTS(N, A, O, P)
% -> V_P_N> = L*U1*A2>
V2PTS(N, B, P, R)
% -> V_R_N> = L*U1*A2> + L*U2*B2>
MASS P=M, R=M
Q1' = U1
Q2' = U2
GRAVITY(G*N1>)
% -> FORCE_P> = G*M*N1>
% -> FORCE_R> = G*M*N1>
ZERO = FR() + FRSTAR()
% -> ZERO[1] = -L*M*(2*G*SIN(Q1)+L*(U2^2*SIN(Q1-Q2)+2*U1'+COS(Q1-Q2)*U2'))
% -> ZERO[2] = -L*M*(G*SIN(Q2)-L*(U1^2*SIN(Q1-Q2)-U2'-COS(Q1-Q2)*U1'))
KANE()
INPUT M=1,G=9.81,L=1
INPUT Q1=.1,Q2=.2,U1=0,U2=0
INPUT TFINAL=10, INTEGSTP=.01
CODE DYNAMICS() some_filename.c
```

The parser can be used as follows:

```python
>>> from sympy.parsing.autolev import parse_autolev
>>> sympy_code = parse_autolev(open('double_pendulum.al'), include_
... numeric=True)
```

# The include_pydy flag is False by default. Setting it to True will
# enable PyDy simulation code to be outputted if applicable.

```python
>>> print(sympy_code)
import sympy.physics.mechanics as me
import sympy as sm
import math as m
import numpy as np

q1, q2, u1, u2 = me.dynamicsymbols('q1 q2 u1 u2')
l, m, g=sm.symbols('l m g', real=True)
frame_n=me.ReferenceFrame('n')
frame_a=me.ReferenceFrame('a')
frame_b=me.ReferenceFrame('b')
frame_a.orient(frame_n, 'Axis', [q1, frame_n.z])
frame_b.orient(frame_n, 'Axis', [q2, frame_n.z])
frame_a.set_ang_vel(frame_n, u1*frame_n.z)
frame_b.set_ang_vel(frame_n, u2*frame_n.z)
point_o=me.Point('o')
particle_p=me.Particle('p', me.Point('p_pt'), sm.Symbol('m'))
particle_r=me.Particle('r', me.Point('r_pt'), sm.Symbol('m'))
particle_p.point.set_pos(point_o, l*frame_a.x)
particle_r.point.set_pos(particle_p.point, l*frame_b.x)
point_o.set_vel(frame_n, 0)
particle_p.mass = m
particle_r.mass = m
force_p = particle_p.mass*(g*frame_n.x)
force_r = particle_r.mass*(g*frame_n.x)
kane = me.KanesMethod(frame_n, q_ind=[q1,q2], u_ind=[u1, u2], kd_eqs = kd_eqs)
fr, frstar = kane.kanes_equations([particle_p, particle_r], forceList)
zero = fr+frstar

---PyDy code for integration---
from pydy.system import System
sys = System(kane, constants = {l:1, m:1, g:9.81}, specifieds={})
```

(continues on next page)
The commented code is not part of the output code. The print statements demonstrate how to get responses similar to the ones in the Autolev file. Note that we need to use SymPy functions like `.ang_vel_in()`, `.dcm()` etc in many cases unlike directly printing out the variables like zero. If you are completely new to SymPy mechanics, the *SymPy Mechanics for Autolev Users guide* (page 1781) guide should help. You might also have to use basic SymPy simplifications and manipulations like `trigsimp()`, `expand()`, `evalf()` etc for getting outputs similar to Autolev. Refer to the *SymPy Tutorial* to know more about these.

### Gotchas

- Don’t use variable names that conflict with Python’s reserved words. This is one example where this is violated:

```autolev
%Autolev Code
%------------------
LAMBDA = EIG(M)
```

```python
#SymPy Code
#------------------
lambda = sm.Matrix([i.evalf() for i in m.eigenvals().keys()])
```

- Make sure that the names of vectors and scalars are different. Autolev treats these differently but these will get overwritten in Python. The parser currently allows the names of bodies and scalars/vectors to coincide but doesn’t do this between scalars and vectors. This should probably be changed in the future.

```autolev
%Autolev Code
%------------------
VARIABLES X,Y
FRAMES A
A> = X*A1> + Y*A2>
A = X+Y
```

```python
#SymPy Code
#------------------
x, y = me.dynamicsymbols('x y')
frame_a = me.ReferenceFrame('a')
a = x*frame_a.x + y*frame_a.y
a = x + y
# Note how `frame_a` is named differently so it doesn't cause a problem.
# On the other hand, 'a' gets rewritten from a scalar to a vector.
# This should be changed in the future.
```
When dealing with Matrices returned by functions, one must check the order of the values as they may not be the same as in Autolev. This is especially the case for eigenvalues and eigenvectors.

```autolev
%Autolev Code
%------------
EIG(M, E1, E2)
% -> [5; 14; 13]
E2ROW = ROWS(E2, 1)
EIGVEC> = VECTOR(A, E2ROW)
```

```sympy
#SymPy Code
#----------
e1 = sm.Matrix([i.evalf() for i in m.eigenvals().keys()])
# sm.Matrix([5;13;14]) different order
e2 = sm.Matrix([i[2][0].evalf() for i in m.eigenvects()]).reshape(m.
   -shape[0], m.shape[1])
e2row = e2.row(0)
# This result depends on the order of the vectors in the eigenvecs.
eigenvec = e2row[0]*a.x + e2row[1]*a.y + e2row[2]*a.y
```

When using EVALUATE, use something like 90*UNITS(deg,rad) for angle substitutions as radians are the default in SymPy. You could also add np.deg2rad() directly in the SymPy code.

This need not be done for the output code (generated on parsing the CODE commands) as the parser takes care of this when deg units are given in the INPUT declarations.

The DEGREES setting, on the other hand, works only in some cases like in SIMPROT where an angle is expected.

```autolev
%Autolev Code
%------------
A> = Q1*A1> + Q2*A2>
B> = EVALUATE(A>, Q1:30*UNITS(DEG,RAD))
```

```sympy
#SymPy Code
#----------
a = q1*a.frame_a.x + q2*frame_a.y
b = a.subs({q1:30*0.0174533})
# b = a.subs({q1:np.deg2rad(30)})
```

Most of the Autolev settings have not been parsed and have no effect on the parser. The only ones that work somewhat are COMPLEX and DEGREES. It is advised to look into alternatives to these in SymPy and Python.

The REPRESENT command is not supported. Use the MATRIX, VECTOR or DYADIC commands instead. Autolev 4.1 suggests these over REPRESENT as well while still allowing it but the parser doesn’t parse it.
• Do not use variables declarations of the type \texttt{\textsc{wo}3\textsc{rd}2,4}. The parser can only handle one variable name followed by one pair of curly braces and any number of ‘s. You would have to declare all the cases manually if you want to achieve something like \texttt{\textsc{wo}3\textsc{rd}2,4}.

• The parser can handle normal versions of most commands but it may not parse functions with Matrix arguments properly in most cases. Eg:

\[ M=\text{COEF}([E1;E2],[U1,U2,U3]) \]

This would compute the coefficients of U1, U2 and U3 in E1 and E2. It is preferable to manually construct a Matrix using the regular versions of these commands.

```plaintext
%Autolev Code
%-------------------
% COEF([E1;E2],[U1,U2,U3])
M = [COEF(E1,U1),COEF(E1,U2),COEF(E1,U3) & ;COEF(E2,U1),COEF(E2,U2),COEF(E2,U3)]
```

• \textsc{motionvariable} declarations must be used for the generalized coordinates and speeds and all other variables must be declared in regular \texttt{variable} declarations. The parser requires this to distinguish between them to pass the correct parameters to the Kane’s method object.

It is also preferred to always declare the speeds corresponding to the coordinates and to pass in the kinematic differential equations. The parser is able to handle some cases where this isn’t the case by introducing some dummy variables of its own but SymPy on its own does require them.

Also note that older Autolev declarations like \texttt{\textsc{variables} \textsc{u}{3}'} are not supported either.

```plaintext
%Autolev Code
%-------------------
MOTIONVARIABLES' Q{2}', U{2}'
% ---- OTHER LINES ----
Q1' = U1
Q2' = U2
% ---- OTHER LINES ----
ZERO = FR() + FRSTAR()
```

```plaintext
#SymPy Code
#-------------------
q1, q2, u1, u2 = me.dynamicsymbols('q1 q2 u1 u2')
q1d, q2d, u1d, u2d = me.dynamicsymbols('q1 q2 u1 u2', 1)

# ---- other lines ----
kd_eqs = [q1d - u1, q2d - u2]
kane = me.KanesMethod(frame_n, q_ind=[q1,q2], u_ind=[u1, u2], kd_eqs = kd_eqs)
fr, frstar = kane.kanes_equations([particle_p, particle_r], forceList)
zero = fr+frstar
```
• Need to change `me.dynamicsymbols._t` to `me.dynamicsymbols('t')` for all occurrences of it in the Kane’s equations. For example have a look at line 10 of this spring damper example. This equation is used in forming the Kane’s equations so we need to change `me.dynamicsymbols._t` to `me.dynamicsymbols('t')` in this case.

The main reason that this needs to be done is because PyDy requires time dependent specifieds to be explicitly laid out while Autolev simply takes care of the stray time variables in the equations by itself.

The problem is that PyDy’s System class does not accept `dynamicsymbols._t` as a specified. Refer to issue #396. This change is not actually ideal so a better solution should be figured out in the future.

• The parser creates SymPy symbols and `dynamicsymbols` by parsing variable declarations in the Autolev Code.

For intermediate expressions which are directly initialized the parser does not create SymPy symbols. It just assigns them to the expression.

On the other hand, when a declared variable is assigned to an expression, the parser stores the expression against the variable in a dictionary so as to not reassign it to a completely different entity. This constraint is due to the inherent nature of Python and how it differs from a language like Autolev.

Also, Autolev seems to be able to assume whether to use a variable or the rhs expression that variable has been assigned to in equations even without an explicit `RHS()` call in some cases. For the parser to work correctly however, it is better to use `RHS()` wherever a variable’s rhs expression is meant to be used.

```autolev
%Autolev Code
%----------------
VARIABLES X, Y
E = X + Y
X = 2*Y

RHS_X = RHS(X)
I1 = X
I2 = Y
I3 = X + Y

INERTIA B,I1,I2,I3
% -> I_B_BO>> = I1*B1>*B1> + I2*B2>*B2> + I3*B3>*B3>
```

```sympy
#SymPy Code
#-------
x,y = me.dynamicsymbols('x y')
e = x + y  # No symbol is made out of 'e'

# an entry like {x:2*y} is stored in an rhs dictionary
rhs_x = 2*y
```

(continues on next page)
```
i1 = x  # again these are not made into SymPy symbols
i2 = y
i3 = x + y

body_b.inertia = (me.inertia(body_b_f, i1, i2, i3), b_cm)
# This prints as:
# x*b_f.x*b_f.x + y*b_f.y*b_f.y + (x+y)*b_f.z*b_f.z
# while Autolev's output has I1,I2 and I3 in it.
# Autolev however seems to know when to use the RHS of I1,I2 and I3
# based on the context.
```

- This is how the SOLVE command is parsed:

```
%Solve Code
%--------------
SOLVE(ZERO,X,Y)
A = RHS(X)*2 + RHS(Y)
```

```
#SymPy Code
#-------------
print(sm.solve(zero,x,y))
# Behind the scenes the rhs of x
# is set to sm.solve(zero,x,y)[x].
a = sm.solve(zero,x,y)[x]*2 + sm.solve(zero,x,y)[y]
```

The indexing like [x] and [y] doesn't always work so you might want to look at the underlying dictionary that solve returns and index it correctly.

- Inertia declarations and Inertia functions work somewhat differently in the context of the parser. This might be hard to understand at first but this had to be done to bridge the gap due to the differences in SymPy and Autolev. Here are some points about them:

1. Inertia declarations (INERTIA B,I1,I2,I3) set the inertias of rigid bodies.

2. Inertia setters of the form I_C_D>> = expr however; set the inertias only when C is a body. If C is a particle then I_C_D>> = expr simply parses to i_c_d = expr and i_c_d acts like a regular variable.

3. When it comes to inertia getters (I_C_D>> used in an expression or INERTIA commands), these MUST be used with the EXPRESS command to specify the frame as SymPy needs this information to compute the inertia dyadic.

```
%Solve Code
%-------------------
INERTIA B,I1,I2,I3
I_B_BO>> = X*A1>*A1> + Y*A2>*A2>  % Parser will set the inertia of B
I_P_Q>> = X*A1>*A1> + Y^2*A2>*A2>  % Parser just parses it as i_p_q = expr
E1 = 2*EXPRESS(I_B_O>>,A)
E2 = I_P_Q>>
```

(continues on next page)
\[ E3 = \text{EXPRESS}(I_P_O>>, A) \]
\[ E4 = \text{EXPRESS}(	ext{INERTIA}(O), A) \]

% In E1 we are using the EXPRESS command with I_B_O>> which makes
% the parser and SymPy compute the inertia of Body B about point O.

% In E2 we are just using the dyadic object I_P_Q>> (as I_P_Q>> = expr
% doesn't act as a setter) defined above and not asking the parser
% or SymPy to compute anything.

% E3 asks the parser to compute the inertia of P about point O.

% E4 asks the parser to compute the inertias of all bodies wrt about O.

• In an inertia declaration of a body, if the inertia is being set about a point other than the
center of mass, one needs to make sure that the position vector setter for that point and
the center of mass appears before the inertia declaration as SymPy will throw an error
otherwise.

% Autolev Code
%-----------------
\[ P_SO_O> = X*A1> \]
\[ \text{INERTIA } S_(O) I1,I2,I3 \]

• Note that all Autolev commands have not been implemented. The parser now covers the
important ones in their basic forms. If you are doubtful whether a command is included
or not, please have a look at this file in the source code. Search for “<command>” to
verify this. Looking at the code for the specific command will also give an idea about
what form it is expected to work in.

Limitations and Issues

• A lot of the issues have already been discussed in the Gotchas section. Some of these
are:
  - Vector names coinciding with scalar names are overwritten in Python.
  - Some convenient variable declarations aren’t parsed.
  - Some convenient forms of functions to return matrices aren’t parsed.
  - Settings aren’t parsed.
  - symbols and rhs expressions work very differently in Python which might cause un-
desirable results.
  - Dictionary indexing for the parsed code of the SOLVE command is not proper in many
cases.
  - Need to change dynamicsymbols._t to dynamicsymbols('t') for the PyDy simula-
tion code to work properly.

Here are some other ones:
• Eigenvectors do not seem to work as expected. The values in Autolev and SymPy are not
the same in many cases.

• Block matrices aren’t parsed by the parser. It would actually be easier to make a change
in SymPy to allow matrices to accept other matrices for arguments.

• The SymPy equivalent of the TAYLOR command .series() does not work with
dynamicsymbols().

• Only DEPENDENT constraints are currently parsed. Need to parse AUXILIARY constraints
as well. This should be done soon as it isn’t very difficult.

• None of the energy and momentum functions are parsed right now. It would be nice
to get these working as well. Some changes should probably be made to SymPy. For
instance, SymPy doesn’t have a function equivalent to NICHECK().

• The numerical integration parts work properly only in the case of the KANE command
with no arguments. Things like KANE(F1, F2) do not currently work.

• Also, the PyDy numerical simulation code works only for cases where the matrix say ZERO
= FR() + FRSTAR() is solved for. It doesn’t work well when the matrix has some other
equations plugged in as well. One hurdle faced in achieving this was that PyDy’s System
class automatically takes in the forcing_full and mass_matrix_full and solves them
without giving the user the flexibility to specify the equations. It would be nice to add
this functionality to the System class.

Future Improvements

1. Completing Dynamics Online

The parser has been built by referring to and parsing codes from the Autolev Tutorial and
the book Dynamics Online: Theory and Implementation Using Autolev. Basically, the process
involved going through each of these codes, validating the parser results and improving the
rules if required to make sure the codes parsed well.

The parsed codes of these are available on GitLab here. The repo is private so access needs
to be requested. As of now, most codes till Chapter 4 of Dynamics Online have been parsed.
Completing all the remaining codes of the book (namely, 2-10, 2-11, rest of Ch4, Ch5 and Ch6
(less important) ) would make the parser more complete.

2. Fixing Issues

The second thing to do would be to go about fixing the problems described above in the
Gotchas (page 1774) and Limitations and Issues (page 1779) sections in order of priority and
ease. Many of these require changes in the parser code while some of these are better fixed
by adding some functionality to SymPy.
3. Switching to an AST

The parser is currently built using a kind of Concrete Syntax Tree (CST) using the ANTLR framework. It would be ideal to switch from a CST to an Abstract Syntax Tree (AST). This way, the parser code will be independent of the ANTLR grammar which makes it a lot more flexible. It would also be easier to make changes to the grammar and the rules of the parser.

SymPy Mechanics for Autolev Users

Introduction

Autolev (now superseded by MotionGenesis) is a domain specific programming language which is used for symbolic multibody dynamics. The SymPy mechanics module now has enough power and functionality to be a fully featured symbolic dynamics module. The PyDy package extends the SymPy output to the numerical domain for simulation, analyses and visualization. Autolev and SymPy Mechanics have a lot in common but there are also many differences between them. This page shall expand upon their differences. It is meant to be a go-to reference for Autolev users who want to transition to SymPy Mechanics.

It would be nice to have a basic understanding of SymPy and SymPy Mechanics before going over this page. If you are completely new to Python, you can check out the official Python Tutorial. Check out the SymPy Documentation (page ??), especially the tutorial to get a feel for SymPy. For an introduction to Multibody dynamics in Python, this lecture is very helpful.

You might also find the Autolev Parser (page 1771) which is a part of SymPy to be helpful.
### Some Key Differences

<table>
<thead>
<tr>
<th>Autolev</th>
<th>SymPy Mechanics</th>
</tr>
</thead>
<tbody>
<tr>
<td>Autolev is a domain specific programming language designed to perform multibody dynamics. Since it is a language of its own, it has a very rigid language specification. It predefines, assumes and computes many things based on the input code. Its code is a lot cleaner and concise as a result of this.</td>
<td>SymPy is a library written in the general purpose language Python. Although Autolev’s code is more compact, SymPy (by virtue of being an add on to Python) is more flexible. The users have more control over what they can do. For example, one can create a class in their code for let’s say a type of rigibodies with common properties. The wide array of scientific Python libraries available is also a big plus.</td>
</tr>
<tr>
<td>Autolev generates Matlab, C, or Fortran code from a small set of symbolic mathematics.</td>
<td>SymPy generates numerical Python, C or Octave/Matlab code from a large set of symbolic mathematics created with SymPy. It also builds on the popular scientific Python stack such as NumPy, SciPy, IPython, matplotlib, Cython and Theano.</td>
</tr>
<tr>
<td>Autolev uses 1 (one) based indexing. The initial element of a sequence is found using a[1].</td>
<td>Python uses 0 (zero) based indexing. The initial element of a sequence is found using a[0].</td>
</tr>
<tr>
<td>Autolev is case insensitive.</td>
<td>SymPy code being Python code is case sensitive.</td>
</tr>
<tr>
<td>One can define their own commands in Autolev by making .R and .A files which can be used in their programs.</td>
<td>SymPy code is Python code, so one can define functions in their code. This is a lot more convenient.</td>
</tr>
<tr>
<td>Autolev is proprietary.</td>
<td>SymPy is open source.</td>
</tr>
</tbody>
</table>
Rough Autolev-SymPy Equivalents

The tables below give rough equivalents for some common Autolev expressions. These are not exact equivalents, but rather should be taken as hints to get you going in the right direction. For more detail read the built-in documentation on SymPy vectors (page 1640), SymPy mechanics (page 1721) and PyDy.

In the tables below, it is assumed that you have executed the following commands in Python:

```
import sympy.physics.mechanics as me
import sympy as sm
```
### Mathematical Equivalents

<table>

<tr>
<td>Variables q, s</td>
<td><code>q, s = me.dynamicsymbols(q, s)</code></td>
<td></td>
</tr>
<tr>
<td>Variables x''</td>
<td><code>x = me.dynamicsymbols('x')</code></td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>xd = me.dynamicsymbols('x', 1)</code></td>
<td></td>
</tr>
<tr>
<td></td>
<td><code>xd2 = me.dynamicsymbols('x', 2)</code></td>
<td></td>
</tr>
</tbody>
</table>

**Examples**

- **SymPy**
  - `sm.diag(1,1,1,1)`
  - `A.T`
  - `M**-1`
  - `M[2, 3]`
  - `M.det()`
  - `A.row(0)`
  - `A.rows`
  - `A.col(0)`
  - `A.cols`
  - `A + B*C`
- **Autolev**
  - `ColMatrix = [1; 2; 3; 4]`
  - `RowMatrix = [1, 2, 3, 4]`
  - `MO[1, 1] = d`
  - `MO = sm.Matrix([[a, b], [c, 0]])`

**Notes**

- SymPy Documentation, Release 1.12.1

### Numerical Evaluation and Visualization

Autolev’s CODE Option() command allows one to generate Matlab, C, or Fortran code for numerical evaluation and visualization. Option can be Dynamics, ODE, Nonlinear or Algebraic.

Numerical evaluation for dynamics can be achieved using PyDy. One can pass in the KanesMethod object to the System class along with the values for the constants, specifieds, initial conditions and time steps. The equations of motion can then be integrated. The plotting is achieved using matplotlib. Here is an example from the PyDy Documentation on how it is done:

```python
from numpy import array, linspace, sin
from pydy.system import System

sys = System(kane,
              constants = {mass: 1.0, stiffness: 1.0,
                            damping: 0.2, gravity: 9.8},
              specifieds = {force: lambda x, t: sin(t)},
              initial_conditions = {position: 0.1, speed: -1.0},
              times = linspace(0.0, 10.0, 1000))

y = sys.integrate()

import matplotlib.pyplot as plt
plt.plot(sys.times, y)
plt.legend((str(position), str(speed)))
plt.show()
```

For information on all the things PyDy can accomplish refer to the PyDy Documentation.

The tools in the PyDy workflow are:

- **SymPy**: SymPy is a Python library for
symbolic computation. It provides computer algebra capabilities either as a standalone application, as a library to other applications, or live on the web as SymPy Live or SymPy Gamma.

- **NumPy**: NumPy is a library for the Python programming language, adding support for large, multi-dimensional arrays and matrices, along with a large collection of high-level mathematical functions to operate on these arrays.

- **SciPy**: SciPy is an open source Python library used for scientific computing and technical computing. SciPy contains modules for optimization, linear algebra, integration, interpolation, special functions, FFT, signal and image processing, ODE solvers and other tasks common in science and engineering.

- **IPython**: IPython is a command shell for interactive computing in multiple programming languages, originally developed for the Python programming language, that offers introspection, rich media, shell syntax, tab completion, and history.

- **Aesara**: Aesara is a numerical computation library for Python. In Aesara, computations are expressed using a NumPy-esque syntax and compiled to run efficiently on either CPU or GPU architectures.

- **Cython**: Cython is a superset of the Python programming language, designed to give C-like performance with code that is mostly written in Python. Cython is a compiled language that generates CPython extension modules.

- **matplotlib**: matplotlib is a plotting library for the Python programming language and its numerical mathematics extension NumPy.

One will be able to write code equivalent to the Matlab, C or Fortran code generated by Autolev using these scientific computing tools. It is recommended to go over these modules to gain an understanding of scientific computing with Python.

**Mechanics API Reference**

**Masses, Inertias & Particles, RigidBodys (Docstrings)**

```python
class sympy.physics.mechanics.particle.Particle(name, point, mass)
A particle.

Parameters

- **name**: str
  Name of particle

- **point**: Point
  A physics/mechanics Point which represents the position, velocity, and acceleration of this Particle

- **mass**: sympifyable
  A SymPy expression representing the Particle's mass

Explanation

Particles have a non-zero mass and lack spatial extension; they take up no space. Values need to be supplied on initialization, but can be changed later.

Examples

```python
>>> from sympy.physics.mechanics import Particle, Point
>>> po = Point('po')
>>> m = Symbol('m')
>>> pa = Particle('pa', po, m)
>>> # Or you could change these later
>>> pa.mass = m
>>> pa.point = po
```

```python
def angular_momentum(point, frame)
Angular momentum of the particle about the point.

Parameters

- **point**: Point
  The point about which angular momentum of the particle is desired.

- **frame**: ReferenceFrame
  The frame in which angular momentum is desired.
```
**Explanation**

The angular momentum $H$, about some point $O$ of a particle, $P$, is given by:

$$H = \text{cross}(r, m \times v)$$

where $r$ is the position vector from point $O$ to the particle $P$, $m$ is the mass of the particle, and $v$ is the velocity of the particle in the inertial frame, $N$.

**Examples**

```python
>>> from sympy.physics.mechanics import Particle, Point,
    ReferenceFrame
>>> from sympy.physics.mechanics import dynamicsymbols
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> m, v, r = dynamicsymbols('m v r')
>>> N = ReferenceFrame('N')
>>> O = Point('O')
>>> A = O.locatenew('A', r * N.x)
>>> P = Particle('P', A, m)
>>> P.point.set_vel(N, v * N.y)
>>> P.angular_momentum(O, N)
m*r*v*N.z
```

**kinetic_energy**(*frame*)

Kinetic energy of the particle.

**Parameters**

- **frame** : ReferenceFrame

  The Particle’s velocity is typically defined with respect to an inertial frame but any relevant frame in which the velocity is known can be supplied.

**Explanation**

The kinetic energy, $T$, of a particle, $P$, is given by:

$$T = \frac{1}{2} (\text{dot}(m \times v, v))$$

where $m$ is the mass of particle $P$, and $v$ is the velocity of the particle in the supplied ReferenceFrame.
Examples

```python
>>> from sympy.physics.mechanics import Particle, Point,
>>> from sympy import symbols

m, v, r = symbols('m v r')
N = ReferenceFrame('N')
O = Point('O')
P = Particle('P', O, m)
P.point.set_vel(N, v * N.y)
P.kinetic_energy(N)
m*v**2/2
```

`linear_momentum(frame)`

Linear momentum of the particle.

**Parameters**

- `frame` : ReferenceFrame
  The frame in which linear momentum is desired.

**Explanation**

The linear momentum $L$, of a particle $P$, with respect to frame $N$ is given by:

$$L = m \cdot v$$

where $m$ is the mass of the particle, and $v$ is the velocity of the particle in the frame $N$.

Examples

```python
>>> from sympy.physics.mechanics import Particle, Point,
>>> from sympy.physics.mechanics import dynamicsymbols
>>> from sympy.physics.vector import init_vprinting

init_vprinting(pretty_print=False)
m, v = dynamicsymbols('m v')
N = ReferenceFrame('N')
P = Point('P')
A = Particle('A', P, m)
P.set_vel(N, v * N.x)
A.linear_momentum(N)
m*v*N.x
```

`property mass`

Mass of the particle.

`parallel_axis(point, frame)`

Returns an inertia dyadic of the particle with respect to another point and frame.

**Parameters**

- `point` : sympy.physics.vector.Point
The point to express the inertia dyadic about.

**frame** : sympy.physics.vector.ReferenceFrame

The reference frame used to construct the dyadic.

**Returns**

<table>
<thead>
<tr>
<th>inertia</th>
<th>sympy.physics.vector.Dyadic</th>
</tr>
</thead>
</table>

The inertia dyadic of the particle expressed about the provided point and frame.

**property point**

Point of the particle.

**property potential_energy**

The potential energy of the Particle.

**Examples**

```python
>>> from sympy.physics.mechanics import Particle, Point
>>> from sympy import symbols
>>> m, g, h = symbols('m g h')
>>> O = Point('O')
>>> P = Particle('P', O, m)
>>> P.potential_energy = m * g * h
>>> P.potential_energy
```

```python
5.8. Topics
```

**class** sympy.physics.mechanics.rigidbody.RigidBody(name, masscenter, frame, mass, inertia)

An idealized rigid body.

**Explanation**

This is essentially a container which holds the various components which describe a rigid body: a name, mass, center of mass, reference frame, and inertia.

All of these need to be supplied on creation, but can be changed afterwards.

**Examples**

```python
>>> from sympy import Symbol
>>> from sympy.physics.mechanics import ReferenceFrame, Point, RigidBody
>>> from sympy.physics.mechanics import outer
>>> m = Symbol('m')
>>> A = ReferenceFrame('A')
>>> P = Point('P')
>>> I = outer(A.x, A.x)
>>> inertia_tuple = (I, P)
>>> B = RigidBody('B', P, A, m, inertia_tuple)
>>> # Or you could change them afterwards
```
>>> m2 = Symbol('m2')
>>> B.mass = m2

Attributes

<table>
<thead>
<tr>
<th>name</th>
<th>(string) The body’s name.</th>
</tr>
</thead>
<tbody>
<tr>
<td>masscenter</td>
<td>(Point) The point which represents the center of mass of the rigid body.</td>
</tr>
<tr>
<td>frame</td>
<td>(ReferenceFrame) The ReferenceFrame which the rigid body is fixed in.</td>
</tr>
<tr>
<td>mass</td>
<td>(Sympifyable) The body’s mass.</td>
</tr>
<tr>
<td>inertia</td>
<td>((Dyadic, Point)) The body’s inertia about a point; stored in a tuple as shown above.</td>
</tr>
</tbody>
</table>

angular_momentum(point, frame)

Returns the angular momentum of the rigid body about a point in the given frame.

Parameters

- **point** : Point
  The point about which angular momentum is desired.

- **frame** : ReferenceFrame
  The frame in which angular momentum is desired.

Explanation

The angular momentum \( H \) of a rigid body \( B \) about some point \( O \) in a frame \( N \) is given by:

\[
H = \text{dot}(I, w) + \text{cross}(r, M \times v)
\]

where \( I \) is the central inertia dyadic of \( B \), \( w \) is the angular velocity of body \( B \) in the frame, \( N \), \( r \) is the position vector from point \( O \) to the mass center of \( B \), and \( v \) is the velocity of the mass center in the frame, \( N \).

Examples

```python
>>> from sympy.physics.mechanics import Point, ReferenceFrame, outer
>>> from sympy.physics.mechanics import RigidBody, dynamicsymbols
>>> from sympy.physics.vector import init_vprinting
>>> init_vprinting(pretty_print=False)
>>> M, v, r, omega = dynamicsymbols('M v r omega')
>>> N = ReferenceFrame('N')
>>> b = ReferenceFrame('b')
>>> b.set_ang_vel(N, omega * b.x)
>>> P = Point('P')
>>> P.set_vel(N, 1 * N.x)
>>> I = outer(b.x, b.x)
```
property central_inertia
The body's central inertia dyadic.

property frame
The ReferenceFrame fixed to the body.

property inertia
The body’s inertia about a point; stored as (Dyadic, Point).

kinetic_energy(frame)
Kinetic energy of the rigid body.

Parameters
frame : ReferenceFrame
The RigidBody’s angular velocity and the velocity of it’s mass center are typically defined with respect to an inertial frame but any relevant frame in which the velocities are known can be supplied.

Explanation
The kinetic energy, $T$, of a rigid body, $B$, is given by:

$$T = \frac{1}{2} \left( \dot{\text{dot}}(\text{dot}(I, w), w) + \dot{\text{dot}}(m * v, v) \right)$$

where $I$ and $m$ are the central inertia dyadic and mass of rigid body $B$, respectively, $\omega$ is the body’s angular velocity and $v$ is the velocity of the body’s mass center in the supplied ReferenceFrame.

Examples

```python
>>> from sympy.physics.mechanics import Point, ReferenceFrame, outer
>>> from sympy.physics.mechanics import RigidBody
>>> from sympy import symbols
>>> M, v, r, omega = symbols('M v r omega')
>>> N = ReferenceFrame('N')
>>> b = ReferenceFrame('b')
>>> b.set_ang_vel(N, omega * b.x)
>>> P = Point('P')
>>> P.set_vel(N, v * N.x)
>>> I = outer (b.x, b.x)
>>> inertia_tuple = (I, P)
>>> B = RigidBody('B', P, b, M, inertia_tuple)
>>> B.kinetic_energy(N)
M*v**2/2 + omega**2/2
```

linear_momentum(frame)
Linear momentum of the rigid body.
Parameters

frame : ReferenceFrame

The frame in which linear momentum is desired.

Explanation

The linear momentum $L$, of a rigid body $B$, with respect to frame $N$ is given by:

$$L = M \cdot v^*$$

where $M$ is the mass of the rigid body and $v^*$ is the velocity of the mass center of $B$ in the frame, $N$.

Examples

```python
>>> from sympy.physics.mechanics import Point, ReferenceFrame, outer
>>> from sympy.physics.mechanics import RigidBody, dynamicsymbols
>>> init_vprinting(pretty_print=False)
>>> M, v = dynamicsymbols('M v')
>>> N = ReferenceFrame('N')
>>> P = Point('P')
>>> P.set_vel(N, v * N.x)
>>> I = outer(N.x, N.x)
>>> Inertia_tuple = (I, P)
>>> B = RigidBody('B', P, N, M, Inertia_tuple)
>>> B.linear_momentum(N)
M*v*N.x
```

property mass

The body’s mass.

property masscenter

The body’s center of mass.

parallel_axis(point, frame=None)

Returns the inertia dyadic of the body with respect to another point.

Parameters

point : sympy.physics.vector.Point

The point to express the inertia dyadic about.

frame : sympy.physics.vector.ReferenceFrame

The reference frame used to construct the dyadic.

Returns

inertia : sympy.physics.vector.Dyadic

The inertia dyadic of the rigid body expressed about the provided point.

property potential_energy

The potential energy of the RigidBody.
Examples

```python
>>> from sympy.physics.mechanics import RigidBody, Point, outer,
   ReferenceFrame
>>> from sympy import symbols

>>> M, g, h = symbols('M g h')
>>> b = ReferenceFrame('b')
>>> P = Point('P')
>>> I = outer(b.x, b.x)
>>> Inertia_tuple = (I, P)
>>> B = RigidBody('B', P, b, M, Inertia_tuple)
>>> B.potential_energy = M * g * h
```

```
sympy.physics.mechanics.functions.inertia(frame, ixx, iyy, izz, ixy=0, iyz=0, izx=0)
```

Simple way to create inertia Dyadic object.

**Parameters**

- `frame`: ReferenceFrame
  
The frame the inertia is defined in

- `ixx`: Sympifyable
  
  the xx element in the inertia dyadic

- `iyy`: Sympifyable
  
  the yy element in the inertia dyadic

- `izz`: Sympifyable
  
  the zz element in the inertia dyadic

- `ixy`: Sympifyable
  
  the xy element in the inertia dyadic

- `iyz`: Sympifyable
  
  the yz element in the inertia dyadic

- `izx`: Sympifyable
  
  the zx element in the inertia dyadic

**Explanation**

If you do not know what a Dyadic is, just treat this like the inertia tensor. Then, do the easy thing and define it in a body-fixed frame.
Examples

```python
>>> from sympy.physics.mechanics import ReferenceFrame, inertia
>>> N = ReferenceFrame('N')
>>> inertia(N, 1, 2, 3)
(N.x|N.x) + 2*(N.y|N.y) + 3*(N.z|N.z)
```

sympy.physics.mechanics.functions.inertia_of_point_mass(mass, pos_vec, frame)
Inertia dyadic of a point mass relative to point O.

Parameters

- **mass** : Sympyfiable
  Mass of the point mass
- **pos_vec** : Vector
  Position from point O to point mass
- **frame** : ReferenceFrame
  Reference frame to express the dyadic in

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.mechanics import ReferenceFrame, inertia_of_point_mass
>>> N = ReferenceFrame('N')
>>> r, m = symbols('r m')
>>> px = r * N.x
>>> inertia_of_point_mass(m, px, N)
m*r**2*(N.y|N.y) + m*r**2*(N.z|N.z)
```

sympy.physics.mechanics.functions.linear_momentum(frame, *body)
Linear momentum of the system.

Parameters

- **frame** : ReferenceFrame
  The frame in which linear momentum is desired.
- **body1, body2, body3...** : Particle and/or RigidBody
  The body (or bodies) whose linear momentum is required.

Explanation

This function returns the linear momentum of a system of Particle’s and/or RigidBody’s. The linear momentum of a system is equal to the vector sum of the linear momentum of its constituents. Consider a system, S, comprised of a rigid body, A, and a particle, P. The linear momentum of the system, L, is equal to the vector sum of the linear momentum of the particle, L1, and the linear momentum of the rigid body, L2, i.e.

\[ L = L1 + L2 \]
Examples

```python
from sympy.physics.mechanics import Point, Particle, ReferenceFrame
N = ReferenceFrame('N')
P = Point('P')
P.set_vel(N, 10 * N.x)
Pa = Particle('Pa', P, 1)
Ac = Point('Ac')
Ac.set_vel(N, 25 * N.y)
I = outer(N.x, N.x)
A = RigidBody('A', Ac, N, 20, (I, Ac))
linear_momentum(N, A, Pa)
10*N.x + 500*N.y
```

sympy.physics.mechanics.functions.angular_momentum(point, frame, *body)
Angular momentum of a system.

**Parameters**

point : Point
    The point about which angular momentum of the system is desired.
frame : ReferenceFrame
    The frame in which angular momentum is desired.
body1, body2, body3... : Particle and/or RigidBody
    The body (or bodies) whose angular momentum is required.

**Explanation**

This function returns the angular momentum of a system of Particle’s and/or RigidBody’s. The angular momentum of such a system is equal to the vector sum of the angular momentum of its constituents. Consider a system, S, comprised of a rigid body, A, and a particle, P. The angular momentum of the system, H, is equal to the vector sum of the angular momentum of the particle, H1, and the angular momentum of the rigid body, H2, i.e.

\[ H = H_1 + H_2 \]

**Examples**

```python
from sympy.physics.mechanics import Point, Particle, ReferenceFrame
from sympy.physics.mechanics import RigidBody, outer, angular_momentum
N = ReferenceFrame('N')
O = Point('O')
O.set_vel(N, 0 * N.x)
P = O.locatenew('P', 1 * N.x)
P.set_vel(N, 10 * N.x)
Pa = Particle('Pa', P, 1)
P.set_vel(N, 10 * N.x)
Ac = O.locatenew('Ac', 2 * N.y)
```
sympy.physics.mechanics.functions.kinetic_energy(frame, *body)
Kinetic energy of a multibody system.

**Parameters**

- **frame**: ReferenceFrame
  The frame in which the velocity or angular velocity of the body is defined.

- **body1, body2, body3...**: Particle and/or RigidBody
  The body (or bodies) whose kinetic energy is required.

**Explanation**

This function returns the kinetic energy of a system of Particle’s and/or RigidBody’s. The kinetic energy of such a system is equal to the sum of the kinetic energies of its constituents. Consider a system, S, comprising a rigid body, A, and a particle, P. The kinetic energy of the system, T, is equal to the vector sum of the kinetic energy of the particle, T1, and the kinetic energy of the rigid body, T2, i.e.

\[
T = T_1 + T_2
\]

Kinetic energy is a scalar.

**Examples**

```python
>>> from sympy.physics.mechanics import Point, Particle, ReferenceFrame
>>> from sympy.physics.mechanics import RigidBody, outer, kinetic_energy
>>> N = ReferenceFrame('N')
>>> O = Point('O')
>>> O.set_vel(N, 0 * N.x)
>>> P = O.locatenew('P', 1 * N.x)
>>> P.set_vel(N, 10 * N.x)
>>> Pa = Particle('Pa', P, 1)
>>> Ac = O.locatenew('Ac', 2 * N.y)
>>> Ac.set_vel(N, 5 * N.y)
>>> a = ReferenceFrame('a')
>>> a.set_ang_vel(N, 10 * N.z)
>>> I = outer(N.z, N.z)
>>> A = RigidBody('A', Ac, a, 20, (I, Ac))
>>> angular_momentum(O, N, Pa, A)
10*N.z

>>> kinetic_energy(N, Pa, A)
350
```
Potential energy of a multibody system.

Parameters

body1, body2, body3... : Particle and/or RigidBody

The body (or bodies) whose potential energy is required.

Explanation

This function returns the potential energy of a system of Particle’s and/or RigidBody’s. The potential energy of such a system is equal to the sum of the potential energy of its constituents. Consider a system, S, comprising a rigid body, A, and a particle, P. The potential energy of the system, V, is equal to the vector sum of the potential energy of the particle, V1, and the potential energy of the rigid body, V2, i.e.

\[ V = V_1 + V_2 \]

Potential energy is a scalar.

Examples

```python
>>> from sympy.physics.mechanics import Point, Particle, ReferenceFrame
>>> from sympy.physics.mechanics import RigidBody, outer, potential_energy
>>> from sympy import symbols

M, m, g, h = symbols('M m g h')
N = ReferenceFrame('N')
O = Point('O')
O.set_vel(N, 0 * N.x)
P = O.locatenew('P', 1 * N.x)
Pa = Particle('Pa', P, m)
Ac = O.locatenew('Ac', 2 * N.y)
a = ReferenceFrame('a')
I = outer(N.z, N.z)
A = RigidBody('A', Ac, a, M, (I, Ac))
Pa.potential_energy = m * g * h
A.potential_energy = M * g * h
potential_energy(Pa, A)
M*g*h + g*h*m
```

Lagrangian of a multibody system.

Parameters

frame : ReferenceFrame

The frame in which the velocity or angular velocity of the body is defined to determine the kinetic energy.

body1, body2, body3... : Particle and/or RigidBody

The body (or bodies) whose Lagrangian is required.
Explanation

This function returns the Lagrangian of a system of Particle’s and/or RigidBody’s. The Lagrangian of such a system is equal to the difference between the kinetic energies and potential energies of its constituents. If T and V are the kinetic and potential energies of a system then it’s Lagrangian, L, is defined as

\[ L = T - V \]

The Lagrangian is a scalar.

Examples

```python
>>> from sympy.physics.mechanics import Point, Particle, ReferenceFrame
>>> from sympy.physics.mechanics import RigidBody, outer, Lagrangian
>>> from sympy import symbols

>>> M, m, g, h = symbols('M m g h')
>>> N = ReferenceFrame('N')
>>> O = Point('O')
>>> O.set_vel(N, 0 * N.x)
>>> P = O.locatenew('P', 1 * N.x)
>>> P.set_vel(N, 10 * N.x)
>>> Pa = Particle('Pa', P, 1)
>>> Ac = O.locatenew('Ac', 2 * N.y)
>>> Ac.set_vel(N, 5 * N.y)
>>> a = ReferenceFrame('a')
>>> a.set_ang_vel(N, 10 * N.z)
>>> I = outer(N.z, N.z)
>>> A = RigidBody('A', Ac, a, 20, (I, Ac))
>>> Pa.potential_energy = m * g * h
>>> A.potential_energy = M * g * h
>>> Lagrangian(N, Pa, A)
-M*g*h - g*h*m + 350
```

Body (Docstrings)

class sympy.physics.mechanics.body.Body(name, masscenter=None, mass=None, frame=None, central_inertia=None)

Body is a common representation of either a RigidBody or a Particle SymPy object depending on what is passed in during initialization. If a mass is passed in and central_inertia is left as None, the Particle object is created. Otherwise a RigidBody object will be created.

Parameters

- **name** : String
  
  Defines the name of the body. It is used as the base for defining body specific properties.

- **masscenter** : Point, optional
  
  A point that represents the center of mass of the body or particle. If no point is given, a point is generated.
**mass** : Sympifyable, optional

A Sympifyable object which represents the mass of the body. If no mass is passed, one is generated.

**frame** : ReferenceFrame, optional

The ReferenceFrame that represents the reference frame of the body. If no frame is given, a frame is generated.

**central_inertia** : Dyadic, optional

Central inertia dyadic of the body. If none is passed while creating RigidBody, a default inertia is generated.

**Explanation**

The attributes that Body possesses will be the same as a Particle instance or a Rigid Body instance depending on which was created. Additional attributes are listed below.

**Examples**

Default behaviour. This results in the creation of a RigidBody object for which the mass, mass center, frame and inertia attributes are given default values.

```python
>>> from sympy.physics.mechanics import Body
>>> body = Body('name_of_body')
```

This next example demonstrates the code required to specify all of the values of the Body object. Note this will also create a RigidBody version of the Body object.

```python
>>> from sympy import Symbol
>>> from sympy.physics.mechanics import ReferenceFrame, Point, inertia
>>> from sympy.physics.mechanics import Body
>>> mass = Symbol('mass')
>>> masscenter = Point('masscenter')
>>> frame = ReferenceFrame('frame')
>>> ixx = Symbol('ixx')
>>> body_inertia = inertia(frame, ixx, 0, 0)
>>> body = Body('name_of_body', masscenter, mass, frame, body_inertia)
```

The minimal code required to create a Particle version of the Body object involves simply passing in a name and a mass.

```python
>>> from sympy import Symbol
>>> from sympy.physics.mechanics import Body
>>> mass = Symbol('mass')
>>> body = Body('name_of_body', mass=mass)
```

The Particle version of the Body object can also receive a masscenter point and a reference frame, just not an inertia.
Attributes

<table>
<thead>
<tr>
<th>name</th>
<th>(string) The body’s name</th>
</tr>
</thead>
<tbody>
<tr>
<td>mass-center</td>
<td>(Point) The point which represents the center of mass of the rigid body</td>
</tr>
<tr>
<td>frame</td>
<td>(ReferenceFrame) The reference frame which the body is fixed in</td>
</tr>
<tr>
<td>mass</td>
<td>(Sympifiable) The body’s mass</td>
</tr>
<tr>
<td>inertia</td>
<td>((Dyadic, Point) The body’s inertia around its center of mass. This attribute is specific to the rigid body form of Body and is left undefined for the Particle form</td>
</tr>
<tr>
<td>loads</td>
<td>(iterable) This list contains information on the different loads acting on the Body. Forces are listed as a (point, vector) tuple and torques are listed as (reference frame, vector) tuples</td>
</tr>
</tbody>
</table>

```
ang_vel_in(body)
Returns this body’s angular velocity with respect to the provided rigid body or reference frame.

Parameters

body: Body or ReferenceFrame
The rigid body or reference frame to calculate the angular velocity in.

Example
```
```python
>>> from sympy.physics.mechanics import Body, ReferenceFrame
>>> A = Body('A')
>>> N = ReferenceFrame('N')
>>> B = Body('B', frame=N)
>>> A.frame.set_ang_vel(N, 5*N.x)
>>> A.ang_vel_in(B)
5*N.x
>>> A.ang_vel_in(N)
5*N.x
```

apply_force(force, point=None, reaction_body=None, reaction_point=None)
Add force to the body(s).

Parameters

force: Vector
The force to be applied.

point: Point, optional
The point on self on which force is applied. By default self’s masscenter.

reaction_body: Body, optional
Second body on which equal and opposite force is to be applied.

reaction_point : Point, optional
The point on other body on which equal and opposite force is applied. By default masscenter of other body.

**Explanation**

Applies the force on self or equal and oppposite forces on self and other body if both are given on the desired point on the bodies. The force applied on other body is taken opposite of self, i.e, -force.

**Example**

```python
>>> from sympy import symbols
>>> from sympy.physics.mechanics import Body, Point, dynamicsymbols
>>> m, g = symbols('m g')
>>> B = Body('B')
>>> force1 = m*g*B.z
>>> B.apply_force(force1)  #Applying force on B's masscenter
>>> B.loads
[[(B_masscenter, g*m*B_frame.z)]]
```

We can also remove some part of force from any point on the body by adding the opposite force to the body on that point.

```python
>>> f1, f2 = dynamicsymbols('f1 f2')
>>> P = Point('P')  #Considering point P on body B
>>> B.apply_force(f1*B.x + f2*B.y, P)
>>> B.loads
[[(B_masscenter, g*m*B_frame.z), (P, f1(t)*B_frame.x + f2(t)*B_frame.y)]]
```

Let's remove f1 from point P on body B.

```python
>>> B.apply_force(-f1*B.x, P)
>>> B.loads
[[(B_masscenter, g*m*B_frame.z), (P, f2(t)*B_frame.y)]]
```

To further demonstrate the use of apply_force attribute, consider two bodies connected through a spring.

```python
>>> from sympy.physics.mechanics import Body, dynamicsymbols
>>> N = Body('N')  #Newtonian Frame
>>> x = dynamicsymbols('x')
>>> B1 = Body('B1')
>>> B2 = Body('B2')
>>> spring_force = x*N.x
```

Now let’s apply equal and opposite spring force to the bodies.

```python
>>> P1 = Point('P1')
>>> P2 = Point('P2')
>>> B1.apply_force(spring_force, point=P1, reaction_body=B2, reaction_point=P2)
```
We can check the loads(forces) applied to bodies now.

```python
>>> B1.loads
[(P1, x(t)*N_frame.x)]
>>> B2.loads
[(P2, -x(t)*N_frame.x)]
```

**Notes**

If a new force is applied to a body on a point which already has some force applied on it, then the new force is added to the already applied force on that point.

`apply_torque(torque, reaction_body=None)`

Add torque to the body(s).

**Parameters**

- **torque**: Vector
  - The torque to be applied.

- **reaction_body**: Body, optional
  - Second body on which equal and opposite torque is to be applied.

**Explanation**

Applies the torque on self or equal and opposite torquess on self and other body if both are given. The torque applied on other body is taken opposite of self, i.e, -torque.

**Example**

```python
>>> from sympy import symbols
>>> from sympy.physics.mechanics import Body, dynamicsymbols
>>> t = symbols('t')
>>> B = Body('B')
>>> torque1 = t*B.z
>>> B.apply_torque(torque1)
>>> B.loads
[(B_frame, t*B_frame.z)]
```

We can also remove some part of torque from the body by adding the opposite torque to the body.

```python
>>> t1, t2 = dynamicsymbols('t1 t2')
>>> B.apply_torque(t1*B.x + t2*B.y)
>>> B.loads
[(B_frame, t1(t)*B_frame.x + t2(t)*B_frame.y + t*B_frame.z)]
```

Let’s remove t1 from Body B.
To further demonstrate the use, let us consider two bodies such that a torque $T$ is acting on one body, and $-T$ on the other.

```python
from sympy.physics.mechanics import Body, dynamicsymbols
N = Body('N') #Newtonion frame
B1 = Body('B1')
B2 = Body('B2')
v = dynamicsymbols('v')
T = v*N.y #Torque

Now let's apply equal and opposite torque to the bodies.

```python
B1.apply_torque(T, B2)
```

We can check the loads (torques) applied to bodies now.

```python
B1.loads
[(B1_frame, v(t)*N_frame.y)]
B2.loads
[(B2_frame, - v(t)*N_frame.y)]
```

**Notes**

If a new torque is applied on body which already has some torque applied on it, then the new torque is added to the previous torque about the body’s frame.

**clear_loads()**

Clears the Body’s loads list.

**Example**

```python
from sympy.physics.mechanics import Body
B = Body('B')
force = B.x + B.y
B.apply_force(force)
B.loads
[(B_masscenter, B_frame.x + B_frame.y)]
B.clear_loads()
B.loads
[]
```

**dcm(body)**

Returns the direction cosine matrix of this body relative to the provided rigid body or reference frame.

**Parameters**

- **body**: Body or ReferenceFrame
The rigid body or reference frame to calculate the dcm.

**Example**

```python
>>> from sympy.physics.mechanics import Body
>>> A = Body('A')
>>> B = Body('B')
>>> A.frame.orient_axis(B.frame, B.frame.x, 5)
>>> A.dcm(B)
Matrix([[1, 0, 0], [0, cos(5), sin(5)], [0, -sin(5), cos(5)]])
>>> A.dcm(B.frame)
Matrix([[1, 0, 0], [0, cos(5), sin(5)], [0, -sin(5), cos(5)]])
```

**property inertia**

The body’s inertia about a point; stored as (Dyadic, Point).

**kinetic_energy**(frame)

Kinetic energy of the body.

**Parameters**

- **frame**: ReferenceFrame or Body

  The Body’s angular velocity and the velocity of it’s mass center are typically defined with respect to an inertial frame but any relevant frame in which the velocities are known can be supplied.

**Examples**

```python
>>> from sympy.physics.mechanics import Body, ReferenceFrame, Point
>>> from sympy import symbols
>>> m, v, r, omega = symbols('m v r omega')
>>> N = ReferenceFrame('N')
>>> O = Point('O')
>>> P = Body('P', masscenter=O, mass=m)
>>> P.masscenter.set_vel(N, v * N.y)
>>> P.kinetic_energy(N)
m*v**2/2

>>> N = ReferenceFrame('N')
>>> b = ReferenceFrame('b')
>>> b.set_ang_vel(N, omega * b.x)
>>> P = Point('P')
>>> P.set_vel(N, v * N.x)
>>> B = Body('B', masscenter=P, frame=b)
>>> B.kinetic_energy(N)
B.ixx*omega**2/2 + B.mass*v**2/2
```
masscenter_vel(body)

Returns the velocity of the mass center with respect to the provided rigid body or reference frame.

Parameters

body: Body or ReferenceFrame

The rigid body or reference frame to calculate the velocity in.

Example

```python
>>> from sympy.physics.mechanics import Body
>>> A = Body('A')
>>> B = Body('B')
>>> A.masscenter.set_vel(B.frame, 5*B.frame.x)
>>> A.masscenter_vel(B)
5*B_frame.x
>>> A.masscenter_vel(B.frame)
5*B_frame.x
```

parallel_axis(point, frame=None)

Returns the inertia dyadic of the body with respect to another point.

Parameters

point : sympy.physics.vector.Point

The point to express the inertia dyadic about.

frame : sympy.physics.vector.ReferenceFrame

The reference frame used to construct the dyadic.

Returns

inertia : sympy.physics.vector.Dyadic

The inertia dyadic of the rigid body expressed about the provided point.

Example

```python
>>> from sympy.physics.mechanics import Body
>>> A = Body('A')
>>> P = A.masscenter.locatenew('point', 3 * A.x + 5 * A.y)
>>> A.parallel_axis(P).to_matrix(A.frame)
Matrix([[A_ixx + 25*A_mass, A_iyx - 15*A_mass, A_izx],
        [A_iyx - 15*A_mass, A_iyy + 9*A_mass, A_iyz],
        [A_izx, A_iyz, A_izz + 34*A_mass]])
```
remove_load(about=None)

Remove load about a point or frame.

Parameters

about : Point or ReferenceFrame, optional

The point about which force is applied, and is to be removed. If about
is None, then the torque about self’s frame is removed.

Example

```python
>>> from sympy.physics.mechanics import Body, Point
>>> B = Body('B')
>>> P = Point('P')
>>> f1 = B.x
>>> f2 = B.y
>>> B.apply_force(f1)
>>> B.apply_force(f2, P)
>>> B.loads
[(B_masscenter, B_frame.x), (P, B_frame.y)]

>>> B.remove_load(P)
>>> B.loads
[(B_masscenter, B_frame.x)]
```

property x

The basis Vector for the Body, in the x direction.

property y

The basis Vector for the Body, in the y direction.

property z

The basis Vector for the Body, in the z direction.

Kane’s Method & Lagrange’s Method (Docstrings)

class sympy.physics.mechanics.kane.KanesMethod(frame, q_ind, u_ind, kd_eqs=None, q_dependent=None, configuration_constraints=None, u_dependent=None, velocity_constraints=None, acceleration_constraints=None, u_auxiliary=None, bodies=None, forcelist=None, explicit_kinematics=True)

Kane’s method object.
Explanation

This object is used to do the "book-keeping" as you go through and form equations of motion in the way Kane presents in: Kane, T., Levinson, D. Dynamics Theory and Applications. 1985 McGraw-Hill

The attributes are for equations in the form [M] udot = forcing.

Notes

The mass matrices and forcing vectors related to kinematic equations are given in the explicit form by default. In other words, the kinematic mass matrix is \( k_{kq} = I \). In order to get the implicit form of those matrices/vectors, you can set the `explicit_kinematics` attribute to `False`. So \( k_{kq} \) is not necessarily an identity matrix. This can provide more compact equations for non-simple kinematics (see #22626).

Examples

This is a simple example for a one degree of freedom translational spring-mass-damper. In this example, we first need to do the kinematics. This involves creating generalized speeds and coordinates and their derivatives. Then we create a point and set its velocity in a frame.

```python
>>> from sympy import symbols
>>> from sympy.physics.mechanics import dynamicsymbols, ReferenceFrame
>>> from sympy.physics.mechanics import Point, Particle, KanesMethod
>>> q, u = dynamicsymbols('q u')
>>> qd, ud = dynamicsymbols('q u', 1)
>>> m, c, k = symbols('m c k')
>>> N = ReferenceFrame('N')
>>> P = Point('P')
>>> P.set_vel(N, u * N.x)
```

Next we need to arrange/store information in the way that KanesMethod requires. The kinematic differential equations need to be stored in a dict. A list of forces/torques must be constructed, where each entry in the list is a (Point, Vector) or (ReferenceFrame, Vector) tuple, where the Vectors represent the Force or Torque. Next a particle needs to be created, and it needs to have a point and mass assigned to it. Finally, a list of all bodies and particles needs to be created.

```python
>>> kd = [qd - u]
>>> FL = [(P, (-k * q - c * u) * N.x)]
>>> pa = Particle('pa', P, m)
>>> BL = [pa]
```

Finally we can generate the equations of motion. First we create the KanesMethod object and supply an inertial frame, coordinates, generalized speeds, and the kinematic differential equations. Additional quantities such as configuration and motion constraints, dependent coordinates and speeds, and auxiliary speeds are also supplied here (see the online documentation). Next we form \( FR^* \) and \( FR \) to complete: \( Fr + Fr^* = 0 \). We have the equations of motion at this point. It makes sense to rearrange them though, so we calculate the mass matrix and the forcing terms, for E.o.M. in the form: \([MM]\) udot =
forcing, where MM is the mass matrix, udot is a vector of the time derivatives of the generalized speeds, and forcing is a vector representing “forcing” terms.

```python
>>> KM = KanesMethod(N, q_ind=[q], u_ind=[u], kd_eqs=kd)
>>> (fr, frstar) = KM.kanes_equations(BL, FL)
>>> forcing = KM.forcing
>>> rhs = MM.inv() * forcing
>>> rhs
Matrix([[(-c*u(t) - k*q(t))/m]])
>>> KM.linearize(A_and_B=True)[0]
Matrix([ 0, 1],
[-k/m, -c/m]])
```

Please look at the documentation pages for more information on how to perform linearization and how to deal with dependent coordinates & speeds, and how do deal with bringing non-contributing forces into evidence.

</tbody>
</table>

**property auxiliary_eqs**

A matrix containing the auxiliary equations.

**property forcing**

The forcing vector of the system.

**property forcing_full**

The forcing vector of the system, augmented by the kinematic differential equations in explicit or implicit form.

**property forcing_kin**

The kinematic “forcing vector” of the system.
**kanes_equations** *(bodies=None, loads=None)*

Method to form Kane’s equations, \( Fr + Fr^* = 0 \).

**Parameters**

**bodies** : iterable

An iterable of all RigidBody’s and Particle’s in the system. A system must have at least one body.

**loads** : iterable

Takes in an iterable of (Particle, Vector) or (ReferenceFrame, Vector) tuples which represent the force at a point or torque on a frame. Must be either a non-empty iterable of tuples or None which corresponds to a system with no constraints.

**Explanation**

Returns \((Fr, Fr^*)\). In the case where auxiliary generalized speeds are present (say, \( s \) auxiliary speeds, \( o \) generalized speeds, and \( m \) motion constraints) the length of the returned vectors will be \( o - m + s \) in length. The first \( o - m \) equations will be the constrained Kane’s equations, then the \( s \) auxiliary Kane’s equations. These auxiliary equations can be accessed with the auxiliary_eqs property.

**kindiffdict()**

Returns a dictionary mapping \( q' \) to \( u \).

**linearize**, *(new_method=None, **kwargs)*

Linearize the equations of motion about a symbolic operating point.

**Explanation**

If kwarg \( A_and_B \) is False (default), returns \( M, A, B, r \) for the linearized form, \( M*[q', u']^T = A*[q_ind, u_ind]^T + B*r \).

If kwarg \( A_and_B \) is True, returns \( A, B, r \) for the linearized form \( dx = A*x + B*r \), where \( x = [q_ind, u_ind]^T \). Note that this is computationally intensive if there are many symbolic parameters. For this reason, it may be more desirable to use the default \( A_and_B=False \), returning \( M, A, \) and \( B \). Values may then be substituted in to these matrices, and the state space form found as \( A = P^T*M.inv()*A, B = P^T*M.inv()*B, \) where \( P = \text{Linearizer.perm_mat} \).

In both cases, \( r \) is found as all dynamicsymbols in the equations of motion that are not part of \( q, u, q' \), or \( u' \). They are sorted in canonical form.

The operating points may be also entered using the \( \text{op_point} \) kwarg. This takes a dictionary of \{symbol: value\}, or a an iterable of such dictionaries. The values may be numeric or symbolic. The more values you can specify beforehand, the faster this computation will run.

For more documentation, please see the Linearizer class.

**property mass_matrix**

The mass matrix of the system.
property mass_matrix_full

The mass matrix of the system, augmented by the kinematic differential equations in explicit or implicit form.

property mass_matrix_kin

The kinematic “mass matrix” $k_{kq}$ of the system.

rhs(inv_method=None)

Returns the system’s equations of motion in first order form. The output is the right hand side of:

$$
\begin{align*}
\dot{x} &= \begin{bmatrix} \dot{q} \\ \dot{u} \end{bmatrix} := f(q, u, r, p, t) \\
\end{align*}
$$

The right hand side is what is needed by most numerical ODE integrators.

Parameters

inv_method : str

The specific sympy inverse matrix calculation method to use. For a list of valid methods, see inv() (page 1340)

to_linearizer()

Returns an instance of the Linearizer class, initiated from the data in the Kane's Method class. This may be more desirable than using the linearize class method, as the Linearizer object will allow more efficient recalculation (i.e. about varying operating points).

class sympy.physics.mechanics.lagrange.LagrangesMethod(Lagrangian, qs, forcelist=None, bodies=None, frame=None, hol_coneqs=None, nonhol_coneqs=None)

Lagrange’s method object.

Explanation

This object generates the equations of motion in a two step procedure. The first step involves the initialization of LagrangesMethod by supplying the Lagrangian and the generalized coordinates, at the bare minimum. If there are any constraint equations, they can be supplied as keyword arguments. The Lagrange multipliers are automatically generated and are equal in number to the constraint equations. Similarly any non-conservative forces can be supplied in an iterable (as described below and also shown in the example) along with a ReferenceFrame. This is also discussed further in the __init__ method.
Examples

This is a simple example for a one degree of freedom translational spring-mass-damper. In this example, we first need to do the kinematics. This involves creating generalized coordinates and their derivatives. Then we create a point and set its velocity in a frame.

```python
>>> from sympy.physics.mechanics import LagrangesMethod, Lagrangian
>>> from sympy.physics.mechanics import ReferenceFrame, Particle, Point
>>> from sympy.physics.mechanics import dynamicsymbols
>>> from sympy import symbols

>>> q = dynamicsymbols('q')
>>> qd = dynamicsymbols('q', 1)
>>> m, k, b = symbols('m k b')
>>> N = ReferenceFrame('N')
>>> P = Point('P')
>>> P.set_vel(N, qd * N.x)
```

We need to then prepare the information as required by LagrangesMethod to generate equations of motion. First we create the Particle, which has a point attached to it. Following this the lagrangian is created from the kinetic and potential energies. Then, an iterable of nonconservative forces/torques must be constructed, where each item is a (Point, Vector) or (ReferenceFrame, Vector) tuple, with the Vectors representing the nonconservative forces or torques.

```python
>>> Pa = Particle('Pa', P, m)
>>> Pa.potential_energy = k * q**2 / 2.0
>>> L = Lagrangian(N, Pa)
>>> fl = [(P, -b * qd * N.x)]
```

Finally we can generate the equations of motion. First we create the LagrangesMethod object. To do this one must supply the Lagrangian, and the generalized coordinates. The constraint equations, the force list, and the inertial frame may also be provided, if relevant. Next we generate Lagrange’s equations of motion, such that: Lagrange’s equations of motion = 0. We have the equations of motion at this point.

```python
>>> l = LagrangesMethod(L, [q], forcelist = fl, frame = N)
>>> print(l.form_lagranges_equations())
Matrix([[b*Derivative(q(t), t) + 1.0*k*q(t) + m*Derivative(q(t), (t, 2))]])
```

We can also solve for the states using the ‘rhs’ method.

```python
>>> print(l.rhs())
Matrix([[Derivative(q(t), t)], [(-b*Derivative(q(t), t) - 1.0*k*q(t))/m]])
```

Please refer to the docstrings on each method for more details.

property forcing

Returns the forcing vector from ‘lagranges_equations’ method.

property forcing_full

Augments qdots to the forcing vector above.

form_lagranges_equations()

Method to form Lagrange’s equations of motion.

Returns a vector of equations of motion using Lagrange’s equations of the second kind.

linearize(q_ind=None, qd_ind=None, q_dep=None, qd_dep=None, **kwargs)

Linearize the equations of motion about a symbolic operating point.

Explanation

If kwarg A and B is False (default), returns M, A, B, r for the linearized form, M*[q’, u’]^T = A*[q_ind, u_ind]^T + B*r.

If kwarg A and B is True, returns A, B, r for the linearized form dx = A*x + B*r, where x = [q_ind, u_ind]^T. Note that this is computationally intensive if there are many symbolic parameters. For this reason, it may be more desirable to use the default A and B=False, returning M, A, and B. Values may then be substituted in to these matrices, and the state space form found as A = P*T*M.inv()*A, B = P*T*M.inv()*B, where P = Linearizer:perm_mat.

In both cases, r is found as all dynamicsymbols in the equations of motion that are not part of q, u, q’, or u’. They are sorted in canonical form.

The operating points may be also entered using the op_point kwarg. This takes a dictionary of {symbol: value}, or a an iterable of such dictionaries. The values may be numeric or symbolic. The more values you can specify beforehand, the faster this computation will run.

For more documentation, please see the Linearizer class.

property mass_matrix

Returns the mass matrix, which is augmented by the Lagrange multipliers, if necessary.
**Explanation**

If the system is described by ‘n’ generalized coordinates and there are no constraint equations then an n X n matrix is returned.

If there are ‘n’ generalized coordinates and ‘m’ constraint equations have been supplied during initialization then an n X (n+m) matrix is returned. The (n + m - 1)th and (n + m)th columns contain the coefficients of the Lagrange multipliers.

**property mass_matrix_full**

Augments the coefficients of qdots to the mass_matrix.

**rhs**(inv_method=None, **kwargs)

Returns equations that can be solved numerically.

**Parameters**

inv_method : str

The specific sympy inverse matrix calculation method to use. For a list of valid methods, see inv() (page 1340)

**solve_multipliers**(op_point=None, sol_type='dict')

Solves for the values of the lagrange multipliers symbolically at the specified operating point.

**Parameters**

op_point : dict or iterable of dicts, optional

Point at which to solve at. The operating point is specified as a dictionary or iterable of dictionaries of {symbol: value}. The value may be numeric or symbolic itself.

sol_type : str, optional

Solution return type. Valid options are: - ‘dict’: A dict of {symbol : value} (default) - 'Matrix': An ordered column matrix of the solution

**to_linearizer**(q_ind=None, qd_ind=None, q_dep=None, qd_dep=None)

Returns an instance of the Linearizer class, initiated from the data in the Lagranges-Method class. This may be more desirable than using the linearize class method, as the Linearizer object will allow more efficient recalculation (i.e. about varying operating points).

**Parameters**

q_ind, qd_ind : array_like, optional

The independent generalized coordinates and speeds.

q_dep, qd_dep : array_like, optional

The dependent generalized coordinates and speeds.
class sympy.physics.mechanics.joint.Joint(name, parent, child, coordinates=None, speeds=None, parent_point=None, child_point=None, parent_axis=None, child_axis=None, parent_interframe=None, child_interframe=None, parent_joint_pos=None, child_joint_pos=None)

Abstract base class for all specific joints.

**Parameters**

- **name** : string
  A unique name for the joint.

- **parent** : Body
  The parent body of joint.

- **child** : Body
  The child body of joint.

- **coordinates** : iterable of dynamicsymbols, optional
  Generalized coordinates of the joint.

- **speeds** : iterable of dynamicsymbols, optional
  Generalized speeds of joint.

- **parent_point** : Point or Vector, optional
  Attachment point where the joint is fixed to the parent body. If a vector is provided, then the attachment point is computed by adding the vector to the body’s mass center. The default value is the parent’s mass center.

- **child_point** : Point or Vector, optional
  Attachment point where the joint is fixed to the child body. If a vector is provided, then the attachment point is computed by adding the vector to the body’s mass center. The default value is the child’s mass center.

- **parent_axis** : Vector, optional
  Deprecated since version 1.12: Axis fixed in the parent body which aligns with an axis fixed in the child body. The default is the x axis of parent’s reference frame. For more information on this deprecation, see *New Joint intermediate frames* (page 215).

- **child_axis** : Vector, optional
  Deprecated since version 1.12: Axis fixed in the child body which aligns with an axis fixed in the parent body. The default is the x axis of child’s reference frame. For more information on this deprecation, see *New Joint intermediate frames* (page 215).
**parent_interframe** : ReferenceFrame, optional

Intermediate frame of the parent body with respect to which the joint transformation is formulated. If a Vector is provided then an inter-frame is created which aligns its X axis with the given vector. The default value is the parent’s own frame.

**child_interframe** : ReferenceFrame, optional

Intermediate frame of the child body with respect to which the joint transformation is formulated. If a Vector is provided then an inter-frame is created which aligns its X axis with the given vector. The default value is the child’s own frame.

**parent_joint_pos** : Point or Vector, optional

Deprecated since version 1.12: This argument is replaced by parent point and will be removed in a future version. See Change in joint attachment point argument (page 216) for more information.

**child_joint_pos** : Point or Vector, optional

Deprecated since version 1.12: This argument is replaced by child_point and will be removed in a future version. See Change in joint attachment point argument (page 216) for more information.

**Explanation**

A joint subtracts degrees of freedom from a body. This is the base class for all specific joints and holds all common methods acting as an interface for all joints. Custom joint can be created by inheriting Joint class and defining all abstract functions.

The abstract methods are:

- `_generate_coordinates`
- `_generate_speeds`
- `_orient_frames`
- `_set_angular_velocity`
- `_set_linear_velocity`

**Notes**

When providing a vector as the intermediate frame, a new intermediate frame is created which aligns its X axis with the provided vector. This is done with a single fixed rotation about a rotation axis. This rotation axis is determined by taking the cross product of the body.x axis with the provided vector. In the case where the provided vector is in the -body.x direction, the rotation is done about the body.y axis.

- Matrix of the joint’s generalized speeds.
class sympy.physics.mechanics.joint.PinJoint(name, parent, child, 
coordinates=None, speeds=None, 
parent_point=None, parent_axis=None, 
child_point=None, child_axis=None, 
parent_interframe=None, child_interframe=None, 
joint_axis=None, 
parent_joint_pos=None, child_joint_pos=None)

Pin (Revolute) Joint.

**Parameters**

- **name**: string
  A unique name for the joint.

- **parent**: Body
  The parent body of joint.

- **child**: Body
  The child body of joint.

- **coordinates**: dynamicsymbol, optional
  Generalized coordinates of the joint.

- **speeds**: dynamicsymbol, optional
  Generalized speeds of joint.
**parent_point** : Point or Vector, optional
Attachment point where the joint is fixed to the parent body. If a vector is provided, then the attachment point is computed by adding the vector to the body’s mass center. The default value is the parent’s mass center.

**child_point** : Point or Vector, optional
Attachment point where the joint is fixed to the child body. If a vector is provided, then the attachment point is computed by adding the vector to the body’s mass center. The default value is the child’s mass center.

**parent_axis** : Vector, optional
Deprecated since version 1.12: Axis fixed in the parent body which aligns with an axis fixed in the child body. The default is the x axis of parent’s reference frame. For more information on this deprecation, see *New Joint intermediate frames* (page 215).

**child_axis** : Vector, optional
Deprecated since version 1.12: Axis fixed in the child body which aligns with an axis fixed in the parent body. The default is the x axis of child’s reference frame. For more information on this deprecation, see *New Joint intermediate frames* (page 215).

**parent_interframe** : ReferenceFrame, optional
Intermediate frame of the parent body with respect to which the joint transformation is formulated. If a Vector is provided then an interframe is created which aligns its X axis with the given vector. The default value is the parent’s own frame.

**child_interframe** : ReferenceFrame, optional
Intermediate frame of the child body with respect to which the joint transformation is formulated. If a Vector is provided then an interframe is created which aligns its X axis with the given vector. The default value is the child’s own frame.

**joint_axis** : Vector
The axis about which the rotation occurs. Note that the components of this axis are the same in the parent_interframe and child_interframe.

**parent_joint_pos** : Point or Vector, optional
Deprecated since version 1.12: This argument is replaced by parent_point and will be removed in a future version. See *Change in joint attachment point argument* (page 216) for more information.

**child_joint_pos** : Point or Vector, optional
Deprecated since version 1.12: This argument is replaced by child_point and will be removed in a future version. See *Change in joint attachment point argument* (page 216) for more information.
**Explanation**

A pin joint is defined such that the joint rotation axis is fixed in both the child and parent and the location of the joint is relative to the mass center of each body. The child rotates an angle, $\theta$, from the parent about the rotation axis and has a simple angular speed, $\omega$, relative to the parent. The direction cosine matrix between the child interframe and parent interframe is formed using a simple rotation about the joint axis. The page on the joints framework gives a more detailed explanation of the intermediate frames.

**Examples**

A single pin joint is created from two bodies and has the following basic attributes:

```python
>>> from sympy.physics.mechanics import Body, PinJoint
>>> parent = Body('P')
>>> child = Body('C')
>>> joint = PinJoint('PC', parent, child)
```

To further demonstrate the use of the pin joint, the kinematics of simple double pendulum that rotates about the Z axis of each connected body can be created as follows.
First create bodies to represent the fixed ceiling and one to represent each pendulum bob.

```python
>>> ceiling = Body('C')
>>> upper_bob = Body('U')
>>> lower_bob = Body('L')
```

The first joint will connect the upper bob to the ceiling by a distance of \(l_1\) and the joint axis will be about the Z axis for each body.

```python
>>> ceiling_joint = PinJoint('P1', ceiling, upper_bob,
... child_point=-l1*upper_bob.frame.x,
... joint_axis=ceiling.frame.z)
```

The second joint will connect the lower bob to the upper bob by a distance of \(l_2\) and the joint axis will also be about the Z axis for each body.

```python
>>> pendulum_joint = PinJoint('P2', upper_bob, lower_bob,
... child_point=-l2*lower_bob.frame.x,
... joint_axis=upper_bob.frame.z)
```

Once the joints are established the kinematics of the connected bodies can be accessed. First the direction cosine matrices of pendulum link relative to the ceiling are found:

```python
>>> upper_bob.frame.dcm(ceiling.frame)
Matrix([%
[ cos(q_P1(t)), sin(q_P1(t)), 0],
[-sin(q_P1(t)), cos(q_P1(t)), 0],
[ 0, 0, 1]])
```

```python
>>> trigsimp(lower_bob.frame.dcm(ceiling.frame))
Matrix([%
[ cos(q_P1(t) + q_P2(t)), sin(q_P1(t) + q_P2(t)), 0],
[-sin(q_P1(t) + q_P2(t)), cos(q_P1(t) + q_P2(t)), 0],
[ 0, 0, 1]])
```

The position of the lower bob’s masscenter is found with:

```python
>>> lower_bob.masscenter.pos_from(ceiling.masscenter)
l1*U_frame.x + l2*L_frame.x
```

The angular velocities of the two pendulum links can be computed with respect to the ceiling.

```python
>>> upper_bob.frame.ang_vel_in(ceiling.frame)
u_P1(t)*C_frame.z
```

```python
>>> lower_bob.frame.ang_vel_in(ceiling.frame)
u_P1(t)*C_frame.z + u_P2(t)*U_frame.z
```

And finally, the linear velocities of the two pendulum bobs can be computed with respect to the ceiling.
>>> upper_bob.masscenter.vel(ceiling.frame)
l1*u_P1(t)*U_frame.y
>>> lower_bob.masscenter.vel(ceiling.frame)
l1*u_P1(t)*U_frame.y + l2*(u_P1(t) + u_P2(t))*L_frame.y

property joint_axis

Axis about which the child rotates with respect to the parent.

class sympy.physics.mechanics.joint.PrismaticJoint(name, parent, child, coordinates=None, speeds=None, parent_point=None, child_point=None, parent_axis=None, child_axis=None, parent_interframe=None, child_interframe=None, joint_axis=None, parent_joint_pos=None, child_joint_pos=None)

Prismatic (Sliding) Joint.
Parameters

name : string
A unique name for the joint.

parent : Body
The parent body of joint.

child : Body
The child body of joint.

coordinates : dynamicsymbol, optional
Generalized coordinates of the joint. The default value is
dynamicsymbols(f'q_{joint.name}').

speeds : dynamicsymbol, optional
Generalized speeds of joint. The default value is
dynamicsymbols(f'u_{joint.name}').

parent_point : Point or Vector, optional
Attachment point where the joint is fixed to the parent body. If a
vector is provided, then the attachment point is computed by adding
the vector to the body’s mass center. The default value is the parent’s
mass center.

child_point : Point or Vector, optional
Attachment point where the joint is fixed to the child body. If a vector
is provided, then the attachment point is computed by adding the
vector to the body’s mass center. The default value is the child’s mass center.

**parent_axis** : Vector, optional

Deprecated since version 1.12: Axis fixed in the parent body which aligns with an axis fixed in the child body. The default is the x axis of parent’s reference frame. For more information on this deprecation, see *New Joint intermediate frames* (page 215).

**child_axis** : Vector, optional

Deprecated since version 1.12: Axis fixed in the child body which aligns with an axis fixed in the parent body. The default is the x axis of child’s reference frame. For more information on this deprecation, see *New Joint intermediate frames* (page 215).

**parent_interframe** : ReferenceFrame, optional

Intermediate frame of the parent body with respect to which the joint transformation is formulated. If a Vector is provided then an inter-frame is created which aligns its X axis with the given vector. The default value is the parent’s own frame.

**child_interframe** : ReferenceFrame, optional

Intermediate frame of the child body with respect to which the joint transformation is formulated. If a Vector is provided then an inter-frame is created which aligns its X axis with the given vector. The default value is the child’s own frame.

**joint_axis** : Vector

The axis along which the translation occurs. Note that the components of this axis are the same in the parent_interframe and child_interframe.

**parent_joint_pos** : Point or Vector, optional

Deprecated since version 1.12: This argument is replaced by parent_point and will be removed in a future version. See *Change in joint attachment point argument* (page 216) for more information.

**child_joint_pos** : Point or Vector, optional

Deprecated since version 1.12: This argument is replaced by child_point and will be removed in a future version. See *Change in joint attachment point argument* (page 216) for more information.

**Explanation**

It is defined such that the child body translates with respect to the parent body along the body-fixed joint axis. The location of the joint is defined by two points, one in each body, which coincide when the generalized coordinate is zero. The direction cosine matrix between the parent_interframe and child_interframe is the identity matrix. Therefore, the direction cosine matrix between the parent and child frames is fully defined by the definition of the intermediate frames. The page on the joints framework gives a more detailed explanation of the intermediate frames.
Examples

A single prismatic joint is created from two bodies and has the following basic attributes:

```python
>>> from sympy.physics.mechanics import Body, PrismaticJoint
>>> parent = Body('P')
>>> parent
P
>>> child = Body('C')
>>> child
C
>>> joint = PrismaticJoint('PC', parent, child)
>>> joint
PrismaticJoint: PC parent: P child: C
>>> joint.name
'PC'
>>> joint.parent
P
>>> joint.child
C
>>> joint.parent_point
P_masscenter
>>> joint.child_point
C_masscenter
>>> joint.parent_axis
P_frame.x
>>> joint.child_axis
C_frame.x
>>> joint.coordinates
Matrix([[q_PC(t)])
>>> joint.speeds
Matrix([[u_PC(t)])
>>> joint.child.frame.ang_vel_in(joint.parent.frame)
0
>>> joint.child.frame.dcm(joint.parent.frame)
Matrix([ [1, 0, 0], [0, 1, 0], [0, 0, 1]])
>>> joint.child_point.pos_from(joint.parent_point)
q_PC(t)*P_frame.x
```

To further demonstrate the use of the prismatic joint, the kinematics of two masses sliding, one moving relative to a fixed body and the other relative to the moving body about the X axis of each connected body can be created as follows.

```python
>>> from sympy.physics.mechanics import PrismaticJoint, Body
```

First create bodies to represent the fixed ceiling and one to represent a particle.

```python
>>> wall = Body('W')
>>> Part1 = Body('P1')
>>> Part2 = Body('P2')
```
The first joint will connect the particle to the ceiling and the joint axis will be about the X axis for each body.

\[
\text{>>> } J1 = \text{PrismaticJoint('J1', wall, Part1)}
\]

The second joint will connect the second particle to the first particle and the joint axis will also be about the X axis for each body.

\[
\text{>>> } J2 = \text{PrismaticJoint('J2', Part1, Part2)}
\]

Once the joint is established the kinematics of the connected bodies can be accessed. First the direction cosine matrices of Part relative to the ceiling are found:

\[
\text{>>> Part1.dcm(wall)}
\text{Matrix(}
\begin{bmatrix}
1, 0, 0, \\
0, 1, 0, \\
0, 0, 1
\end{bmatrix}
\]

\[
\text{>>> Part2.dcm(wall)}
\text{Matrix(}
\begin{bmatrix}
1, 0, 0, \\
0, 1, 0, \\
0, 0, 1
\end{bmatrix}
\]

The position of the particles' mass center is found with:

\[
\text{>>> Part1.masscenter.pos_from(wall.masscenter)}
q_{J1(t)}*W_{frame}.x
\]

\[
\text{>>> Part2.masscenter.pos_from(wall.masscenter)}
q_{J1(t)}*W_{frame}.x + q_{J2(t)}*P1_{frame}.x
\]

The angular velocities of the two particle links can be computed with respect to the ceiling.

\[
\text{>>> Part1.ang_vel_in(wall)}
0
\]

\[
\text{>>> Part2.ang_vel_in(wall)}
0
\]

And finally, the linear velocities of the two particles can be computed with respect to the ceiling.

\[
\text{>>> Part1.masscenter_vel(wall)}
u_{J1(t)}*W_{frame}.x
\]

\[
\text{>>> Part2.masscenter.vel(wall.frame)}
u_{J1(t)}*W_{frame}.x + \text{Derivative}(q_{J2(t)}, t)*P1_{frame}.x
\]

**property joint_axis**

Axis along which the child translates with respect to the parent.

```python
class sympy.physics.mechanics.joint.CylindricalJoint(name, parent, child,
rotation_coordinate=None, translation_coordinate=None, rotation_speed=None, translation_speed=None,
parent_point=None, child_point=None, parent_interframe=None, child_interframe=None, joint_axis=None)
```

Cylindrical Joint.
Parameters

**name** : string

A unique name for the joint.

**parent** : Body

The parent body of joint.

**child** : Body

The child body of joint.

**rotation_coordinate** : dynamicsymbol, optional

Generalized coordinate corresponding to the rotation angle. The default value is `dynamicsymbols(f'q0_{joint.name}')`.

**translation_coordinate** : dynamicsymbol, optional

Generalized coordinate corresponding to the translation distance. The default value is `dynamicsymbols(f'q1_{joint.name}')`.

**rotation_speed** : dynamicsymbol, optional

Generalized speed corresponding to the angular velocity. The default value is `dynamicsymbols(f'u0_{joint.name}')`.

**translation_speed** : dynamicsymbol, optional

Generalized speed corresponding to the translation velocity. The default value is `dynamicsymbols(f'u1_{joint.name}')`.

**parent_point** : Point or Vector, optional

Attachment point where the joint is fixed to the parent body. If a vector is provided, then the attachment point is computed by adding the vector to the body’s mass center. The default value is the parent’s mass center.

**child_point** : Point or Vector, optional
Attachment point where the joint is fixed to the child body. If a vector is provided, then the attachment point is computed by adding the vector to the body’s mass center. The default value is the child’s mass center.

**parent_interframe**: ReferenceFrame, optional

Intermediate frame of the parent body with respect to which the joint transformation is formulated. If a Vector is provided then an interframe is created which aligns its X axis with the given vector. The default value is the parent’s own frame.

**child_interframe**: ReferenceFrame, optional

Intermediate frame of the child body with respect to which the joint transformation is formulated. If a Vector is provided then an interframe is created which aligns its X axis with the given vector. The default value is the child’s own frame.

**joint_axis**: Vector, optional

The rotation as well as translation axis. Note that the components of this axis are the same in the parent_interframe and child_interframe.

**Explanation**

A cylindrical joint is defined such that the child body both rotates about and translates along the body-fixed joint axis with respect to the parent body. The joint axis is both the rotation axis and translation axis. The location of the joint is defined by two points, one in each body, which coincide when the generalized coordinate corresponding to the translation is zero. The direction cosine matrix between the child interframe and parent interframe is formed using a simple rotation about the joint axis. The page on the joints framework gives a more detailed explanation of the intermediate frames.

**Examples**

A single cylindrical joint is created between two bodies and has the following basic attributes:

```python
>>> from sympy.physics.mechanics import Body, CylindricalJoint
>>> parent = Body('P')
>>> parent
P
>>> child = Body('C')
>>> child
C
>>> joint = CylindricalJoint('PC', parent, child)
>>> joint
CylindricalJoint: PC  parent: P  child: C
>>> joint.name
'PC'
>>> joint.parent
P
>>> joint.child
```
C
>>> joint.parent_point
P_masscenter
>>> joint.child_point
C_masscenter
>>> joint.parent_axis
P_frame.x
>>> joint.child_axis
C_frame.x
>>> joint.coordinates
Matrix([[q0_PC(t)],
        [q1_PC(t)]])
>>> joint.speeds
Matrix([[u0_PC(t)],
        [u1_PC(t)]])
>>> joint.child.frame.ang_vel_in(joint.parent.frame)
u0_PC(t)*P_frame.x
>>> joint.child.frame.dcm(joint.parent.frame)
Matrix([[1, 0, 0],
        [0, cos(q0_PC(t)), sin(q0_PC(t))],
        [0, -sin(q0_PC(t)), cos(q0_PC(t))]])
>>> joint.child_point.pos_from(joint.parent_point)
q1_PC(t)*P_frame.x
>>> child.masscenter.vel(parent.frame)
u1_PC(t)*P_frame.x

To further demonstrate the use of the cylindrical joint, the kinematics of two cylindrical joints perpendicular to each other can be created as follows.

```python
>>> from sympy import symbols
>>> from sympy.physics.mechanics import Body, CylindricalJoint
>>> r, l, w = symbols('r l w')
```

First create bodies to represent the fixed floor with a fixed pole on it. The second body represents a freely moving tube around that pole. The third body represents a solid flag freely translating along and rotating around the Y axis of the tube.

```python
>>> floor = Body('floor')
>>> tube = Body('tube')
>>> flag = Body('flag')
```

The first joint will connect the first tube to the floor with it translating along and rotating around the Z axis of both bodies.

```python
>>> floor_joint = CylindricalJoint('C1', floor, tube, joint_axis=floor.z)
```

The second joint will connect the tube perpendicular to the flag along the Y axis of both the tube and the flag, with the joint located at a distance $r$ from the tube’s center of mass and a combination of the distances $l$ and $w$ from the flag’s center of mass.
\begin{verbatim}
>>> flag_joint = CylindricalJoint('C2', tube, flag,
...                                 parent_point=r * tube.y,
...                                 child_point=-w * flag.y + l * flag.z,
...                                 joint_axis=tube.y)

Once the joints are established the kinematics of the connected bodies can be accessed. First the direction cosine matrices of both the body and the flag relative to the floor are found:

```python
>>> tube.dcm(floor)
Matrix([[cos(q0_C1(t)), sin(q0_C1(t)), 0],
       [-sin(q0_C1(t)), cos(q0_C1(t)), 0],
       [0, 0, 1]])

>>> flag.dcm(floor)
Matrix([[cos(q0_C1(t))*cos(q0_C2(t)), sin(q0_C1(t))*cos(q0_C2(t)), -sin(q0_→C2(t))],
       [-sin(q0_C1(t)), cos(q0_C1(t)), 0],
       [sin(q0_C2(t))*cos(q0_C1(t)), sin(q0_C1(t))*sin(q0_C2(t)), cos(q0_→C2(t))]])
```

The position of the flag's center of mass is found with:

```python
>>> flag.masscenter.pos_from(floor.masscenter)
q1_C1(t)*floor_frame.z + (r + q1_C2(t))*tube_frame.y + w*flag_frame.y - l*flag_frame.z
```

The angular velocities of the two tubes can be computed with respect to the floor.

```python
>>> tube.ang_vel_in(floor)
u0_C1(t)*floor_frame.z

>>> flag.ang_vel_in(floor)
u0_C1(t)*floor_frame.z + u0_C2(t)*tube_frame.y
```

Finally, the linear velocities of the two tube centers of mass can be computed with respect to the floor, while expressed in the tube’s frame.

```python
>>> tube.masscenter.vel(floor.frame).to_matrix(tube.frame)
Matrix([[0],
       [0],
       [u1_C1(t)]])

>>> flag.masscenter.vel(floor.frame).to_matrix(tube.frame).simplify()
Matrix([[-l*u0_C2(t)*cos(q0_C2(t)) - r*u0_C1(t) - w*u0_C1(t) - q1_C2(t)*u0_→C1(t)],
       [-l*u0_C1(t)*sin(q0_C2(t)) + Derivative(q1_C2(t), t)],
       [l*u0_C2(t)*sin(q0_C2(t)) + u1_→C1(t)]])
```
\end{verbatim}

rotation_speed=None, planar_speeds=None, 
parent_point=None, child_point=None, 
parent_interframe=None, child_interframe=None)
```

Planar Joint.
Parameters

**name** : string
A unique name for the joint.

**parent** : Body
The parent body of joint.

**child** : Body
The child body of joint.

**rotation_coordinate** : dynamicsymbol, optional
Generalized coordinate corresponding to the rotation angle. The default value is `dynamicsymbols(f'q0_{joint.name}')`.

**planar_coordinates** : iterable of dynamicsymbols, optional
Two generalized coordinates used for the planar translation. The default value is `dynamicsymbols(f'q1_{joint.name} q2_{joint.name}')`.

**rotation_speed** : dynamicsymbol, optional
Generalized speed corresponding to the angular velocity. The default value is `dynamicsymbols(f'u0_{joint.name}')`.

**planar_speeds** : dynamicsymbols, optional
Two generalized speeds used for the planar translation velocity. The default value is `dynamicsymbols(f'u1_{joint.name} u2_{joint.name}')`.

**parent_point** : Point or Vector, optional
Attachment point where the joint is fixed to the parent body. If a vector is provided, then the attachment point is computed by adding the vector to the body’s mass center. The default value is the parent’s mass center.
child_point : Point or Vector, optional

Attachment point where the joint is fixed to the child body. If a vector is provided, then the attachment point is computed by adding the vector to the body's mass center. The default value is the child's mass center.

parent_interframe : ReferenceFrame, optional

Intermediate frame of the parent body with respect to which the joint transformation is formulated. If a Vector is provided then an inter-frame is created which aligns its X axis with the given vector. The default value is the parent's own frame.

child_interframe : ReferenceFrame, optional

Intermediate frame of the child body with respect to which the joint transformation is formulated. If a Vector is provided then an inter-frame is created which aligns its X axis with the given vector. The default value is the child's own frame.

Explanation

A planar joint is defined such that the child body translates over a fixed plane of the parent body as well as rotate about the rotation axis, which is perpendicular to that plane. The origin of this plane is the parent_point and the plane is spanned by two nonparallel planar vectors. The location of the child_point is based on the planar vectors ($\vec{v}_1, \vec{v}_2$) and generalized coordinates ($q_1, q_2$), i.e. $\vec{r} = q_1\vec{v}_1 + q_2\vec{v}_2$. The direction cosine matrix between the child_interframe and parent_interframe is formed using a simple rotation ($q_0$) about the rotation axis.

In order to simplify the definition of the PlanarJoint, the rotation_axis and planar_vectors are set to be the unit vectors of the parent_interframe according to the table below. This ensures that you can only define these vectors by creating a separate frame and supplying that as the interframe. If you however would only like to supply the normals of the plane with respect to the parent and child bodies, then you can also supply those to the parent_interframe and child_interframe arguments. An example of both of these cases is in the examples section below and the page on the joints framework provides a more detailed explanation of the intermediate frames.

<table>

<td>parent_interframe.y</td>
</tr>
<tr>
<td>planar_vectors[1]</td>
<td>parent_interframe.z</td>
</tr>
</tbody>
</table>

Examples

A single planar joint is created between two bodies and has the following basic attributes:

```python
>>> from sympy.physics.mechanics import Body, PlanarJoint
>>> parent = Body('P')
>>> parent
P
>>> child = Body('C')
```
```python
>>> child
C
>>> joint = PlanarJoint('PC', parent, child)
>>> joint
PlanarJoint: PC  parent: P  child: C
>>> joint.name
'PC'
>>> joint.parent
P
>>> joint.child
C
>>> joint.parent_point
P_masscenter
>>> joint.child_point
C_masscenter
>>> joint.rotation_axis
P_frame.x
>>> joint.planar_vectors
[P_frame.y, P_frame.z]
>>> joint.rotation_coordinate
q0_PC(t)
>>> joint.planar_coordinates
Matrix([[q1_PC(t)],
        [q2_PC(t)]])
>>> joint.coordinates
Matrix([[q0_PC(t)],
        [q1_PC(t)],
        [q2_PC(t)]])
>>> joint.rotation_speed
u0_PC(t)
>>> joint.planar_speeds
Matrix([[u1_PC(t)],
        [u2_PC(t)]])
>>> joint.speeds
Matrix([[u0_PC(t)],
        [u1_PC(t)],
        [u2_PC(t)]]))
>>> joint.child.frame.ang_vel_in(joint.parent.frame)
u0_PC(t)*P_frame.x
>>> joint.child.frame.dcm(joint.parent.frame)
Matrix([[1, 0, 0],
        [0, cos(q0_PC(t)), sin(q0_PC(t))],
        [0, -sin(q0_PC(t)), cos(q0_PC(t))]])
>>> joint.child_point.pos_from(joint.parent_point)
q1_PC(t)*P_frame.y + q2_PC(t)*P_frame.z
>>> child.masscenter.vel(parent.frame)
u1_PC(t)*P_frame.y + u2_PC(t)*P_frame.z
```
To further demonstrate the use of the planar joint, the kinematics of a block sliding on a slope, can be created as follows.

```python
>>> from sympy import symbols
>>> from sympy.physics.mechanics import PlanarJoint, Body, ReferenceFrame
>>> a, d, h = symbols('a d h')
```

First create bodies to represent the slope and the block.

```python
>>> ground = Body('G')
>>> block = Body('B')
```

To define the slope you can either define the plane by specifying the `planar_vectors` or/and the `rotation_axis`. However it is advisable to create a rotated intermediate frame, so that the `parent_vectors` and `rotation_axis` will be the unit vectors of this intermediate frame.

```python
>>> slope = ReferenceFrame('A')
>>> slope.orient_axis(ground.frame, ground.y, a)
```

The planar joint can be created using these bodies and intermediate frame. We can specify the origin of the slope to be d above the slope’s center of mass and the block’s center of mass to be a distance h above the slope’s surface. Note that we can specify the normal of the plane using the rotation axis argument.

```python
>>> joint = PlanarJoint('PC', ground, block, parent_point=d * ground.x,
... child_point=-h * block.x, parent_...
... child_frame=slope)
```

Once the joint is established the kinematics of the bodies can be accessed. First the `rotation_axis`, which is normal to the plane and the `plane_vectors`, can be found.

```python
>>> joint.rotation_axis
A.x
>>> joint.planar_vectors
[A.y, A.z]
```

The direction cosine matrix of the block with respect to the ground can be found with:

```python
>>> block.dcm(ground)
Matrix([[cos(a), 0, -sin(a)],
[ sin(a)*sin(q0_PC(t)), cos(q0_PC(t)), sin(q0_PC(t))*cos(a)],
[ sin(a)*cos(q0_PC(t)), -sin(q0_PC(t)), cos(a)*cos(q0_PC(t))]])
```

The angular velocity of the block can be computed with respect to the ground.

```python
>>> block.ang_vel_in(ground)
u0_PC(t)*A.x
```

The position of the block’s center of mass can be found with:

```python
>>> block.masscenter.pos_from(ground.masscenter)
d*G_frame.x + h*B_frame.x + q1_PC(t)*A.y + q2_PC(t)*A.z
```
Finally, the linear velocity of the block’s center of mass can be computed with respect to the ground.

```
>>> block.masscenter.vel(ground.frame)
ul_PC(t)*A.y + u2_PC(t)*A.z
```

In some cases it could be your preference to only define the normals of the plane with respect to both bodies. This can most easily be done by supplying vectors to the interframe arguments. What will happen in this case is that an interframe will be created with its x axis aligned with the provided vector. For a further explanation of how this is done see the notes of the Joint class. In the code below, the above example (with the block on the slope) is recreated by supplying vectors to the interframe arguments. Note that the previously described option is however more computationally efficient, because the algorithm now has to compute the rotation angle between the provided vector and the 'x' axis.

```
>>> from sympy import symbols, cos, sin
>>> from sympy.physics.mechanics import PlanarJoint, Body
>>> a, d, h = symbols('a d h')
>>> ground = Body('G')
>>> block = Body('B')
>>> joint = PlanarJoint(
...   'PC', ground, block, parent_point=d * ground.x,
...   child_point=-h * block.x, child_interframe=block.x,
...   parent_interframe=cos(a) * ground.x + sin(a) * ground.z)
>>> block.dcm(ground).simplify()
Matrix([
    [  cos(a), 0, sin(a) ],
    [-sin(a)*sin(q0_PC(t)), cos(q0_PC(t)), sin(q0_PC(t))*cos(a) ],
    [-sin(a)*cos(q0_PC(t)), -sin(q0_PC(t)), cos(a)*cos(q0_PC(t)) ]])
```

class sympy.physics.mechanics.joint.SphericalJoint(name, parent, child, coordinates=None, speeds=None, parent_point=None, child_point=None, parent_interframe=None, child_interframe=None, rot_type='BODY', amounts=None, rot_order=123)

Spherical (Ball-and-Socket) Joint.

Parameters

- **name**: string
  A unique name for the joint.
- **parent**: Body
  The parent body of joint.
- **child**: Body
  The child body of joint.
- **coordinates**: iterable of dynamicsymbols, optional
Generalized coordinates of the joint.

**speeds**: iterable of dynamicsymbols, optional

Generalized speeds of joint.

**parent_point**: Point or Vector, optional

Attachment point where the joint is fixed to the parent body. If a vector is provided, then the attachment point is computed by adding the vector to the body’s mass center. The default value is the parent’s mass center.

**child_point**: Point or Vector, optional

Attachment point where the joint is fixed to the child body. If a vector is provided, then the attachment point is computed by adding the vector to the body’s mass center. The default value is the child’s mass center.

**parent_interframe**: ReferenceFrame, optional

Intermediate frame of the parent body with respect to which the joint transformation is formulated. If a Vector is provided then an inter-frame is created which aligns its X axis with the given vector. The default value is the parent’s own frame.

**child_interframe**: ReferenceFrame, optional

Intermediate frame of the child body with respect to which the joint transformation is formulated. If a Vector is provided then an inter-frame is created which aligns its X axis with the given vector. The default value is the child’s own frame.

**rot_type**: str, optional

The method used to generate the direction cosine matrix. Supported methods are:

- 'Body': three successive rotations about new intermediate axes, also called “Euler and Tait-Bryan angles”
- 'Space': three successive rotations about the parent frames’ unit vectors

The default method is 'Body'.

**amounts**: Expressions defining the rotation angles or direction cosine matrix. These must match the rot_type. See examples below for details. The input types are:

- 'Body': 3-tuple of expressions, symbols, or functions
- 'Space': 3-tuple of expressions, symbols, or functions

The default amounts are the given coordinates.

**rot_order**: str or int, optional

If applicable, the order of the successive of rotations. The string ‘123’ and integer 123 are equivalent, for example. Required for ‘Body’ and ‘Space’. The default value is 123.
**Explanation**

A spherical joint is defined such that the child body is free to rotate in any direction, without allowing a translation of the child_point. As can also be seen in the image, the parent_point and child_point are fixed on top of each other, i.e. the joint_point. This rotation is defined using the `parent_interframe.orient(child_interframe, rot_type, amounts, rot_order)` (page 1678) method. The default rotation consists of three relative rotations, i.e. body-fixed rotations. Based on the direction cosine matrix following from these rotations, the angular velocity is computed based on the generalized coordinates and generalized speeds.

**Examples**

A single spherical joint is created from two bodies and has the following basic attributes:

```python
code
>>> from sympy.physics.mechanics import Body, SphericalJoint
>>> parent = Body('P')
>>> parent
P
>>> child = Body('C')
>>> child
C
>>> joint = SphericalJoint('PC', parent, child)
>>> joint
SphericalJoint: PC parent: P child: C
>>> joint.name
'PC'
>>> joint.parent
P
>>> joint.child
C
>>> joint.parent_point
P_masscenter
>>> joint.child_point
C_masscenter
>>> joint.parent_interframe
P_frame
>>> joint.child_interframe
C_frame
>>> joint.coordinates
Matrix([[q0_PC(t)],
        [q1_PC(t)],
        [q2_PC(t)]])
>>> joint.speeds
Matrix([[u0_PC(t)],
        [u1_PC(t)],
        [u2_PC(t)]]))
>>> child.frame.ang_vel_in(parent.frame).to_matrix(child.frame)
Matrix([[u0_PC(t)*cos(q1_PC(t))*cos(q2_PC(t)) + u1_PC(t)*sin(q2_PC(t))]],
(continues on next page)
```
[
[-u0_PC(t)*sin(q2_PC(t))*cos(q1_PC(t)) + u1_PC(t)*cos(q2_PC(t))],
[u0_PC(t)*sin(q1_PC(t)) + u2_PC(t)]
]

>> child.frame.x.to_matrix(parent.frame)
Matrix([[cos(q1_PC(t))*cos(q2_PC(t))],
[sin(q0_PC(t))*sin(q1_PC(t))*cos(q2_PC(t)) + sin(q2_PC(t))*cos(q0_PC(t))],
[sin(q0_PC(t))*sin(q2_PC(t)) - sin(q1_PC(t))*cos(q0_PC(t))*cos(q2_PC(t))]])

>> joint.child_point.pos_from(joint.parent_point)

To further demonstrate the use of the spherical joint, the kinematics of a spherical joint with a ZXZ rotation can be created as follows.

```
>>> from sympy import symbols
>>> from sympy.physics.mechanics import Body, SphericalJoint
>>> l1 = symbols('l1')
```

First create bodies to represent the fixed floor and a pendulum bob.

```
>>> floor = Body('F')
>>> bob = Body('B')
```

The joint will connect the bob to the floor, with the joint located at a distance of \( l1 \) from the child’s center of mass and the rotation set to a body-fixed ZXZ rotation.

```
>>> joint = SphericalJoint('S', floor, bob, child_point=l1 * bob.y, ...
... rot_type='body', rot_order='ZXZ')
```

Now that the joint is established, the kinematics of the connected body can be accessed.

The position of the bob’s mass center is found with:

```
>>> bob.masscenter.pos_from(floor.masscenter)
- l1*B_frame.y
```

The angular velocities of the pendulum link can be computed with respect to the floor.

```
>>> bob.frame.ang_vel_in(floor.frame).to_matrix(...
... floor.frame).simplify()
Matrix([[u1_S(t)*cos(q0_S(t)) + u2_S(t)*sin(q0_S(t))*sin(q1_S(t))],
[u1_S(t)*sin(q0_S(t)) - u2_S(t)*sin(q1_S(t))*cos(q0_S(t))],
[u0_S(t) + u2_S(t)*cos(q1_S(t))]])
```

Finally, the linear velocity of the bob’s center of mass can be computed.

```
>>> bob.masscenter.vel(floor.frame).to_matrix(bob.frame)
Matrix([[l1*(u0_S(t)*cos(q1_S(t)) + u2_S(t))],
[0],
[-l1*(u0_S(t)*sin(q1_S(t))*sin(q2_S(t)) + u1_S(t)*cos(q2_S(t)))]])
```

```python
class sympy.physics.mechanics.joint.WeldJoint(name, parent, child, 
parent_point=None, 
child_point=None, 
parent_interframe=None, 
child_interframe=None)
```

Weld Joint.

**Parameters**

- **name**: string
  - A unique name for the joint.

- **parent**: Body
The parent body of joint.

**child** : Body

The child body of joint.

**parent_point** : Point or Vector, optional

Attachment point where the joint is fixed to the parent body. If a vector is provided, then the attachment point is computed by adding the vector to the body’s mass center. The default value is the parent’s mass center.

**child_point** : Point or Vector, optional

Attachment point where the joint is fixed to the child body. If a vector is provided, then the attachment point is computed by adding the vector to the body’s mass center. The default value is the child’s mass center.

**parent_interframe** : ReferenceFrame, optional

Intermediate frame of the parent body with respect to which the joint transformation is formulated. If a Vector is provided then an inter-frame is created which aligns its X axis with the given vector. The default value is the parent’s own frame.

**child_interframe** : ReferenceFrame, optional

Intermediate frame of the child body with respect to which the joint transformation is formulated. If a Vector is provided then an inter-frame is created which aligns its X axis with the given vector. The default value is the child’s own frame.

**Explanation**

A weld joint is defined such that there is no relative motion between the child and parent bodies. The direction cosine matrix between the attachment frame (parent_interframe and child_interframe) is the identity matrix and the attachment points (parent_point and child_point) are coincident. The page on the joints framework gives a more detailed explanation of the intermediate frames.

**Examples**

A single weld joint is created from two bodies and has the following basic attributes:

```python
code
>>> from sympy.physics.mechanics import Body, WeldJoint
>>> parent = Body('P')
>>> child = Body('C')
>>> joint = WeldJoint('PC', parent, child)
>>> joint
WeldJoint: PC parent: P child: C
```
To further demonstrate the use of the weld joint, two relatively-fixed bodies rotated by a quarter turn about the Y axis can be created as follows:

```python
from sympy import symbols, pi
from sympy.physics.mechanics import ReferenceFrame, Body, WeldJoint
l1, l2 = symbols('l1 l2')
```

First create the bodies to represent the parent and rotated child body.

```python
>>> parent = Body('P')
>>> child = Body('C')
```

Next the intermediate frame specifying the fixed rotation with respect to the parent can be created.

```python
>>> rotated_frame = ReferenceFrame('Pr')
>>> rotated_frame.orient_axis(parent.frame, parent.y, pi / 2)
```

The weld between the parent body and child body is located at a distance $l_1$ from the parent’s center of mass in the X direction and $l_2$ from the child’s center of mass in the child’s negative X direction.

```python
>>> weld = WeldJoint('weld', parent, child, parent_point=parent_masscenter, child_point=parent_masscenter + [l1 * parent.x, -l2 * child.x, 0], parent_interframe=rotated_frame)
```

Now that the joint has been established, the kinematics of the bodies can be accessed. The direction cosine matrix of the child body with respect to the parent can be found:
As can also been seen from the direction cosine matrix, the parent X axis is aligned with the child’s Z axis: >>> parent.x == child.z True

The position of the child’s center of mass with respect to the parent’s center of mass can be found with:

>>> child.masscenter.pos_from(parent.masscenter)
l1*P_frame.x + l2*C_frame.x

The angular velocity of the child with respect to the parent is 0 as one would expect.

>>> child.ang_vel_in(parent)
0

**class** sympy.physics.mechanics.jointsmethod.JointsMethod(newtonion, *joints)

Method for formulating the equations of motion using a set of interconnected bodies with joints.

**Parameters**

- **newtonion**: Body or ReferenceFrame
  - The newtonion(inertial) frame.

- ***joints**: Joint
  - The joints in the system
Examples

This is a simple example for a one degree of freedom translational spring-mass-damper.

```python
>>> from sympy import symbols
>>> from sympy.physics.mechanics import Body, JointsMethod, PrismaticJoint
>>> from sympy.physics.vector import dynamicsymbols
>>> c, k = symbols('c k')
>>> x, v = dynamicsymbols('x v')
>>> wall = Body('W')
>>> body = Body('B')
>>> J = PrismaticJoint('J', wall, body, coordinates=x, speeds=v)
>>> wall.apply_force(c*v*wall.x, reaction_body=body)
>>> wall.apply_force(k*x*wall.x, reaction_body=body)
>>> method = JointsMethod(wall, J)
>>> method.form_eoms()
Matrix([[B_mass*Derivative(v(t), t) - c*v(t) - k*x(t)]])
>>> M = method.mass_matrix_full
>>> F = method.forcing_full
>>> rhs = M.LUsolve(F)
>>> rhs
Matrix([[v(t)],
        [(-c*v(t) - k*x(t))/B_mass]])
```

Notes

JointsMethod currently only works with systems that do not have any configuration or motion constraints.

Attributes

| q, u | (iterable) Iterable of the generalized coordinates and speeds |
| bodies | (iterable) Iterable of Body objects in the system. |
| loads | (iterable) Iterable of (Point, vector) or (ReferenceFrame, vector) tuples describing the forces on the system. |
| mass_matrix | (Matrix, shape(n, n)) The system’s mass matrix |
| forcing | (Matrix, shape(n, 1)) The system’s forcing vector |
| mass_matrix_full | (Matrix, shape(2*n, 2*n)) The “mass matrix” for the u’s and q’s |
| forcing_full | (Matrix, shape(2*n, 1)) The “forcing vector” for the u’s and q’s |
| method | (KanesMethod or Lagrange’s method) Method’s object. |
| kdes | (iterable) Iterable of kde in they system. |

**property bodies**

List of bodies in they system.

**property forcing**

The system’s forcing vector.
property forcing_full
The “forcing vector” for the u’s and q’s.

form_eoms(method=<class 'sympy.physics.mechanics.kane.KanesMethod'>)
Method to form system’s equation of motions.

Parameters
method : Class
Class name of method.

Returns
Matrix
Vector of equations of motions.

Examples

This is a simple example for a one degree of freedom translational spring-mass-damper.

```python
>>> from sympy import S, symbols
>>> from sympy.physics.mechanics import LagrangesMethod,
    dynamicsymbols, Body
>>> from sympy.physics.mechanics import PrismaticJoint, JointsMethod
>>> q = dynamicsymbols('q')
>>> qd = dynamicsymbols('q', 1)
>>> m, k, b = symbols('m k b')
>>> wall = Body('W')
>>> part = Body('P', mass=m)
>>> part.potential_energy = k * q**2 / S(2)
>>> J = PrismaticJoint('J', wall, part, coordinates=q, speeds=qd)
>>> wall.apply_force(b * qd * wall.x, reaction_body=part)
>>> method = JointsMethod(wall, J)
>>> method.form_eoms(LagrangesMethod)
Matrix([[b*Derivative(q(t), t) + k*q(t) + m*Derivative(q(t), (t,) 2))]])

We can also solve for the states using the ‘rhs’ method.

```python
>>> method.rhs()
Matrix([[Derivative(q(t), t)],
        [(-b*Derivative(q(t), t) - k*q(t))/m]])
```

property kdes
List of the generalized coordinates.

property loads
List of loads on the system.

property mass_matrix
The system’s mass matrix.

property mass_matrix_full
The “mass matrix” for the u’s and q’s.
property method
Object of method used to form equations of systems.

property q
List of the generalized coordinates.

rhs(inv_method=None)
Returns equations that can be solved numerically.

Parameters
inv_method : str
  The specific sympy inverse matrix calculation method to use. For a
  list of valid methods, see inv() (page 1340)

Returns
Matrix
  Numerically solvable equations.

See also:
sympy.physics.mechanics.kane.KanesMethod.rhs (page 1814)
KanesMethod's rhs function.
sympy.physics.mechanics.lagrange.LagrangesMethod.rhs (page 1817)
LagrangesMethod's rhs function.

property u
List of the generalized speeds.

SymbolicSystem (Docstrings)

class sympy.physics.mechanics.system.SymbolicSystem(coord_states, right_hand_side, speeds=None, mass_matrix=None, coordinate_derivatives=None, alg_con=None, output_eqns={}, coord_idxs=None, speed_idxs=None, bodies=None, loads=None)

SymbolicSystem is a class that contains all the information about a system in a symbolic
format such as the equations of motions and the bodies and loads in the system.

There are three ways that the equations of motion can be described for Symbolic System:

[1] Explicit form where the kinematics and dynamics are combined
  \[ x' = F_1(x, t, r, p) \]

[2] Implicit form where the kinematics and dynamics are combined
  \[ M_2(x, p) x' = F_2(x, t, r, p) \]

[3] Implicit form where the kinematics and dynamics are separate
  \[ M_3(q, p) u' = F_3(q, u, t, r, p) q' = G(q, u, t, r, p) \]
where

\(x\) : states, e.g. \([q, u]t\) : time \(r\) : specified (exogenous) inputs \(p\) : constants \(q\) : generalized coordinates \(u\) : generalized speeds \(F_1\) : right hand side of the combined equations in explicit form \(F_2\) : right hand side of the combined equations in implicit form \(F_3\) : right hand side of the dynamical equations in implicit form \(M_2\) : mass matrix of the combined equations in implicit form \(M_3\) : mass matrix of the dynamical equations in implicit form \(G\) : right hand side of the kinematical differential equations

### Parameters

**coord_states** : ordered iterable of functions of time

This input will either be a collection of the coordinates or states of the system depending on whether or not the speeds are also given. If speeds are specified this input will be assumed to be the coordinates otherwise this input will be assumed to be the states.

**right_hand_side**

([Matrix]) This variable is the right hand side of the equations of motion in any of the forms. The specific form will be assumed depending on whether a mass matrix or coordinate derivatives are given.

**speeds**

([ordered iterable of functions of time, optional]) This is a collection of the generalized speeds of the system. If given it will be assumed that the first argument (coord_states) will represent the generalized coordinates of the system.

**mass_matrix**

([Matrix, optional]) The matrix of the implicit forms of the equations of motion (forms [2] and [3]). The distinction between the forms is determined by whether or not the coordinate derivatives are passed in. If they are given form [3] will be assumed otherwise form [2] is assumed.

**coordinate_derivatives**

([Matrix, optional]) The right hand side of the kinematical equations in explicit form. If given it will be assumed that the equations of motion are being entered in form [3].

**alg_con**

([Iterable, optional]) The indexes of the rows in the equations of motion that contain algebraic constraints instead of differential equations. If the equations are input in form [3], it will be assumed the indexes are referencing the mass_matrix/right_hand_side combination and not the coordinate_derivatives.

**output_eqns**

([Dictionary, optional]) Any output equations that are desired to be tracked are stored in a dictionary where the key corresponds to the name given for the specific equation and the value is the equation itself in symbolic form

**coord_idxs**

([Iterable, optional]) If coord_states corresponds to the states rather than the coordinates this variable will tell SymbolicSystem which indexes of the states correspond to generalized coordinates.
speed_idxs
[Iterable, optional] If coord_states corresponds to the states rather than the coordinates this variable will tell SymbolicSystem which indexes of the states correspond to generalized speeds.

bodies
[iterable of Body/Rigidbody objects, optional] Iterable containing the bodies of the system

loads
[iterable of load instances (described below), optional] Iterable containing the loads of the system where forces are given by (point of application, force vector) and torques are given by (reference frame acting upon, torque vector). Ex [(point, force), (ref_frame, torque)]

Example
As a simple example, the dynamics of a simple pendulum will be input into a SymbolicSystem object manually. First some imports will be needed and then symbols will be set up for the length of the pendulum (l), mass at the end of the pendulum (m), and a constant for gravity (g).

```python
>>> from sympy import Matrix, sin, symbols
>>> from sympy.physics.mechanics import dynamicsymbols, SymbolicSystem
>>> l, m, g = symbols('l m g')
```

The system will be defined by an angle of theta from the vertical and a generalized speed of omega will be used where omega = theta_dot.

```python
>>> theta, omega = dynamicsymbols('theta omega')
```

Now the equations of motion are ready to be formed and passed to the SymbolicSystem object.

```python
>>> kin_explicit_rhs = Matrix([omega])
>>> dyn_implicit_mat = Matrix([l**2 * m])
>>> dyn_implicit_rhs = Matrix([-g * l * m * sin(theta)])
>>> symsystem = SymbolicSystem([theta], dyn_implicit_rhs, [omega], ...
                               dyn_implicit_mat)
```

Notes
m : number of generalized speeds n : number of generalized coordinates o : number of states

</tbody>
</table>

**property alg_con**

Returns a list with the indices of the rows containing algebraic constraints in the combined form of the equations of motion

**property bodies**

Returns the bodies in the system

**property comb_explicit_rhs**

Returns the right hand side of the equations of motion in explicit form, \( x' = F \), where the kinematical equations are included
property comb_implicit_mat
Returns the matrix, $M$, corresponding to the equations of motion in implicit form
(form [2]), $M \mathbf{x}' = \mathbf{F}$, where the kinematical equations are included

property comb_implicit_rhs
Returns the column matrix, $\mathbf{F}$, corresponding to the equations of motion in implicit
form (form [2]), $M \mathbf{x}' = \mathbf{F}$, where the kinematical equations are included

compute_explicit_form()
If the explicit right hand side of the combined equations of motion is to provided
upon initialization, this method will calculate it. This calculation can potentially
take awhile to compute.

constant_symbols()
Returns a column matrix containing all of the symbols in the system that do not
depend on time

property coordinates
Returns the column matrix of the generalized coordinates

property dyn_implicit_mat
Returns the matrix, $M$, corresponding to the dynamic equations in implicit form, $M$
$\mathbf{x}' = \mathbf{F}$, where the kinematical equations are not included

property dyn_implicit_rhs
Returns the column matrix, $\mathbf{F}$, corresponding to the dynamic equations in implicit
form, $M \mathbf{x}' = \mathbf{F}$, where the kinematical equations are not included

dynamic_symbols()
Returns a column matrix containing all of the symbols in the system that depend on
time

property kin_explicit_rhs
Returns the right hand side of the kinematical equations in explicit form, $q' = \mathbf{G}$

property loads
Returns the loads in the system

property speeds
Returns the column matrix of generalized speeds

property states
Returns the column matrix of the state variables

Linearization (Docstrings)

class sympy.physics.mechanics.linearize.Linearizer(f_0, f_1, f_2, f_3, f_4, f_c, f_v,
f_a, q, u, q_i=None, q_d=None, u_i=None, u_d=None, r=None, lams=None)

This object holds the general model form for a dynamic system. This model is used for
computing the linearized form of the system, while properly dealing with constraints
leading to dependent coordinates and speeds.
Attributes

<table>
<thead>
<tr>
<th>f_0, f_1, f_2, f_3, f_4, f_c, f_v, f_a</th>
<th>(Matrix) Matrices holding the general system form.</th>
</tr>
</thead>
<tbody>
<tr>
<td>q, u, r</td>
<td>(Matrix) Matrices holding the generalized coordinates, speeds, and input vectors.</td>

</tr>
</tbody>
</table>

**linearize**(*op_point=None, A_and_B=False, simplify=False*)

Linearize the system about the operating point. Note that q_op, u_op, qd_op, ud_op must satisfy the equations of motion. These may be either symbolic or numeric.

**Parameters**

- **op_point**: dict or iterable of dicts, optional
  
  Dictionary or iterable of dictionaries containing the operating point conditions. These will be substituted into the linearized system before the linearization is complete. Leave blank if you want a completely symbolic form. Note that any reduction in symbols (whether substituted for numbers or expressions with a common parameter) will result in faster runtime.

- **A_and_B**: bool, optional
  
  If A_and_B=False (default), (M, A, B) is returned for forming [M]*[q, u]^T = [A]*[q_ind, u_ind]^T + [B]*r. If A_and_B=True, (A, B) is returned for forming dx = [A]*x + [B]*r; where x = [q_ind, u_ind]^T.

- **simplify**: bool, optional
  
  Determines if returned values are simplified before return. For large expressions this may be time consuming. Default is False.

**Potential Issues**

Note that the process of solving with A_and_B=True is computationally intensive if there are many symbolic parameters. For this reason, it may be more desirable to use the default A_and_B=False, returning M, A, and B. More values may then be substituted in to these matrices later on. The state space form can then be found as A = P^T*M.LUsolve(A), B = P^T*M.LUsolve(B), where P = Linearizer.perm_mat.
Expression Manipulation (Docstrings)

`sympy.physics.mechanics.msubs(expr, *sub_dicts, smart=False, **kwargs)`

A custom subs for use on expressions derived in physics.mechanics. Traverses the expression tree once, performing the subs found in sub_dicts. Terms inside Derivative expressions are ignored:

**Examples**

```python
>>> from sympy.physics.mechanics import dynamicsymbols, msubs
>>> x = dynamicsymbols('x')
>>> msubs(x.diff() + x, {x: 1})
Derivative(x(t), t) + 1
```

Note that sub_dicts can be a single dictionary, or several dictionaries:

```python
>>> x, y, z = dynamicsymbols('x, y, z')
>>> sub1 = {x: 1, y: 2}
>>> sub2 = {z: 3, x.diff(): 4}
>>> msubs(x.diff() + x + y + z, sub1, sub2)
10
```

If smart=True (default False), also checks for conditions that may result in nan, but if simplified would yield a valid expression. For example:

```python
>>> from sympy import sin, tan
>>> (sin(x)/tan(x)).subs(x, 0)
nan
>>> msubs(sin(x)/tan(x), {x: 0}, smart=True)
1
```

It does this by first replacing all tan with sin/cos. Then each node is traversed. If the node is a fraction, subs is first evaluated on the denominator. If this results in 0, simplification of the entire fraction is attempted. Using this selective simplification, only subexpressions that result in 1/0 are targeted, resulting in faster performance.

`sympy.physics.mechanics.find_dynamicsymbols(expression, exclude=None, reference_frame=None)`

Find all dynamicsymbols in expression.

**Parameters**

- **expression**: SymPy expression
- **exclude**: iterable of dynamicsymbols, optional
- **reference_frame**: ReferenceFrame, optional
  
  The frame with respect to which the dynamic symbols of the given vector is to be determined.
**Explanation**

If the optional exclude kwarg is used, only dynamicsymbols not in the iterable exclude are returned. If we intend to apply this function on a vector, the optional reference_frame is also used to inform about the corresponding frame with respect to which the dynamic symbols of the given vector is to be determined.

**Examples**

```python
>>> from sympy.physics.mechanics import dynamicsymbols, find_dynamicsymbols
>>> from sympy.physics.mechanics import ReferenceFrame

>>> x, y = dynamicsymbols('x, y')
>>> expr = x + x.diff()*y
>>> find_dynamicsymbols(expr)
{x(t), y(t), Derivative(x(t), t)}
>>> find_dynamicsymbols(expr, exclude=[x, y])
{Derivative(x(t), t)}

>>> a, b, c = dynamicsymbols('a, b, c')
>>> A = ReferenceFrame('A')
>>> v = a*A.x + b*A.y + c*A.z
>>> find_dynamicsymbols(v, reference_frame=A)
{a(t), b(t), c(t)}
```

**Printing (Docstrings)**

**mechanics_printing**

This function is the same as `sympy.physics.vector.printing.init_vprinting` (page 1710).

**mprint**

This function is the same as `sympy.physics.vector.printing.vprint` (page 1712).

**mpprint**

This function is the same as `sympy.physics.vector.printing.vpprint` (page 1712).
Quantum Mechanics

Abstract
Contains Docstrings of Physics-Quantum module

Quantum Functions

Anticommutator

The anti-commutator: \( \{A, B\} = A*B + B*A \).

```python
class sympy.physics.quantum.anticommutator.AntiCommutator(A, B)
```

The standard anticommutator, in an unevaluated state.

**Parameters**
- **A**: Expr
  - The first argument of the anticommutator \( \{A, B\} \).
- **B**: Expr
  - The second argument of the anticommutator \( \{A, B\} \).

**Explanation**

Evaluating an anticommutator is defined [R688] as: \( \{A, B\} = A*B + B*A \). This class returns the anticommutator in an unevaluated form. To evaluate the anticommutator, use the `.doit()` method.

Canonical ordering of an anticommutator is \( \{A, B\} \) for \( A < B \). The arguments of the anticommutator are put into canonical order using `__cmp__`. If \( B < A \), then \( \{A, B\} \) is returned as \( \{B, A\} \).

**Examples**

```python
>>> from sympy import symbols
>>> from sympy.physics.quantum import AntiCommutator
>>> from sympy.physics.quantum import Operator, Dagger
>>> x, y = symbols('x,y')
>>> A = Operator('A')
>>> B = Operator('B')
```

Create an anticommutator and use `doit()` to multiply them out.
>>> ac = AntiCommutator(A,B); ac
{A,B}
>>> ac.doit()
A*B + B*A

The commutator orders it arguments in canonical order:

>>> ac = AntiCommutator(B,A); ac
{A,B}

Commutative constants are factored out:

>>> AntiCommutator(3*x*A,x*y*B)
3*x**2*y*{A,B}

Adjoint operations applied to the anticommutator are properly applied to the arguments:

>>> Dagger(AntiCommutator(A,B))
{Dagger(A),Dagger(B)}

References

[R688] 

doit(**hints)
  Evaluate anticommutator

Clebsch-Gordan Coefficients

Clebsch-Gordon Coefficients.

class sympy.physics.quantum.cg.CG(j1, m1, j2, m2, j3, m3)
  Class for Clebsch-Gordan coefficient.

  Parameters
  j1, m1, j2, m2 : Number, Symbol
    Angular momenta of states 1 and 2.
  j3, m3 : Number, Symbol
    Total angular momentum of the coupled system.

Explanation

Clebsch-Gordan coefficients describe the angular momentum coupling between two systems. The coefficients give the expansion of a coupled total angular momentum state and an uncoupled tensor product state. The Clebsch-Gordan coefficients are defined as [R689]:

\[ C^{j_3,m_3}_{j_1,m_1,j_2,m_2} = \langle j_1,m_1;j_2,m_2|j_3,m_3 \rangle \]
Examples

Define a Clebsch-Gordan coefficient and evaluate its value

```python
>>> from sympy.physics.quantum.cg import CG
>>> from sympy import S

>>> cg = CG(S(3)/2, S(3)/2, S(1)/2, -S(1)/2, 1, 1)
>>> cg
CG(3/2, 3/2, 1/2, -1/2, 1, 1)
>>> cg.doit()
sqrt(3)/2
```

Compare [R690].

Wigner3j (page 1862)

Wigner-3j symbols

References

[R689], [R690]

```python
class sympy.physics.quantum.cg.Wigner3j(j1, m1, j2, m2, j3, m3)
```

Class for the Wigner-3j symbols.

Parameters

- **j1, m1, j2, m2, j3, m3** : Number, Symbol
  - Terms determining the angular momentum of coupled angular momentum systems.

Explanation

Wigner 3j-symbols are coefficients determined by the coupling of two angular momenta. When created, they are expressed as symbolic quantities that, for numerical parameters, can be evaluated using the .doit() method [R691].

Examples

Declare a Wigner-3j coefficient and calculate its value

```python
>>> from sympy.physics.quantum.cg import Wigner3j
>>> w3j = Wigner3j(6, 0, 4, 0, 2, 0)
>>> w3j
Wigner3j(6, 0, 4, 0, 2, 0)
>>> w3j.doit()
sqrt(715)/143
```
Clebsch-Gordan coefficients

Wigner-3j symbols

Class for the Wigner-9j symbols

See also:

Wigner-3j symbols

Simplify and combine CG coefficients.

Explanation

This function uses various symmetry and properties of sums and products of Clebsch-Gordan coefficients to simplify statements involving these terms [R692].

Examples

Simplify the sum over CG(a, alpha, 0, 0, a, alpha) for all alpha to 2*a+1

```
>>> from sympy.physics.quantum.cg import CG, cg_simp
>>> a = CG(1,1,0,0,1,1)
>>> b = CG(1,0,0,0,1,0)
>>> c = CG(1,-1,0,0,1,-1)
>>> cg_simp(a+b+c)
3
```

See also:

Clebsch-Gordan coefficients

[R692]

Commutator

The commutator: \([A,B] = A*B - B*A\).

```python
class sympy.physics.quantum.commutator.Commutator(A, B)
    The standard commutator, in an unevaluated state.

Parameters
    A : Expr
        The first argument of the commutator [A,B].
    B : Expr
        The second argument of the commutator [A,B].
```

Explanation

Evaluating a commutator is defined [R693] as: \([A, B] = A*B - B*A\). This class returns the commutator in an unevaluated form. To evaluate the commutator, use the `.doit()` method.

Canonical ordering of a commutator is \([A, B]\) for \(A < B\). The arguments of the commutator are put into canonical order using `__cmp__`. If \(B < A\), then \([B, A]\) is returned as \(-[A, B]\).

Examples

```python
>>> from sympy.physics.quantum import Commutator, Dagger, Operator
>>> from sympy.abc import x, y
>>> A = Operator('A')
>>> B = Operator('B')
>>> C = Operator('C')

Create a commutator and use `.doit()` to evaluate it:

```python
>>> comm = Commutator(A, B)
>>> comm
[A,B]
>>> comm.doit()
A*B - B*A
```

The commutator orders its arguments in canonical order:

```python
>>> comm = Commutator(B, A); comm
-[A,B]
```

Commutative constants are factored out:
Using `.expand(commutator=True)`, the standard commutator expansion rules can be applied:

```python
>>> Commutator(A+B, C).expand(commutator=True)
[A,C] + [B,C]
```

```python
>>> Commutator(A, B+C).expand(commutator=True)
[A,B] + [A,C]
```

```python
>>> Commutator(A*B, C).expand(commutator=True)
[A,C]*B + A*[B,C]
```

```python
>>> Commutator(A, B*C).expand(commutator=True)
[A,B]*C + B*[A,C]
```

Adjoint operations applied to the commutator are properly applied to the arguments:

```python
>>> Dagger(Commutator(A, B))
-[Dagger(A),Dagger(B)]
```

```
References

[R693]

`doit(**hints)`

Evaluate commutator

Constants

Constants (like hbar) related to quantum mechanics.

```python
class sympy.physics.quantum.constants.HBar
Reduced Plank's constant in numerical and symbolic form [R694].
```

Examples

```python
>>> from sympy.physics.quantum.constants import hbar
>>> hbar.evalf()
1.05457162000000e-34
```
Dagger

Hermitian conjugation.

**class sympy.physics.quantum.dagger.Dagger(arg)**

General Hermitian conjugate operation.

**Parameters**

| arg : Expr |
|
| The SymPy expression that we want to take the dagger of. |

**Explanation**

Take the Hermetian conjugate of an argument [R695]. For matrices this operation is equivalent to transpose and complex conjugate [R696].

**Examples**

Daggering various quantum objects:

```python
>>> from sympy.physics.quantum.dagger import Dagger
>>> from sympy.physics.quantum.state import Ket, Bra
>>> from sympy.physics.quantum.operator import Operator

>>> Dagger(Ket('psi'))
<psi|

>>> Dagger(Bra('phi'))
|phi>

>>> Dagger(Operator('A'))
Dagger(A)
```

Inner and outer products:

```python
>>> from sympy.physics.quantum import InnerProduct, OuterProduct

>>> Dagger(InnerProduct(Bra('a'), Ket('b')))
<b|a>

>>> Dagger(OuterProduct(Ket('a'), Bra('b')))
|b><a|
```

Powers, sums and products:

```python
>>> A = Operator('A')
>>> B = Operator('B')

>>> Dagger(A*B)
Dagger(B)*Dagger(A)

>>> Dagger(A+B)
Dagger(A) + Dagger(B)
```

(continues on next page)
Dagger also seamlessly handles complex numbers and matrices:

```python
>>> from sympy import Matrix, I
>>> m = Matrix([[1, I], [2, I]])
>>> m
Matrix([[1, I], [2, I]])
>>> Dagger(m)
Matrix([[1, 2], [-I, -I]])
```

References

[R695], [R696]

Inner Product

Symbolic inner product.

```python
class sympy.physics.quantum.innerproduct.InnerProduct(bra, ket)
```

An unevaluated inner product between a Bra and a Ket [1].

**Parameters**

- `bra`: BraBase or subclass
  The bra on the left side of the inner product.
- `ket`: KetBase or subclass
  The ket on the right side of the inner product.

**Examples**

Create an InnerProduct and check its properties:

```python
>>> from sympy.physics.quantum import Bra, Ket
>>> b = Bra('b')
>>> k = Ket('k')
>>> ip = b*conj(k)
>>> ip
<b|k>
>>> ip.bra
<b|
>>> ip.ket
|k>
```
In simple products of kets and bras inner products will be automatically identified and created:

```python
>>> b*k
<b|k>
```

But in more complex expressions, there is ambiguity in whether inner or outer products should be created:

```python
>>> k*b*k*b
|k><b| * |k>*<b|
```

A user can force the creation of an inner products in a complex expression by using parentheses to group the bra and ket:

```python
>>> k*(b*k)*b
<b|k>*|k>*<b|
```

Notice how the inner product <b|k> moved to the left of the expression because inner products are commutative complex numbers.

## References

[R702]

## Tensor Product

Abstract tensor product.

```python
class sympy.physics.quantum.tensorproduct.TensorProduct(*args)
```

The tensor product of two or more arguments.

For matrices, this uses `matrix_tensor_product` to compute the Kronecker or tensor product matrix. For other objects a symbolic `TensorProduct` instance is returned. The tensor product is a non-commutative multiplication that is used primarily with operators and states in quantum mechanics.

Currently, the tensor product distinguishes between commutative and non-commutative arguments. Commutative arguments are assumed to be scalars and are pulled out in front of the `TensorProduct`. Non-commutative arguments remain in the resulting `TensorProduct`.

### Parameters

- **args** : tuple

  A sequence of the objects to take the tensor product of.
Examples

Start with a simple tensor product of SymPy matrices:

```python
>>> from sympy import Matrix
>>> from sympy.physics.quantum import TensorProduct

>>> m1 = Matrix([[1, 2], [3, 4]])
>>> m2 = Matrix([[1, 0], [0, 1]])
>>> TensorProduct(m1, m2)
Matrix([[1, 0, 2, 0],
       [0, 1, 0, 2],
       [3, 0, 4, 0],
       [0, 3, 0, 4]])

>>> TensorProduct(m2, m1)
Matrix([[1, 2, 0, 0],
       [3, 4, 0, 0],
       [0, 0, 1, 2],
       [0, 0, 3, 4]])
```

We can also construct tensor products of non-commutative symbols:

```python
>>> from sympy import Symbol

>>> A = Symbol('A', commutative=False)
>>> B = Symbol('B', commutative=False)
>>> tp = TensorProduct(A, B)
>>> tp
AxB
```

We can take the dagger of a tensor product (note the order does NOT reverse like the dagger of a normal product):

```python
>>> from sympy.physics.quantum import Dagger

>>> Dagger(tp)
Dagger(A)xDagger(B)
```

Expand can be used to distribute a tensor product across addition:

```python
>>> C = Symbol('C', commutative=False)
>>> tp = TensorProduct(A+B, C)
>>> tp
(A + B)xC
>>> tp.expand(tensorproduct=True)
AxC + BxC
```

```
5.8. Topics

symy.physics.quantum.tensorproduct.tensor_product_simp(e, **hints)
Try to simplify and combine TensorProducts.
In general this will try to pull expressions inside of TensorProducts. It currently only works for relatively simple cases where the products have only scalars, raw TensorProducts, not Add, Pow, Commutators of TensorProducts. It is best to see what it does by showing examples.
```
Examples

```python
>>> from sympy.physics.quantum import tensor_product_simp
>>> from sympy.physics.quantum import TensorProduct
>>> from sympy import Symbol

>>> A = Symbol('A', commutative=False)
>>> B = Symbol('B', commutative=False)
>>> C = Symbol('C', commutative=False)
>>> D = Symbol('D', commutative=False)

First see what happens to products of tensor products:

```python
>>> e = TensorProduct(A, B) * TensorProduct(C, D)
>>> e
```

```
AxB*CxD
```

```python
>>> tensor_product_simp(e)
```

```
(A*C)x(B*D)
```

This is the core logic of this function, and it works inside, powers, sums, commutators and anticommutators as well:

```python
>>> tensor_product_simp(e**2)
```

```
(A*C)x(B*D)**2
```

States and Operators

Cartesian Operators and States

Operators and states for 1D cartesian position and momentum.

TODO:
- Add 3D classes to mappings in operatorset.py

```python
class sympy.physics.quantum.cartesian.PositionBra3D(*args, **kwargs)
3D cartesian position eigenbra

class sympy.physics.quantum.cartesian.PositionKet3D(*args, **kwargs)
3D cartesian position eigenket

class sympy.physics.quantum.cartesian.PositionState3D(*args, **kwargs)
Base class for 3D cartesian position eigenstates

    property position_x
        The x coordinate of the state

    property position_y
        The y coordinate of the state

    property position_z
        The z coordinate of the state

```python
class sympy.physics.quantum.cartesian.PxBra(*args, **kwargs)
1D cartesian momentum eigenbra.
```
property momentum
    The momentum of the state.

class sympy.physics.quantum.cartesian.PxKet(*args, **kwargs)
    1D cartesian momentum eigenket.

property momentum
    The momentum of the state.

class sympy.physics.quantum.cartesian.PxOp(*args, **kwargs)
    1D cartesian momentum operator.

class sympy.physics.quantum.cartesian.XBra(*args, **kwargs)
    1D cartesian position eigenbra.

property position
    The position of the state.

class sympy.physics.quantum.cartesian.XKet(*args, **kwargs)
    1D cartesian position eigenket.

property position
    The position of the state.

class sympy.physics.quantum.cartesian.XOp(*args, **kwargs)
    1D cartesian position operator.

class sympy.physics.quantum.cartesian.YOp(*args, **kwargs)
    Y cartesian coordinate operator (for 2D or 3D systems)

class sympy.physics.quantum.cartesian.ZOp(*args, **kwargs)
    Z cartesian coordinate operator (for 3D systems)

Hilbert Space

Hilbert spaces for quantum mechanics.
Authors: * Brian Granger * Matt Curry

class sympy.physics.quantum.hilbert.ComplexSpace(dimension)
    Finite dimensional Hilbert space of complex vectors.

    The elements of this Hilbert space are n-dimensional complex valued vectors with the usual inner product that takes the complex conjugate of the vector on the right.

    A classic example of this type of Hilbert space is spin-1/2, which is ComplexSpace(2). Generalizing to spin-s, the space is ComplexSpace(2*s+1). Quantum computing with N qubits is done with the direct product space ComplexSpace(2)**N.
```
>>> from sympy import symbols
>>> from sympy.physics.quantum.hilbert import ComplexSpace

>>> c1 = ComplexSpace(2)
C(2)
>>> c1.dimension
2

>>> n = symbols('n')
>>> c2 = ComplexSpace(n)
C(n)
>>> c2.dimension
n
class sympy.physics.quantum.hilbert.DirectSumHilbertSpace(*args)
A direct sum of Hilbert spaces [R697].
This class uses the + operator to represent direct sums between different Hilbert spaces.
A DirectSumHilbertSpace object takes an arbitrary number of HilbertSpace objects
as its arguments. Also, addition of HilbertSpace objects will automatically return a
direct sum object.

Examples
```
```
>>> from sympy.physics.quantum.hilbert import ComplexSpace, FockSpace

>>> c = ComplexSpace(2)
>>> f = FockSpace()
>>> hs = c+f
>>> hs
C(2)+F
>>> hs.dimension
oo
>>> list(hs.spaces)
[C(2), F]
```

References

[R697]

classmethod eval(args)
    Evaluates the direct product.

property spaces
    A tuple of the Hilbert spaces in this direct sum.
class sympy.physics.quantum.hilbert.FockSpace

The Hilbert space for second quantization.

Technically, this Hilbert space is a infinite direct sum of direct products of single particle Hilbert spaces [R698]. This is a mess, so we have a class to represent it directly.

Examples

```python
>>> from sympy.physics.quantum.hilbert import FockSpace
>>> hs = FockSpace()
>>> hs
F
>>> hs.dimension
oo
```

References

[R698]

class sympy.physics.quantum.hilbert.HilbertSpace

An abstract Hilbert space for quantum mechanics.

In short, a Hilbert space is an abstract vector space that is complete with inner products defined [R699].

Examples

```python
>>> from sympy.physics.quantum.hilbert import HilbertSpace
>>> hs = HilbertSpace()
>>> hs
H
```

References

[R699]

property dimension

Return the Hilbert dimension of the space.

class sympy.physics.quantum.hilbert.L2(interval)

The Hilbert space of square integrable functions on an interval.

An L2 object takes in a single SymPy Interval argument which represents the interval its functions (vectors) are defined on.
Examples

```python
>>> from sympy import Interval, oo
>>> from sympy.physics.quantum.hilbert import L2
>>> hs = L2(Interval(0, oo))
>>> hs
L2(Interval(0, oo))
>>> hs.dimension
oo
>>> hs.interval
Interval(0, oo)
```

class sympy.physics.quantum.hilbert.TensorPowerHilbertSpace(*args)

An exponentiated Hilbert space [R700].

Tensor powers (repeated tensor products) are represented by the operator ** Identical Hilbert spaces that are multiplied together will be automatically combined into a single tensor power object.

Any Hilbert space, product, or sum may be raised to a tensor power. The TensorPowerHilbertSpace takes two arguments: the Hilbert space; and the tensor power (number).

Examples

```python
>>> from sympy.physics.quantum.hilbert import ComplexSpace, FockSpace
>>> from sympy import symbols

>>> n = symbols('n')
>>> c = ComplexSpace(2)
>>> hs = c**n
>>> hs
C(2)**n
>>> hs.dimension
2**n

>>> c = ComplexSpace(2)
>>> c*c
C(2)**2
>>> f = FockSpace()
>>> c*f*f
C(2)*F**2
```
**References**

[R700]

class sympy.physics.quantum.hilbert.TensorProductHilbertSpace(*args)

A tensor product of Hilbert spaces [R701].

The tensor product between Hilbert spaces is represented by the operator * Products of the same Hilbert space will be combined into tensor powers.

A TensorProductHilbertSpace object takes in an arbitrary number of HilbertSpace objects as its arguments. In addition, multiplication of HilbertSpace objects will automatically return this tensor product object.

**Examples**

```python
>>> from sympy.physics.quantum.hilbert import ComplexSpace, FockSpace
>>> from sympy import symbols

>>> c = ComplexSpace(2)
>>> f = FockSpace()
>>> hs = c*f
>>> hs
C(2)*F
>>> hs.dimension
oo
>>> hs.spaces
(C(2), F)

>>> c1 = ComplexSpace(2)
>>> n = symbols('n')
>>> c2 = ComplexSpace(n)
>>> hs = c1*c2
>>> hs
C(2)*C(n)
>>> hs.dimension
2*n
```

**References**

[R701]

classmethod eval(args)

Evaluates the direct product.

**property spaces**

A tuple of the Hilbert spaces in this tensor product.
Operator

Quantum mechanical operators.

TODO:

• Fix early 0 in apply_operators.
• Debug and test apply_operators.
• Get cse working with classes in this file.
• Doctests and documentation of special methods for InnerProduct, Commutator, Anti-
  Commutator, represent, apply_operators.

```python
class sympy.physics.quantum.operator.DifferentialOperator(*args, **kwargs)
    An operator for representing the differential operator, i.e. d/dx
```

It is initialized by passing two arguments. The first is an arbitrary expression that
involves a function, such as Derivative(f(x), x). The second is the function (e.g. f(x))
which we are to replace with the Wavefunction that this DifferentialOperator is ap-
plied to.

**Parameters**

* expr : Expr
  The arbitrary expression which the appropriate Wavefunction is to be
  substituted into

* func : Expr
  A function (e.g. f(x)) which is to be replaced with the appropriate
  Wavefunction when this DifferentialOperator is applied

**Examples**

You can define a completely arbitrary expression and specify where the Wavefunction is
to be substituted

```python
>>> from sympy import Derivative, Function, Symbol
>>> from sympy.physics.quantum.operator import DifferentialOperator
>>> from sympy.physics.quantum.state import Wavefunction
>>> from sympy.physics.quantum.qapply import qapply

>>> f = Function('f')
>>> x = Symbol('x')
>>> d = DifferentialOperator(1/x*Derivative(f(x), x), f(x))
>>> w = Wavefunction(x**2, x)

>>> d.function
f(x)
>>> d.variables
(x,)
>>> qapply(d*w)
Wavefunction(2, x)
```

**property expr**

Returns the arbitrary expression which is to have the Wavefunction substituted into
it
Examples

```python
>>> from sympy.physics.quantum.operator import DifferentialOperator
>>> from sympy import Function, Symbol, Derivative

>>> x = Symbol('x')
>>> f = Function('f')
>>> d = DifferentialOperator(Derivative(f(x), x), f(x))
>>> d.expr
Derivative(f(x), x)

>>> y = Symbol('y')
>>> d = DifferentialOperator(Derivative(f(x, y), x) + ...
                             Derivative(f(x, y), y), f(x, y))
>>> d.expr
Derivative(f(x, y), x) + Derivative(f(x, y), y)
```

property `free_symbols`

Return the free symbols of the expression.

property `function`

Returns the function which is to be replaced with the Wavefunction.

Examples

```python
>>> from sympy.physics.quantum.operator import DifferentialOperator
>>> from sympy import Symbol, Function, Derivative

>>> x = Symbol('x')
>>> f = Function('f')
>>> d = DifferentialOperator(Derivative(f(x), x), f(x))

>>> d.function
f(x)

>>> y = Symbol('y')
>>> d = DifferentialOperator(Derivative(f(x, y), x) + ...
                             Derivative(f(x, y), y), f(x, y))

>>> d.function
f(x, y)
```

property `variables`

Returns the variables with which the function in the specified arbitrary expression is evaluated.

Examples

```python
>>> from sympy.physics.quantum.operator import DifferentialOperator
>>> from sympy import Symbol, Function, Derivative

>>> x = Symbol('x')
>>> f = Function('f')
>>> d = DifferentialOperator(1/x*Derivative(f(x), x), f(x))
>>> d.variables
(x,)

>>> y = Symbol('y')
```

(continues on next page)
>>> d = DifferentialOperator(Derivative(f(x, y), x) + Derivative(f(x, y), y), f(x, y))
>>> d.variables
(x, y)

class sympy.physics.quantum.operator.HermitianOperator(*args, **kwargs)
A Hermitian operator that satisfies $H = \text{Dagger}(H)$.

Parameters
    args : tuple
        The list of numbers or parameters that uniquely specify the operator.
        For time-dependent operators, this will include the time.

Examples

>>> from sympy.physics.quantum import Dagger, HermitianOperator
>>> H = HermitianOperator('H')
>>> Dagger(H)

class sympy.physics.quantum.operator.IdentityOperator(*args, **kwargs)
An identity operator $I$ that satisfies $op * I = I * op = op$ for any operator $op$.

Parameters
    N : Integer
        Optional parameter that specifies the dimension of the Hilbert space
        of operator. This is used when generating a matrix representation.

Examples

>>> from sympy.physics.quantum import IdentityOperator
>>> IdentityOperator()

class sympy.physics.quantum.operator.Operator(*args, **kwargs)
Base class for non-commuting quantum operators.

An operator maps between quantum states [R703]. In quantum mechanics, observables
(including, but not limited to, measured physical values) are represented as Hermitian
operators [R704].

Parameters
    args : tuple
        The list of numbers or parameters that uniquely specify the operator.
        For time-dependent operators, this will include the time.
**Examples**

Create an operator and examine its attributes:

```python
>>> from sympy.physics.quantum import Operator
>>> from sympy import I

>>> A = Operator('A')
>>> A
A
>>> A.hilbert_space
H
>>> A.label
(A,)
>>> A.is_commutative
False
```

Create another operator and do some arithmetic operations:

```python
>>> B = Operator('B')

>>> C = 2*A*A + I*B
>>> C
2*A**2 + I*B

Operators do not commute:

```python
>>> A.is_commutative
False
>>> B.is_commutative
False
>>> A*B == B*A
False
```

Polynomials of operators respect the commutation properties:

```python
>>> e = (A+B)**3
>>> e.expand()
```

Operator inverses are handled symbolically:

```python
>>> A.inv()
A**(-1)
>>> A*A.inv()
1
```
**SymPy Documentation, Release 1.12.1**

**References**

[R703], [R704]

class sympy.physics.quantum.operator.OuterProduct(*args, **old_assumptions)

An unevaluated outer product between a ket and bra.

This constructs an outer product between any subclass of KetBase and BraBase as $|a><b|$. An OuterProduct inherits from Operator as they act as operators in quantum expressions. For reference see [R705].

**Parameters**

- **ket**: KetBase
  - The ket on the left side of the outer product.

- **bar**: BraBase
  - The bra on the right side of the outer product.

**Examples**

Create a simple outer product by hand and take its dagger:

```python
>>> from sympy.physics.quantum import Ket, Bra, OuterProduct, Dagger
>>> from sympy.physics.quantum import Operator

>>> k = Ket('k')
>>> b = Bra('b')
>>> op = OuterProduct(k, b)
>>> op
|k><b|
>>> op.hilbert_space
H
>>> op.ket
|k>
>>> op.bra
<b|
>>> Dagger(op)
|b><k|
```

In simple products of kets and bras outer products will be automatically identified and created:

```python
>>> k*b
|k><b|
```

But in more complex expressions, outer products are not automatically created:

```python
>>> A = Operator('A')
>>> A*k*b
A*|k><b|
```

A user can force the creation of an outer product in a complex expression by using parentheses to group the ket and bra:
A \cdot (k \cdot b)
A^* |k><b|

References

[R705]

property bra
Return the bra on the right side of the outer product.

property ket
Return the ket on the left side of the outer product.

class sympy.physics.quantum.operator.UnitaryOperator(*args, **kwargs)
A unitary operator that satisfies U*Dagger(U) == 1.

Parameters
args : tuple
The list of numbers or parameters that uniquely specify the operator.
For time-dependent operators, this will include the time.

Examples

>>> from sympy.physics.quantum import Dagger, UnitaryOperator
>>> U = UnitaryOperator('U')
>>> U*Dagger(U)
1

Operator/State Helper Functions

A module for mapping operators to their corresponding eigenstates and vice versa

It contains a global dictionary with eigenstate-operator pairings. If a new state-operator pair is created, this dictionary should be updated as well.

It also contains functions operators_to_state and state_to_operators for mapping between the two. These can handle both classes and instances of operators and states. See the individual function descriptions for details.

TODO List: - Update the dictionary with a complete list of state-operator pairs

sympy.physics.quantum.operatorset.operators_to_state(operators, **options)
Returns the eigenstate of the given operator or set of operators

A global function for mapping operator classes to their associated states. It takes either an Operator or a set of operators and returns the state associated with these.

This function can handle both instances of a given operator or just the class itself (i.e. both XOp() and XOp)

There are multiple use cases to consider:
1) A class or a set of classes is passed: First, we try to instantiate default instances for these operators. If this fails, then the class is simply returned. If we succeed in instantiating default instances, then we try to call state._operators_to_state on the operator instances. If this fails, the class is returned. Otherwise, the instance returned by _operators_to_state is returned.

2) An instance or a set of instances is passed: In this case, state._operators_to_state is called on the instances passed. If this fails, a state class is returned. If the method returns an instance, that instance is returned.

In both cases, if the operator class or set does not exist in the state_mapping dictionary, None is returned.

Parameters
arg: Operator or set
The class or instance of the operator or set of operators to be mapped to a state

Examples

```python
>>> from sympy.physics.quantum.cartesian import XOp, PxOp
>>> from sympy.physics.quantum.operatorset import operators_to_state
>>> from sympy.physics.quantum.operator import Operator

>>> operators_to_state(XOp)
|x>
>>> operators_to_state(XOp())
|x>
>>> operators_to_state(PxOp)
|px>
>>> operators_to_state(PxOp())
|px>
>>> operators_to_state(Operator)
|psi>
>>> operators_to_state(Operator())
|psi>
```

sympy.physics.quantum.operatorset.state_to_operators(state, **options)
Returns the operator or a set of operators corresponding to the given eigenstate

A global function for mapping state classes to their associated operators or sets of operators. It takes either a state class or instance.

This function can handle both instances of a given state or just the class itself (i.e. both XKet() and XKet)

There are multiple use cases to consider:

1) A state class is passed: In this case, we first try instantiating a default instance of the class. If this succeeds, then we try to call state._state_to_operators on that instance. If the creation of the default instance or if the calling of _state_to_operators fails, then either an operator class or a set of operator classes is returned. Otherwise, the appropriate operator instances are returned.

2) A state instance is returned: Here, state._state_to_operators is called for the instance. If this fails, then a class or a set of operator classes is returned. Otherwise, the instances are returned.
In either case, if the state’s class does not exist in state_mapping, None is returned.

**Parameters**

arg: StateBase class or instance (or subclasses)

The class or instance of the state to be mapped to an operator or set of operators

**Examples**

```python
>>> from sympy.physics.quantum.cartesian import XKet, PxKet, XBra, PxBra
>>> from sympy.physics.quantum.operatorset import state_to_operators
>>> from sympy.physics.quantum.state import Ket, Bra

>>> state_to_operators(XKet)
X

>>> state_to_operators(XKet())
X

>>> state_to_operators(PxKet)
Px

>>> state_to_operators(PxKet())
Px

>>> state_to_operators(PxBra)
Px

>>> state_to_operators(PxBra)
Px

>>> state_to_operators(XBra)
X

>>> state_to_operators(Ket)
O

>>> state_to_operators(Bra)
O
```

**Qapply**

Logic for applying operators to states.

Todo: * Sometimes the final result needs to be expanded, we should do this by hand.

sympy.physics.quantum.qapply.qapply(e, **options)

Apply operators to states in a quantum expression.

**Parameters**

- e : Expr
  
The expression containing operators and states. This expression tree will be walked to find operators acting on states symbolically.

- options : dict
  
  A dict of key/value pairs that determine how the operator actions are carried out.

  The following options are valid:

  - dagger: try to apply Dagger operators to the left (default: False).
  - ip_doit: call .doit() in inner products when they are encountered (default: True).
Returns
e : Expr
The original expression, but with the operators applied to states.

Examples

```python
>>> from sympy.physics.quantum import qapply, Ket, Bra
>>> b = Bra('b')
>>> k = Ket('k')
>>> A = k * b
>>> A
|k><b|
>>> qapply(A * b.dual / (b * b.dual))
|k>
>>> qapply(k.dual * A / (k.dual * k), dagger=True)
<b|
>>> qapply(k.dual * A / (k.dual * k))
<k*|k><b|/<k|k>
```

Represent

Logic for representing operators in state in various bases.

TODO:
- Get represent working with continuous hilbert spaces.
- Document default basis functionality.

```python
sympy.physics.quantum.represent.enumerate_states(*args, **options)
```

Returns instances of the given state with dummy indices appended

Operates in two different modes:

1. Two arguments are passed to it. The first is the base state which is to be indexed, and the second argument is a list of indices to append.

2. Three arguments are passed. The first is again the base state to be indexed. The second is the start index for counting. The final argument is the number of kets you wish to receive.

Tries to call state._enumerate_state. If this fails, returns an empty list

Parameters

- `args` : list
  See list of operation modes above for explanation
Examples

```python
>>> from sympy.physics.quantum.cartesian import XBra, XKet
>>> from sympy.physics.quantum.represent import enumerate_states
>>> test = XKet('foo')
>>> enumerate_states(test, 1, 3)
[|foo_1>, |foo_2>, |foo_3>]
>>> test2 = XBra('bar')
>>> enumerate_states(test2, [4, 5, 10])
[<bar_4|, <bar_5|, <bar_10|]
```

```
sympy.physics.quantum.represent.get_basis(expr, *, basis=None, replace_none=True, **options)
```

Returns a basis state instance corresponding to the basis specified in options=s. If no basis is specified, the function tries to form a default basis state of the given expression.

There are three behaviors:

1. The basis specified in options is already an instance of StateBase. If this is the case, it is simply returned. If the class is specified but not an instance, a default instance is returned.

2. The basis specified is an operator or set of operators. If this is the case, the operator_to_state mapping method is used.

3. No basis is specified. If expr is a state, then a default instance of its class is returned. If expr is an operator, then it is mapped to the corresponding state. If it is neither, then we cannot obtain the basis state.

If the basis cannot be mapped, then it is not changed.

This will be called from within represent, and represent will only pass QExpr’s.

TODO (?): Support for Muls and other types of expressions?

**Parameters**

- `expr`: Operator or StateBase
  - Expression whose basis is sought

**Examples**

```python
>>> from sympy.physics.quantum.represent import get_basis
>>> from sympy.physics.quantum.cartesian import XOp, XKet, PxOp, PxKet
>>> x = XKet()
>>> X = XOp()
>>> get_basis(x)
|x>
>>> get_basis(X)
|x>
>>> get_basis(x, basis=PxOp())
|px>
>>> get_basis(x, basis=PxKet)
|px>
```
sympy.physics.quantum.represent.integrate_result(orig_expr, result, **options)

Returns the result of integrating over any unities (\(|x><x|\)) in the given expression. Intended for integrating over the result of representations in continuous bases.

This function integrates over any unities that may have been inserted into the quantum expression and returns the result. It uses the interval of the Hilbert space of the basis state passed to it in order to figure out the limits of integration. The unities option must be specified for this to work.

Note: This is mostly used internally by represent(). Examples are given merely to show the use cases.

**Parameters**

*orig_expr*: quantum expression

The original expression which was to be represented

*result*: Expr

The resulting representation that we wish to integrate over

**Examples**

```python
>>> from sympy import symbols, DiracDelta
>>> from sympy.physics.quantum.represent import integrate_result
>>> from sympy.physics.quantum.cartesian import XOp, XKet
>>> x_ket = XKet()
>>> X_op = XOp()
>>> x, x_1, x_2 = symbols('x, x_1, x_2')
>>> integrate_result(X_op*x_ket, x*DiracDelta(x-x_1)*DiracDelta(x_1-x_2))
    x*DiracDelta(x - x_1)*DiracDelta(x_1 - x_2)
>>> integrate_result(X_op*x_ket, x*DiracDelta(x-x_1)*DiracDelta(x_1-x_2),
                    ...                 unities=[1])
    x*DiracDelta(x - x_2)
```

sympy.physics.quantum.represent.rep_expectation(expr, **options)

Returns an \(<x'|A|x>\) type representation for the given operator.

**Parameters**

*expr*: Operator

Operator to be represented in the specified basis

**Examples**

```python
>>> from sympy.physics.quantum.cartesian import XOp, PxOp, PxKet
>>> from sympy.physics.quantum.represent import rep_expectation
>>> rep_expectation(XOp())
    x_1*DiracDelta(x_1 - x_2)
>>> rep_expectation(XOp(), basis=PxOp())
    <px_2|*X*|px_1>
>>> rep_expectation(XOp(), basis=PxKet())
    <px_2|*X*|px_1>
```
The `rep_innerproduct` function returns an inner product like representation (e.g. \(<x'|x>\)) for the given state. It attempts to calculate inner product with a bra from the specified basis. Should only be passed an instance of KetBase or BraBase.

**Parameters**
- **expr**: KetBase or BraBase
  - The expression to be represented

**Examples**

```python
>>> from sympy.physics.quantum.represent import rep_innerproduct
>>> from sympy.physics.quantum.cartesian import XOp, XKet, PxOp, PxKet
>>> rep_innerproduct(XKet())
DiracDelta(x - x_1)
>>> rep_innerproduct(XKet(), basis=PxOp())
sqrt(2)*exp(-I*px_1*x/hbar)/(2*sqrt(hbar)*sqrt(pi))
>>> rep_innerproduct(PxKet(), basis=XOp())
sqrt(2)*exp(I*px*x_1/hbar)/(2*sqrt(hbar)*sqrt(pi))
```

The `represent` function represents the quantum expression in the given basis.

In quantum mechanics abstract states and operators can be represented in various basis sets. Under this operation the follow transforms happen:

- Ket -> column vector or function
- Bra -> row vector of function
- Operator -> matrix or differential operator

This function is the top-level interface for this action.

This function walks the SymPy expression tree looking for QExpr instances that have a `_represent` method. This method is then called and the object is replaced by the representation returned by this method. By default, the `_represent` method will dispatch to other methods that handle the representation logic for a particular basis set. The naming convention for these methods is the following:

```python
def _represent_FooBasis(self, e, basis, **options)
```

This function will have the logic for representing instances of its class in the basis set having a class named FooBasis.

**Parameters**
- **expr**: Expr
  - The expression to represent.
- **basis**: Operator, basis set
  - An object that contains the information about the basis set. If an operator is used, the basis is assumed to be the orthonormal eigenvectors of that operator. In general though, the basis argument can be any object that contains the basis set information.
**options** : dict

Key/value pairs of options that are passed to the underlying method that finds the representation. These options can be used to control how the representation is done. For example, this is where the size of the basis set would be set.

**Returns**

e : Expr

The SymPy expression of the represented quantum expression.

**Examples**

Here we subclass Operator and Ket to create the z-spin operator and its spin 1/2 up eigenstate. By defining the _represent_SzOp method, the ket can be represented in the z-spin basis.

```python
>>> from sympy.physics.quantum import Operator, represent, Ket
>>> from sympy import Matrix

>>> class SzUpKet(Ket):
...     def _represent_SzOp(self, basis, **options):
...         return Matrix([1, 0])

>>> class SzOp(Operator):
...     pass

>>> sz = SzOp('Sz')
>>> up = SzUpKet('up')
>>> represent(up, basis=sz)
Matrix([[1], [0]])
```

Here we see an example of representations in a continuous basis. We see that the result of representing various combinations of cartesian position operators and kets give us continuous expressions involving DiracDelta functions.

```python
>>> from sympy.physics.quantum.cartesian import XOp, XKet, XBra

>>> X = XOp()
>>> x = XKet()
>>> y = XBra('y')
>>> represent(X*x)
x*DiracDelta(x - x_2)
>>> represent(X*x*y)
x*DiracDelta(x - x_3)*DiracDelta(x_1 - y)
```
Spin

Quantum mechanical angular momentum.

class sympy.physics.quantum.spin.J2Op(*args, **kwargs)
The J^2 operator.

class sympy.physics.quantum.spin.JxBra(j, m)
Eigenbra of Jx.
See JzKet for the usage of spin eigenstates.

See also:

JzKetCoupled (page 1892)
Usage of coupled spin states

class sympy.physics.quantum.spin.JzKet(j, m)
Eigenket of Jz.

Spin state which is an eigenstate of the Jz operator. Uncoupled states, that is states representing the interaction of multiple separate spin states, are defined as a tensor product of states.

Parameters
  j : Number, Symbol
Total spin angular momentum

\[ m, \text{ Number, Symbol} \]

Eigenvalue of the Jz spin operator

**Examples**

**Normal States:**

Defining simple spin states, both numerical and symbolic:

```python
>>> from sympy.physics.quantum.spin import JzKet, JxKet
>>> from sympy import symbols

>>> JzKet(1, 0)
|1,0>

>>> j, m = symbols('j m')

>>> JzKet(j, m)
|j,m>
```

Rewriting the JzKet in terms of eigenkets of the Jx operator: Note: that the resulting eigenstates are JxKet's

```python
>>> JzKet(1,1).rewrite("Jx")
|1,-1>/2 - sqrt(2)*|1,0>/2 + |1,1>/2
```

Get the vector representation of a state in terms of the basis elements of the Jx operator:

```python
>>> from sympy.physics.quantum.represent import represent

>>> represent(JzKet(1,-1), basis=Jx)
Matrix([[1/2], [sqrt(2)/2], [1/2]])
```

Apply innerproducts between states:

```python
>>> from sympy.physics.quantum.innerproduct import InnerProduct

>>> i = InnerProduct(JxBra(1,1), JzKet(1,1))

>>> i
<i,1|1,1>

>>> i.doit()
1/2
```

**Uncoupled States:**

Define an uncoupled state as a TensorProduct between two Jz eigenkets:

```python
>>> from sympy.physics.quantum.tensorproduct import TensorProduct

>>> j1,m1,j2,m2 = symbols('j1 m1 j2 m2')

>>> TensorProduct(JzKet(1,0), JzKet(1,1))
|1,0>x|1,1>

>>> TensorProduct(JzKet(j1,m1), JzKet(j2,m2))
|j1,m1>x|j2,m2>
```
A TensorProduct can be rewritten, in which case the eigenstates that make up the tensor product is rewritten to the new basis:

\[
\text{TensorProduct(JzKet(1,1),JxKet(1,1)).rewrite('Jz')} = |1,1\rangle_x|1,-1\rangle/2 + \sqrt{2}(|1,1\rangle_x|1,0\rangle/2 + |1,1\rangle_x|1,1\rangle/2
\]

The represent method for TensorProduct’s gives the vector representation of the state. Note that the state in the product basis is the equivalent of the tensor product of the vector representation of the component eigenstates:

\[
\text{represent(TensorProduct(JzKet(1,0),JzKet(1,1)))} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}
\]

\[
\text{represent(TensorProduct(JzKet(1,1),JxKet(1,1)), basis=Jz)} = \begin{bmatrix} 1/2 \\ \sqrt{2}/2 \\ 1/2 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}
\]

**class sympy.physics.quantum.spin.JzKetCoupled(j, m, jn, *jcoupling)**

Coupled eigenket of Jz

Spin state that is an eigenket of Jz which represents the coupling of separate spin spaces. The arguments for creating instances of JzKetCoupled are j, m, jn and an optional jcoupling argument. The j and m options are the total angular momentum quantum numbers, as used for normal states (e.g. JzKet).
The other required parameter in \( \mathbf{j}_n \), which is a tuple defining the \( j_n \) angular momentum quantum numbers of the product spaces. So for example, if a state represented the coupling of the product basis state \( |j_1, m_1\rangle \times |j_2, m_2\rangle \), the \( j_n \) for this state would be \((j_1, j_2)\).

The final option is \( j_c \) coupling, which is used to define how the spaces specified by \( j_n \) are coupled, which includes both the order these spaces are coupled together and the quantum numbers that arise from these couplings. The \( j_c \) coupling parameter itself is a list of lists, such that each of the sublists defines a single coupling between the spin spaces. If there are \( N \) coupled angular momentum spaces, that is \( j_n \) has \( N \) elements, then there must be \( N-1 \) sublists. Each of these sublists making up the \( j_c \) coupling parameter have length 3. The first two elements are the indices of the product spaces that are considered to be coupled together. For example, if we want to couple \( j_1 \) and \( j_4 \), the indices would be 1 and 4. If a state has already been coupled, it is referenced by the smallest index that is coupled, so if \( j_2 \) and \( j_4 \) has already been coupled to some \( j_{24} \), then this value can be coupled by referencing it with index 2. The final element of the sublist is the quantum number of the coupled state. So putting everything together, into a valid sublist for \( j_c \) coupling, if \( j_1 \) and \( j_2 \) are coupled to an angular momentum space with quantum number \( j_{12} \) with the value \( j_{12} \), the sublist would be \((1, 2, j_{12})\). \( N-1 \) of these sublists are used in the list for \( j_c \) coupling.

Note the \( j_c \) coupling parameter is optional, if it is not specified, the default coupling is taken. This default value is to coupled the spaces in order and take the quantum number of the coupling to be the maximum value. For example, if the spin spaces are \( j_1, j_2, j_3, j_4 \), then the default coupling couples \( j_1 \) and \( j_2 \) to \( j_{12} = j_1 + j_2 \), then, \( j_{12} \) and \( j_3 \) are coupled to \( j_{123} = j_{12} + j_3 \), and finally \( j_{123} \) and \( j_4 \) to \( j = j_{123} + j_4 \). The \( j_c \) coupling value that would correspond to this is:

\[
((1,2,j_{12}),(1,3,j_{12}+j_3))
\]

**Parameters**

- **args** : tuple
  
The arguments that must be passed are \( j, m, j_n \), and \( j_c \) coupling. The \( j \) value is the total angular momentum. The \( m \) value is the eigenvalue of the \( J_z \) spin operator. The \( j_n \) list are the \( j \) values of angular momentum spaces coupled together. The \( j_c \) coupling parameter is an optional parameter defining how the spaces are coupled together. See the above description for how these coupling parameters are defined.

**Examples**

Defining simple spin states, both numerical and symbolic:

```python
>>> from sympy.physics.quantum.spin import JzKetCoupled
>>> from sympy import symbols

>>> JzKetCoupled(1, 0, (1, 1))
|1,0,j1=1,j2=1>

>>> j, m, j1, j2 = symbols('j m j1 j2')

>>> JzKetCoupled(j, m, (j1, j2))
|j,m,j1=1,j2=2>
```

Defining coupled spin states for more than 2 coupled spaces with various coupling parameters:
Rewriting the JzKetCoupled in terms of eigenkets of the Jx operator: Note: that the resulting eigenstates are JxKetCoupled

\[
JzKetCoupled(1, 1, (1, 1))
\]

\[
\frac{1}{\sqrt{2}} |1,-1,j1=1,j2=1>/2 - \sqrt{2} |1,0,j1=1,j2=1>/2 + |1,1,j1=1,j2=1>/2
\]

The rewrite method can be used to convert a coupled state to an uncoupled state. This is done by passing coupled=False to the rewrite function:

\[
JzKetCoupled(1, 0, (1, 1)).rewrite('Jz', coupled=False)
\]

\[
-\sqrt{2} |1,-1>x|1,1>/2 + \sqrt{2} |1,1>x|1,-1>/2
\]

Get the vector representation of a state in terms of the basis elements of the Jx operator:

\[
represent(JzKetCoupled(1,-1,(S(1)/2,S(1)/2)), basis=Jx)
\]

\[
Matrix([ [ 0 ], [ 1/2 ], [ sqrt(2)/2 ], [ 1/2 ]])
\]

Coupling of uncoupled spin states

**class sympy.physics.quantum.spin.JzOp(*args, **kwargs)**
The Jz operator.

**class sympy.physics.quantum.spin.Rotation(*args, **kwargs)**
Wigner D operator in terms of Euler angles.

Defines the rotation operator in terms of the Euler angles defined by the z-y-z convention for a passive transformation. That is the coordinate axes are rotated first about the z-axis, giving the new x’-y’-z’ axes. Then this new coordinate system is rotated about the new y’-axis, giving new x’’-y’’-z’’ axes. Then this new coordinate system is rotated about the z’’-axis. Conventions follow those laid out in [R706].

**Parameters**

- **alpha** : Number, Symbol
First Euler Angle

**beta** : Number, Symbol
Second Euler angle

**gamma** : Number, Symbol
Third Euler angle

### Examples

A simple example rotation operator:

```python
>>> from sympy import pi
>>> from sympy.physics.quantum.spin import Rotation
>>> Rotation(pi, 0, pi/2)
R(pi,0,pi/2)
```

With symbolic Euler angles and calculating the inverse rotation operator:

```python
>>> from sympy import symbols
>>> a, b, c = symbols('a b c')
>>> Rotation(a, b, c)
R(a,b,c)
>>> Rotation(a, b, c).inverse()
R(-c,-b,-a)
```

### References

[R706]

classmethod **D**(j, m, mp, alpha, beta, gamma)
Wigner D-function.

Returns an instance of the WignerD class corresponding to the Wigner-D function specified by the parameters.

**Parameters**

- **j** : Number
  Total angular momentum
- **m** : Number
  Eigenvalue of angular momentum along axis after rotation
- **mp** : Number

5.8. Topics 1895
Eigenvalue of angular momentum along rotated axis

**alpha** : Number, Symbol
  First Euler angle of rotation

**beta** : Number, Symbol
  Second Euler angle of rotation

**gamma** : Number, Symbol
  Third Euler angle of rotation

### Examples

Return the Wigner-D matrix element for a defined rotation, both numerical and symbolic:

```python
>>> from sympy.physics.quantum.spin import Rotation
>>> from sympy import pi, symbols
>>> alpha, beta, gamma = symbols('alpha beta gamma')
>>> Rotation.D(1, 1, 0, pi, pi/2, -pi)
WignerD(1, 1, 0, pi, pi/2, -pi)
```

See also:

**WignerD (page 1897)**
Symbolic Wigner-D function

**classmethod** d(j, m, mp, beta)
Wigner small-d function.

Returns an instance of the WignerD class corresponding to the Wigner-D function specified by the parameters with the alpha and gamma angles given as 0.

**Parameters**

- **j** : Number
  Total angular momentum
- **m** : Number
  Eigenvalue of angular momentum along axis after rotation
- **mp** : Number
  Eigenvalue of angular momentum along rotated axis
- **beta** : Number, Symbol
  Second Euler angle of rotation
Examples

Return the Wigner-D matrix element for a defined rotation, both numerical and sym-

bolic:

```python
>>> from sympy.physics.quantum.spin import Rotation
>>> from sympy import pi, symbols
>>> beta = symbols('beta')
>>> Rotation.d(1, 1, 0, pi/2)
WignerD(1, 1, 0, 0, pi/2, 0)
```

`WignerD` (page 1897)

Symbolic Wigner-D function

class sympy.physics.quantum.spin.WignerD(*args, **hints)

Wigner-D function

The Wigner D-function gives the matrix elements of the rotation operator in the jm-

representation. For the Euler angles $\alpha, \beta, \gamma$, the D-function is defined such that:

$$< j, m | R(\alpha, \beta, \gamma) | j', m' > = \delta_{jj'} D(j, m, m', \alpha, \beta, \gamma)$$

Where the rotation operator is as defined by the Rotation class [R707]. The Wigner D-function defined in this way gives:

$$D(j, m, m', \alpha, \beta, \gamma) = e^{-im\alpha} d(j, m, m', \beta) e^{-im'\gamma}$$

Where $d$ is the Wigner small-d function, which is given by Rotation.d.

The Wigner small-d function gives the component of the Wigner D-function that is deter-

mined by the second Euler angle. That is the Wigner D-function is:

$$D(j, m, m', \alpha, \beta, \gamma) = e^{-im\alpha} d(j, m, m', \beta) e^{-im'\gamma}$$

Where $d$ is the small-d function. The Wigner D-function is given by Rotation.D.

Note that to evaluate the D-function, the $j, m$ and $mp$ parameters must be integer or half integer numbers.

Parameters

- **j** : Number
  Total angular momentum
- **m** : Number
  Eigenvalue of angular momentum along axis after rotation
- **mp** : Number
  Eigenvalue of angular momentum along rotated axis
- **alpha** : Number, Symbol
  First Euler angle of rotation
- **beta** : Number, Symbol
  Second Euler angle of rotation
**gamma** : Number, Symbol

Third Euler angle of rotation

**Examples**

Evaluate the Wigner-D matrix elements of a simple rotation:

```python
>>> from sympy.physics.quantum.spin import Rotation

```n
```python
>>> from sympy import pi

```n
```python
>>> rot = Rotation.D(1, 1, 0, pi, pi/2, 0)
```

```python
>>> rot
WignerD(1, 1, 0, pi, pi/2, 0)
```

```python
>>> rot.doit()
```

```python
sqrt(2)/2
```

Evaluate the Wigner-d matrix elements of a simple rotation

```python
>>> rot = Rotation.d(1, 1, 0, pi/2)
```

```python
>>> rot
WignerD(1, 1, 0, 0, pi/2, 0)
```

```python
>>> rot.doit()
```

```python
-sqrt(2)/2
```

[R707]

sympy.physics.quantum.spin.couple(expr, jcoupling_list=None)

Couple a tensor product of spin states

This function can be used to couple an uncoupled tensor product of spin states. All of the eigenstates to be coupled must be of the same class. It will return a linear combination of eigenstates that are subclasses of CoupledSpinState determined by Clebsch-Gordan angular momentum coupling coefficients.

**Parameters**

expr : Expr

An expression involving TensorProducts of spin states to be coupled. Each state must be a subclass of SpinState and they all must be the same class.

jcoupling_list : list or tuple

Elements of this list are sub-lists of length 2 specifying the order of the coupling of the spin spaces. The length of this must be N-1, where N is the number of states in the tensor product to be coupled. The elements of this sub-list are the same as the first two elements of each sublist in the jcoupling parameter defined for JzKetCoupled. If this
parameter is not specified, the default value is taken, which couples the first and second product basis spaces, then couples this new coupled space to the third product space, etc

Examples

Couple a tensor product of numerical states for two spaces:

```python
>>> from sympy.physics.quantum.spin import JzKet, couple
>>> from sympy.physics.quantum.tensorproduct import TensorProduct
>>> couple(TensorProduct(JzKet(1, 0), JzKet(1, 1)))
-sqrt(2)*|1,1,j1=1,j2=1>/2 + sqrt(2)*|2,1,j1=1,j2=1>/2
```

Numerical coupling of three spaces using the default coupling method, i.e. first and second spaces couple, then this couples to the third space:

```python
>>> couple(TensorProduct(JzKet(1, 1), JzKet(1, 1), JzKet(1, 0)))
sqrt(6)*|2,2,j1=1,j2=1,j3=1,j(1,2)=2>/3 + sqrt(3)*|3,2,j1=1,j2=1,j3=1,
       -j(1,2)=2>/3
```

Perform this same coupling, but we define the coupling to first couple the first and third spaces:

```python
>>> couple(TensorProduct(JzKet(1, 1), JzKet(1, 1), JzKet(1, 0)), ((1, 3), (1, -2)))
sqrt(2)*|2,2,j1=1,j2=1,j3=1,j(1,3)=1>/2 - sqrt(6)*|2,2,j1=1,j2=1,j3=1,
       -j(1,3)=2>/6 + sqrt(3)*|3,2,j1=1,j2=1,j3=1,j(1,3)=2>/3
```

Couple a tensor product of symbolic states:

```python
>>> from sympy import symbols
>>> j1,m1,j2,m2 = symbols('j1 m1 j2 m2')
>>> couple(TensorProduct(JzKet(j1,m1), JzKet(j2,m2)))
Sum(CG(j1, m1, j2, m2, j, m1 + m2)*|j,m1 + m2,j1=j1,j2=j2>, (j, m1 + m2, 
       -j1 + j2))
```

sympy.physics.quantum.spin.uncouple(expr, jn=None, jcoupling_list=None)
Uncouple a coupled spin state

Gives the uncoupled representation of a coupled spin state. Arguments must be either a spin state that is a subclass of CoupledSpinState or a spin state that is a subclass of SpinState and an array giving the j values of the spaces that are to be coupled

Parameters
expr : Expr
    The expression containing states that are to be coupled. If the states are a subclass of SpinState, the jn and jcoupling parameters must be defined. If the states are a subclass of CoupledSpinState, jn and jcoupling will be taken from the state.

jn : list or tuple
    The list of the j-values that are coupled. If state is a CoupledSpinState, this parameter is ignored. This must be defined if state is not
a subclass of CoupledSpinState. The syntax of this parameter is the same as the \texttt{jn} parameter of \texttt{JzKetCoupled}.

\textbf{jcoupling_list} : list or tuple

The list defining how the j-values are coupled together. If state is a CoupledSpinState, this parameter is ignored. This must be defined if state is not a subclass of CoupledSpinState. The syntax of this parameter is the same as the \texttt{jcoupling} parameter of \texttt{JzKetCoupled}.

\section*{Examples}

Uncouple a numerical state using a CoupledSpinState state:

```python
>>> from sympy.physics.quantum.spin import JzKetCoupled, uncouple
>>> sqrt(2)*|1/2,-1/2>x|1/2,1/2>/2 + sqrt(2)*|1/2,1/2>x|1/2,-1/2>/2
```

Perform the same calculation using a SpinState state:

```python
>>> from sympy.physics.quantum.spin import JzKet
>>> sqrt(2)*|1/2,-1/2>x|1/2,1/2>/2 + sqrt(2)*|1/2,1/2>x|1/2,-1/2>/2
```

Uncouple a numerical state of three coupled spaces using a CoupledSpinState state:

```python
>>> uncouple(JzKetCoupled(1, 1, 1, 1), ((1,3,1),(1,2,1)))
|1,-1>x|1,1>x|1,1>/2 - |1,0>x|1,0>x|1,0>/2 - |1,1>→x|1,1>x|1,-1>/2
```

Perform the same calculation using a SpinState state:

```python
>>> uncouple(JzKet(1, 1), (1, 1, 1), ((1,3,1),(1,2,1)))
|1,-1>x|1,1>x|1,1>/2 - |1,0>x|1,0>x|1,0>/2 - |1,1>→x|1,1>x|1,-1>/2
```

Uncouple a symbolic state using a CoupledSpinState state:

```python
>>> from sympy import symbols
>>> j,m,j1,j2 = symbols('j m j1 j2')
>>> Sum(CG(j1, m1, j2, m2, j, m)*|j1,m1>x|j2,m2>, (m1, -j1, j1), (m2, -j2, j2))
```

Perform the same calculation using a SpinState state

```python
>>> uncouple(JzKet(j, m), (j1, j2))
Sum(CG(j1, m1, j2, m2, j, m)*|j1,m1>x|j2,m2>, (m1, -j1, j1), (m2, -j2, j2))
```
State

Dirac notation for states.

```python
class sympy.physics.quantum.state.Bra(*args, **kwargs)
```
A general time-independent Bra in quantum mechanics.

Inherits from State and BraBase. A Bra is the dual of a Ket [R708]. This class and its subclasses will be the main classes that users will use for expressing Bras in Dirac notation.

**Parameters**

- `args`: tuple
  The list of numbers or parameters that uniquely specify the ket. This will usually be its symbol or its quantum numbers. For time-dependent state, this will include the time.

**Examples**

Create a simple Bra and look at its properties:

```python
>>> from sympy.physics.quantum import Bra
>>> from sympy import symbols, I

>>> b = Bra('psi')
>>> b
<psi|
>>> b.hilbert_space
H
>>> b.is_commutative
False
```

Bra’s know about their dual Ket’s:

```python
>>> b.dual
|psi>
>>> b.dual_class()
<class 'sympy.physics.quantum.state.Ket'>
```

Like Kets, Bras can have compound labels and be manipulated in a similar manner:

```python
>>> n, m = symbols('n,m')
>>> b = Bra(n, m) - I*Bra(m, n)
>>> b
-I<mn| + <nm|
```

Symbols in a Bra can be substituted using `.subs`:

```python
>>> b.subs(n, m)
<mm| - I*<mm|
```
class sympy.physics.quantum.state.BraBase(*args, **kwargs)

Base class for Bras.

This class defines the dual property and the brackets for printing. This is an abstract base class and you should not instantiate it directly, instead use Bra.

class sympy.physics.quantum.state.Ket(*args, **kwargs)

A general time-independent Ket in quantum mechanics.

Inherits from State and KetBase. This class should be used as the base class for all physical, time-independent Kets in a system. This class and its subclasses will be the main classes that users will use for expressing Kets in Dirac notation [R709].

**Parameters**

*args : tuple

The list of numbers or parameters that uniquely specify the ket. This will usually be its symbol or its quantum numbers. For time-dependent state, this will include the time.

**Examples**

Create a simple Ket and looking at its properties:

```python
>>> from sympy.physics.quantum import Ket
>>> from sympy import symbols, I

>>> k = Ket('psi')
>>> k
|psi>
>>> k.hilbert_space
H
>>> k.is_commutative
False
>>> k.label
{'psi'}
```

Ket's know about their associated bra:

```python
>>> k.dual
<psi|
>>> k.dual_class()
<class 'sympy.physics.quantum.state.Bra'>
```

Take a linear combination of two kets:

```python
>>> k0 = Ket(0)
>>> k1 = Ket(1)
>>> 2*I*k0 - 4*k1
2*I*|0> - 4*|1>
```

Compound labels are passed as tuples:
```python
>>> n, m = symbols('n,m')
>>> k = Ket(n,m)
>>> k
|nm>
```

### References

[R709]

class sympy.physics.quantum.state.KetBase(*args, **kwargs)
Base class for Kets.

This class defines the dual property and the brackets for printing. This is an abstract base class and you should not instantiate it directly, instead use Ket.

class sympy.physics.quantum.state.OrthogonalBra(*args, **kwargs)
Orthogonal Bra in quantum mechanics.

class sympy.physics.quantum.state.OrthogonalKet(*args, **kwargs)
Orthogonal Ket in quantum mechanics.

The inner product of two states with different labels will give zero, states with the same label will give one.

```python
>>> from sympy.physics.quantum import OrthogonalBra, OrthogonalKet
>>> from sympy.abc import m, n
>>> (OrthogonalBra(n)*OrthogonalKet(n)).doit()
1
>>> (OrthogonalBra(n)*OrthogonalKet(n+1)).doit()
0
>>> (OrthogonalBra(n)*OrthogonalKet(m)).doit()
<n|m>
```

class sympy.physics.quantum.state.OrthogonalState(*args, **kwargs)
General abstract quantum state used as a base class for Ket and Bra.

class sympy.physics.quantum.state.State(*args, **kwargs)
General abstract quantum state used as a base class for Ket and Bra.

class sympy.physics.quantum.state.StateBase(*args, **kwargs)
Abstract base class for general abstract states in quantum mechanics.

All other state classes defined will need to inherit from this class. It carries the basic structure for all other states such as dual, _eval_adjoint and label.

This is an abstract base class and you should not instantiate it directly, instead use State.

**property dual**
Return the dual state of this one.

**classmethod dual_class()**
Return the class used to construct the dual.

**property operators**
Return the operator(s) that this state is an eigenstate of
class sympy.physics.quantum.state.TimeDepBra(*args, **kwargs)
General time-dependent Bra in quantum mechanics.
This inherits from TimeDepState and BraBase and is the main class that should be used for Bras that vary with time. Its dual is a TimeDepBra.

**Parameters**
*args : tuple
The list of numbers or parameters that uniquely specify the ket.
This will usually be its symbol or its quantum numbers. For time-dependent state, this will include the time as the final argument.

**Examples**
```
>>> from sympy.physics.quantum import TimeDepBra
>>> b = TimeDepBra('psi', 't')
>>> b
<psi;t|
>>> b.time
(t,
>>> b.label
(psi,)
>>> b.hilbert_space
H
>>> b.dual
|psi;t>
```

class sympy.physics.quantum.state.TimeDepKet(*args, **kwargs)
General time-dependent Ket in quantum mechanics.
This inherits from TimeDepState and KetBase and is the main class that should be used for Kets that vary with time. Its dual is a TimeDepBra.

**Parameters**
*args : tuple
The list of numbers or parameters that uniquely specify the ket.
This will usually be its symbol or its quantum numbers. For time-dependent state, this will include the time as the final argument.

**Examples**
Create a TimeDepKet and look at its attributes:
```
>>> from sympy.physics.quantum import TimeDepKet
>>> k = TimeDepKet('psi', 't')
>>> k
|psi;t>
>>> k.time
(t,
>>> k.label
(psi,)
```
TimeDepKets know about their dual bra:

```python
>>> k.dual
<psi;t|
>>> k.dual_class()
<class 'sympy.physics.quantum.state.TimeDepBra'>
```

class sympy.physics.quantum.state.TimeDepState(*args, **kwargs)
Base class for a general time-dependent quantum state.

This class is used as a base class for any time-dependent state. The main difference
between this class and the time-independent state is that this class takes a second argument
that is the time in addition to the usual label argument.

Parameters
  **args** : tuple
      The list of numbers or parameters that uniquely specify the ket.
      This will usually be its symbol or its quantum numbers. For time-
      dependent state, this will include the time as the final argument.

  **property label**
      The label of the state.

  **property time**
      The time of the state.

class sympy.physics.quantum.state.Wavefunction(*args)
Class for representations in continuous bases

This class takes an expression and coordinates in its constructor. It can be used to easily
calculate normalizations and probabilities.

Parameters
  **expr** : Expr
      The expression representing the functional form of the w.f.

  **coords** : Symbol or tuple
      The coordinates to be integrated over, and their bounds

Examples

Particle in a box, specifying bounds in the more primitive way of using Piecewise:

```python
>>> from sympy import Symbol, Piecewise, pi, N
>>> from sympy.functions import sqrt, sin
>>> from sympy.physics.quantum.state import Wavefunction
>>> x = Symbol('x', real=True)
>>> n = 1
>>> L = 1
>>> g = Piecewise((0, x < 0), (0, x > L), (sqrt(2/L)*sin(n*pi*x/L),
```

(continues on next page)
Additionally, you can specify the bounds of the function and the indices in a more compact way:

\[
\begin{align*}
\text{from sympy import symbols, pi, diff} \\
\text{from sympy.functions import sqrt, sin} \\
\text{from sympy.physics.quantum.state import Wavefunction} \\
\text{x, L = symbols('x, L', positive=True)} \\
n = symbols('n', integer=True, positive=True) \\
g = sqrt(2/L)*sin(n*pi*x/L) \\
f = Wavefunction(g, (x, 0, L)) \\
f.norm \\
1 \\
f(L+1) \\
0 \\
f(L-1) \\
sqrt(2)*sin(pi*n*(L - 1)/L)/sqrt(L) \\
f(-1) \\
0 \\
f(0.85) \\
sqrt(2)*sin(0.85*pi*n/L)/sqrt(L) \\
f(0.85, n=1, L=1) \\
sqrt(2)*sin(0.85*pi) \\
f.is_commutative \\
False
\end{align*}
\]

All arguments are automatically sympified, so you can define the variables as strings rather than symbols:

\[
\begin{align*}
\text{expr = x**2} \\
f = Wavefunction(expr, 'x') \\
type(f.variables[0]) \\
<\text{class 'sympy.core.symbol.Symbol'>}
\end{align*}
\]

Derivatives of Wavefunctions will return Wavefunctions:
>>> diff(f, x)
Wavefunction(2*x, x)

**property expr**
Return the expression which is the functional form of the Wavefunction

**Examples**

```python
>>> from sympy.physics.quantum.state import Wavefunction
>>> from sympy import symbols
>>> x, y = symbols('x, y')
>>> f = Wavefunction(x**2, x)
>>> f.expr
x**2
```

**property is_commutative**
Override Function's is_commutative so that order is preserved in represented expressions

**property is_normalized**
Returns true if the Wavefunction is properly normalized

**Examples**

```python
>>> from sympy import symbols, pi
>>> from sympy.functions import sqrt, sin
>>> from sympy.physics.quantum.state import Wavefunction
>>> x, L = symbols('x,L', positive=True)
>>> n = symbols('n', integer=True, positive=True)
>>> g = sqrt(2/L)*sin(n*pi*x/L)
>>> f = Wavefunction(g, (x, 0, L))
>>> f.is_normalized
True
```

**property limits**
Return the limits of the coordinates which the w.f. depends on If no limits are specified, defaults to (-oo, oo).

**Examples**

```python
>>> from sympy.physics.quantum.state import Wavefunction
>>> from sympy import symbols
>>> x, y = symbols('x, y')
>>> f = Wavefunction(x**2, (x, 0, 1))
>>> f.limits
{x: (0, 1)}
>>> f = Wavefunction(x**2, x)
>>> f.limits
```

(continues on next page)
property norm

Return the normalization of the specified functional form.
This function integrates over the coordinates of the Wavefunction, with the bounds specified.

Examples

```python
>>> from sympy import symbols, pi
>>> from sympy.functions import sqrt, sin
>>> from sympy.physics.quantum.state import Wavefunction
>>> x, L = symbols('x,L', positive=True)
>>> n = symbols('n', integer=True, positive=True)
>>> g = sqrt(2/L)*sin(n*pi*x/L)
>>> f = Wavefunction(g, (x, 0, L))
>>> f.norm
1
>>> g = sin(n*pi*x/L)
>>> f = Wavefunction(g, (x, 0, L))
>>> f.norm
sqrt(2)*sqrt(L)/2
```

normalize()

Return a normalized version of the Wavefunction

Examples

```python
>>> from sympy import symbols, pi
>>> from sympy.functions import sin
>>> from sympy.physics.quantum.state import Wavefunction
>>> x = symbols('x', real=True)
>>> L = symbols('L', positive=True)
>>> n = symbols('n', integer=True, positive=True)
>>> g = sin(n*pi*x/L)
>>> f = Wavefunction(g, (x, 0, L))
>>> f.normalize()
Wavefunction(sqrt(2)*sin(pi*n*x/L)/sqrt(L), (x, 0, L))
```

prob()

Return the absolute magnitude of the w.f., $|\psi(x)|^2$

```python
>>> f = Wavefunction(x**2 + y**2, x, (y, -1, 2))
>>> f.limits
{x: (-oo, oo), y: (-1, 2)}
```
Examples

```python
>>> from sympy import symbols, pi
>>> from sympy.functions import sin
>>> from sympy.physics.quantum.state import Wavefunction
>>> x, L = symbols('x, L', real=True)
>>> n = symbols('n', integer=True)
>>> g = sin(n*pi*x/L)
>>> f = Wavefunction(g, (x, 0, L))
>>> f.prob()
Wavefunction(sin(pi*n*x/L)**2, x)
```

**property variables**

Return the coordinates which the wavefunction depends on

Examples

```python
>>> from sympy.physics.quantum.state import Wavefunction
>>> from sympy import symbols

>>> x, y = symbols('x, y')
>>> f = Wavefunction(x*y, x, y)
>>> f.variables
(x, y)

>>> g = Wavefunction(x*y, x)
>>> g.variables
(x,)
```

Quantum Computation

Circuit Plot

Matplotlib based plotting of quantum circuits.

Todo:

- Optimize printing of large circuits.
- Get this to work with single gates.
- Do a better job checking the form of circuits to make sure it is a Mul of Gates.
- Get multi-target gates plotting.
- Get initial and final states to plot.
- Get measurements to plot. Might need to rethink measurement as a gate issue.
- Get scale and figsize to be handled in a better way.
- Write some tests/examples!

```python
class sympy.physics.quantum.circuitplot.CircuitPlot(c, nqubits, **kwargs)
A class for managing a circuit plot.
```
control_line(gate_idx, min_wire, max_wire)
    Draw a vertical control line.

control_point(gate_idx, wire_idx)
    Draw a control point.

not_point(gate_idx, wire_idx)
    Draw a NOT gates as the circle with plus in the middle.

one_qubit_box(t, gate_idx, wire_idx)
    Draw a box for a single qubit gate.

swap_point(gate_idx, wire_idx)
    Draw a swap point as a cross.

two_qubit_box(t, gate_idx, wire_idx)
    Draw a box for a two qubit gate. Does not work yet.

update(kwvars)
    Load the kwars into the instance dict.

sympy.physics.quantum.circuitplot.CreateCGate(name, latexname=None)
    Use a lexical closure to make a controlled gate.

class sympy.physics.quantum.circuitplot.Mx(*args, **kwvars)
    Mock-up of an x measurement gate.
    This is in circuitplot rather than gate.py because it's not a real gate, it just draws one.

class sympy.physics.quantum.circuitplot.Mz(*args, **kwvars)
    Mock-up of a z measurement gate.
    This is in circuitplot rather than gate.py because it’s not a real gate, it just draws one.

sympy.physics.quantum.circuitplot.circuit_plot(c, nqubits, **kwvars)
    Draw the circuit diagram for the circuit with nqubits.

Parameters
  c: circuit
    The circuit to plot. Should be a product of Gate instances.
  nqubits: int
    The number of qubits to include in the circuit. Must be at least as big
    as the largest min_qubits of the gates.

sympy.physics.quantum.circuitplot.labeller(n, symbol='q')
    Autogenerate labels for wires of quantum circuits.

Parameters
  n: int
    number of qubits in the circuit.
  symbol: string
    A character string to precede all gate labels. E.g. ‘q_0’, ‘q_1’, etc.

>>> from sympy.physics.quantum.circuitplot import labeller
>>> labeller(2)
['q_1', 'q_0']

>>> labeller(3,'j')
['j_2', 'j_1', 'j_0']

**Gates**

An implementation of gates that act on qubits.

Gates are unitary operators that act on the space of qubits.

**Medium Term Todo:**

- Optimize Gate._apply_operators_Qubit to remove the creation of many intermediate Qubit objects.
- Add commutation relationships to all operators and use this in gate_sort.
- Fix gate_sort and gate_simp.
- Get multi-target UGates plotting properly.
- Get UGate to work with either sympy/numpy matrices and output either format. This should also use the matrix slots.

```python
class sympy.physics.quantum.gate.CGate(*args, **kwargs)
    A general unitary gate with control qubits.
    A general control gate applies a target gate to a set of targets if all of the control qubits have a particular values (set by CGate.control_value).

    Parameters
    label: tuple
        The label in this case has the form (controls, gate), where controls is a tuple/list of control qubits (as ints) and gate is a Gate instance that is the target operator.

    property controls
        A tuple of control qubits.

    decompose(**options)
        Decompose the controlled gate into CNOT and single qubits gates.

    eval_controls(qubit)
        Return True/False to indicate if the controls are satisfied.

    property gate
        The non-controlled gate that will be applied to the targets.

    property min_qubits
        The minimum number of qubits this gate needs to act on.

    property nqubits
        The total number of qubits this gate acts on.
```

For controlled gate subclasses this includes both target and control qubits, so that, for examples the CNOT gate acts on 2 qubits.
plot_gate(
circ_plot, gate_idx)

Plot the controlled gate. If simplify_cgate is true, simplify C-X and C-Z gates into their more familiar forms.

property targets

A tuple of target qubits.

class sympy.physics.quantum.gate.CGateS(*args, **kwargs)

Version of CGate that allows gate simplifications. I.e. cnot looks like an oplus, cphase has dots, etc.

sympy.physics.quantum.gate.CNOT

alias of CNotGate (page 1912)

class sympy.physics.quantum.gate.CNotGate(*args, **kwargs)

Two qubit controlled-NOT.

This gate performs the NOT or X gate on the target qubit if the control qubits all have the value 1.

Parameters

label : tuple

A tuple of the form (control, target).

Examples

```python
>>> from sympy.physics.quantum.gate import CNOT
>>> from sympy.physics.quantum.qapply import qapply
>>> from sympy.physics.quantum.qubit import Qubit

>>> c = CNOT(1,0)
>>> qapply(c*Qubit('10'))  # note that qubits are indexed from right to left
|11>
```

property controls

A tuple of control qubits.

property gate

The non-controlled gate that will be applied to the targets.

property min_qubits

The minimum number of qubits this gate needs to act on.

property targets

A tuple of target qubits.

class sympy.physics.quantum.gate.Gate(*args, **kwargs)

Non-controlled unitary gate operator that acts on qubits.

This is a general abstract gate that needs to be subclassed to do anything useful.

Parameters

label : tuple, int

A list of the target qubits (as ints) that the gate will apply to.
`get_target_matrix` *(format='sympy')*

The matrix representation of the target part of the gate.

**Parameters**

- `format`: str
  The format string ('sympy', 'numpy', etc.)

**property min_qubits**

The minimum number of qubits this gate needs to act on.

**property nqubits**

The total number of qubits this gate acts on.

For controlled gate subclasses this includes both target and control qubits, so that, for examples the CNOT gate acts on 2 qubits.

**property targets**

A tuple of target qubits.

`sympy.physics.quantum.gate.H`  
alias of `HadamardGate` *(page 1913)*

**class sympy.physics.quantum.gate.HadamardGate(*args, **kwargs)*

The single qubit Hadamard gate.

**Parameters**

- `target`: int
  The target qubit this gate will apply to.

**Examples**

```python
>>> from sympy import sqrt
>>> from sympy.physics.quantum.qubit import Qubit
>>> from sympy.physics.quantum.gate import HadamardGate
>>> from sympy.physics.quantum.qapply import qapply

>>> qapply(HadamardGate(0)*Qubit('1'))
sqrt(2)*|0>/2 - sqrt(2)*|1>/2
```

```
# Hadamard on bell state, applied on 2 qubits.
>>> psi = 1/sqrt(2)*(Qubit('00')+Qubit('11'))
>>> qapply(HadamardGate(0)*HadamardGate(1)*psi)
sqrt(2)*|00>/2 + sqrt(2)*|11>/2
```

**class sympy.physics.quantum.gate.IdentityGate(*args, **kwargs)*

The single qubit identity gate.

**Parameters**

- `target`: int
  The target qubit this gate will apply to.

**class sympy.physics.quantum.gate.OneQubitGate(*args, **kwargs)*

A single qubit unitary gate base class.

`sympy.physics.quantum.gate.Phase`  
alias of `PhaseGate` *(page 1913)*
class sympy.physics.quantum.gate.PhaseGate(*args, **kwargs)

The single qubit phase, or S, gate.
This gate rotates the phase of the state by pi/2 if the state is \( |1\rangle \) and does nothing if the state is \( |0\rangle \).

Parameters
   target : int
      The target qubit this gate will apply to.

sympy.physics.quantum.gate.S
alias of PhaseGate (page 1913)

sympy.physics.quantum.gate.SWAP
alias of SwapGate (page 1914)

class sympy.physics.quantum.gate.SwapGate(*args, **kwargs)

Two qubit SWAP gate.
This gate swap the values of the two qubits.

Parameters
   label : tuple
      A tuple of the form (target1, target2).

   decompose(**options)
      Decompose the SWAP gate into CNOT gates.

sympy.physics.quantum.gate.T
alias of TGate (page 1914)

class sympy.physics.quantum.gate.TGate(*args, **kwargs)

The single qubit \( \pi/8 \) gate.
This gate rotates the phase of the state by pi/4 if the state is \( |1\rangle \) and does nothing if the state is \( |0\rangle \).

Parameters
   target : int
      The target qubit this gate will apply to.

class sympy.physics.quantum.gate.TwoQubitGate(*args, **kwargs)

A two qubit unitary gate base class.

class sympy.physics.quantum.gate.UGate(*args, **kwargs)

General gate specified by a set of targets and a target matrix.

Parameters
   label : tuple
      A tuple of the form (targets, U), where targets is a tuple of the target qubits and U is a unitary matrix with dimension of len(targets).

   get_target_matrix(format='sympy')
      The matrix rep. of the target part of the gate.

      Parameters
         format : str
            The format string ('sympy', 'numpy', etc.)
property targets
A tuple of target qubits.
sympy.physics.quantum.gate.X
alias of XGate (page 1915)
class sympy.physics.quantum.gate.XGate(*args, **kwargs)
The single qubit X, or NOT, gate.
    Parameters
    target : int
        The target qubit this gate will apply to.
sympy.physics.quantum.gate.Y
alias of YGate (page 1915)
class sympy.physics.quantum.gate.YGate(*args, **kwargs)
The single qubit Y gate.
    Parameters
    target : int
        The target qubit this gate will apply to.
sympy.physics.quantum.gate.Z
alias of ZGate (page 1915)
class sympy.physics.quantum.gate.ZGate(*args, **kwargs)
The single qubit Z gate.
    Parameters
    target : int
        The target qubit this gate will apply to.
sympy.physics.quantum.gate.gate_simp(circuit)
Simplifies gates symbolically
    It first sorts gates using gate_sort. It then applies basic simplification rules to the circuit, e.g., XGate**2 = Identity
sympy.physics.quantum.gate.gate_sort(circuit)
Sorts the gates while keeping track of commutation relations
    This function uses a bubble sort to rearrange the order of gate application. Keeps track of Quantum computations special commutation relations (e.g. things that apply to the same Qubit do not commute with each other)
circuit is the Mul of gates that are to be sorted.
sympy.physics.quantum.gate.normalized(normalize)
Set flag controlling normalization of Hadamard gates by 1/√2.
    This is a global setting that can be used to simplify the look of various expressions, by leaving off the leading 1/√2 of the Hadamard gate.
    Parameters
    normalize : bool

5.8. Topics 1915
Should the Hadamard gate include the $1/\sqrt{2}$ normalization factor? When True, the Hadamard gate will have the $1/\sqrt{2}$. When False, the Hadamard gate will not have this factor.

```python
sympy.physics.quantum.gate.random_circuit(ngates, nqubits, gate_space=(
    'sympy.physics.quantum.gate.XGate',
    'sympy.physics.quantum.gate.YGate',
    'sympy.physics.quantum.gate.ZGate',
    'sympy.physics.quantum.gate.PhaseGate',
    'sympy.physics.quantum.gate.TGate',
    'sympy.physics.quantum.gate.HadamardGate',
    'sympy.physics.quantum.gate.CNotGate',
    'sympy.physics.quantum.gate.SwapGate'))
```

Return a random circuit of ngates and nqubits. This uses an equally weighted sample of (X, Y, Z, S, T, H, CNOT, SWAP) gates.

**Parameters**
- **ngates**: int
  The number of gates in the circuit.
- **nqubits**: int
  The number of qubits in the circuit.
- **gate_space**: tuple
  A tuple of the gate classes that will be used in the circuit. Repeating gate classes multiple times in this tuple will increase the frequency they appear in the random circuit.

**Grover’s Algorithm**

Grover’s algorithm and helper functions.

Todo:
- W gate construction (or perhaps -W gate based on Mermin’s book)
- Generalize the algorithm for an unknown function that returns 1 on multiple qubit states, not just one.
- Implement _represent_ZGate in OracleGate

```python
class sympy.physics.quantum.grover.OracleGate(*args, **kwargs)
```

A black box gate.

The gate marks the desired qubits of an unknown function by flipping the sign of the qubits. The unknown function returns true when it finds its desired qubits and false otherwise.
**Parameters**

- **qubits** : int
  
  Number of qubits.

- **oracle** : callable
  
  A callable function that returns a boolean on a computational basis.

**Examples**

Apply an Oracle gate that flips the sign of $|2\rangle$ on different qubits:

```python
>>> from sympy.physics.quantum.qubit import IntQubit
>>> from sympy.physics.quantum.qapply import qapply
>>> from sympy.physics.quantum.grover import OracleGate
>>> f = lambda qubits: qubits == IntQubit(2)
>>> v = OracleGate(2, f)
>>> qapply(v*IntQubit(2))
-|2\rangle
>>> qapply(v*IntQubit(3))
|3\rangle
```

**property search_function**

The unknown function that helps find the sought after qubits.

**property targets**

A tuple of target qubits.

**class** sympy.physics.quantum.grover.WGate(*args, **kwargs)

General n qubit W Gate in Grover's algorithm.

The gate performs the operation $2|\phi\rangle\langle\phi|-1$ on some qubits. $|\phi\rangle = \text{(tensor product of n Hadamards)}*|0\rangle$ with n qubits

**Parameters**

- **nqubits** : int
  
  The number of qubits to operate on

**sympy.physics.quantum.grover.apply_grover**(oracle, nqubits, iterations=None)

Applies grover's algorithm.

**Parameters**

- **oracle** : callable
  
  The unknown callable function that returns true when applied to the desired qubits and false otherwise.

**Returns**

- **state** : Expr
  
  The resulting state after Grover's algorithm has been iterated.
Examples

Apply grover’s algorithm to an even superposition of 2 qubits:

```python
>>> from sympy.physics.quantum.qapply import qapply
>>> from sympy.physics.quantum.qubit import IntQubit
>>> from sympy.physics.quantum.grover import apply_grover
>>> f = lambda qubits: qubits == IntQubit(2)
>>> qapply(apply_grover(f, 2))
|2>
```

`sympy.physics.quantum.grover.grover_iteration(qstate, oracle)`
Applies one application of the Oracle and W Gate, WV.

**Parameters**
- `qstate` : Qubit
  A superposition of qubits.
- `oracle` : OracleGate
  The black box operator that flips the sign of the desired basis qubits.

**Returns**
- `Qubit` : The qubits after applying the Oracle and W gate.

Examples

Perform one iteration of grover’s algorithm to see a phase change:

```python
>>> from sympy.physics.quantum.qapply import qapply
>>> from sympy.physics.quantum.qubit import IntQubit
>>> from sympy.physics.quantum.grover import OracleGate
>>> from sympy.physics.quantum.grover import superposition_basis
>>> from sympy.physics.quantum.grover import grover_iteration
>>> numqubits = 2
>>> basis_states = superposition_basis(numqubits)
>>> f = lambda qubits: qubits == IntQubit(2)
>>> v = OracleGate(numqubits, f)
>>> qapply(grover_iteration(basis_states, v))
|2>
```

`sympy.physics.quantum.grover.superposition_basis(nqubits)`
Creates an equal superposition of the computational basis.

**Parameters**
- `nqubits` : int
  The number of qubits.

**Returns**
- `state` : Qubit
  An equal superposition of the computational basis with nqubits.
Examples

Create an equal superposition of 2 qubits:

```python
>>> from sympy.physics.quantum.grover import superposition_basis
>>> superposition_basis(2)
|0>/2 + |1>/2 + |2>/2 + |3>/2
```

QFT

An implementation of qubits and gates acting on them.

todo:

- Update docstrings.
- Update tests.
- Implement apply using decompose.
- Implement represent using decompose or something smarter. For this to work we first have to implement represent for SWAP.
- Decide if we want upper index to be inclusive in the constructor.
- Fix the printing of Rk gates in plotting.

```python
class sympy.physics.quantum.qft.IQFT(*args, **kwargs)
    The inverse quantum Fourier transform.
        decompose()
            Decomposes IQFT into elementary gates.

class sympy.physics.quantum.qft.QFT(*args, **kwargs)
    The forward quantum Fourier transform.
        decompose()
            Decomposes QFT into elementary gates.
```

```python
sympy.physics.quantum.qft.Rk
    alias of RkGate (page 1919)

class sympy.physics.quantum.qft.RkGate(*args)
    This is the R_k gate of the QTF.
```

Qubit

Qubits for quantum computing.

todo: * Finish implementing measurement logic. This should include POVM. * Update docstrings. * Update tests.

```python
class sympy.physics.quantum.qubit.IntQubit(*args, **kwargs)
    A qubit ket that store integers as binary numbers in qubit values.
        The differences between this class and Qubit are:
            • The form of the constructor.
```
The qubit values are printed as their corresponding integer, rather than the raw qubit values. The internal storage format of the qubit values in the same as Qubit.

**Parameters**

```values : int, tuple```

If a single argument, the integer we want to represent in the qubit values. This integer will be represented using the fewest possible number of qubits. If a pair of integers and the second value is more than one, the first integer gives the integer to represent in binary form and the second integer gives the number of qubits to use. List of zeros and ones is also accepted to generate qubit by bit pattern.

```nqubits : int```

The integer that represents the number of qubits. This number should be passed with keyword `nqubits=N`. You can use this in order to avoid ambiguity of Qubit-style tuple of bits. Please see the example below for more details.

**Examples**

Create a qubit for the integer 5:

```python
>>> from sympy.physics.quantum.qubit import IntQubit
>>> from sympy.physics.quantum.qubit import Qubit
>>> q = IntQubit(5)
>>> q
|5>
```

We can also create an IntQubit by passing a Qubit instance.

```python
>>> q = IntQubit(Qubit('101'))
>>> q
|5>
>>> q.as_int()
5
>>> q.nqubits
3
>>> q.qubit_values
(1, 0, 1)
```

We can go back to the regular qubit form.

```python
>>> Qubit(q)
|101>
```

Please note that IntQubit also accepts a Qubit-style list of bits. So, the code below yields qubits 3, not a single bit 1.

```python
>>> IntQubit([1, 1])
|3>
```

To avoid ambiguity, use `nqubits` parameter. Use of this keyword is recommended especially when you provide the values by variables.
```python
>>> IntQubit(1, nqubits=1)
|1>
>>> a = 1
>>> IntQubit(a, nqubits=1)
|1>
```

class sympy.physics.quantum.qubit.IntQubitBra(*args, **kwargs)
A qubit bra that store integers as binary numbers in qubit values.

class sympy.physics.quantum.qubit.Qubit(*args, **kwargs)
A multi-qubit ket in the computational (z) basis.

We use the normal convention that the least significant qubit is on the right, so \(|0001>\) has a 1 in the least significant qubit.

**Parameters**

values : list, str
The qubit values as a list of ints ([0,0,1,1,]) or a string ('011').

**Examples**

Create a qubit in a couple of different ways and look at their attributes:

```python
>>> from sympy.physics.quantum.qubit import Qubit
>>> Qubit(0,0,0)
|000>
>>> q = Qubit('0101')
>>> q
|0101>
>>> q.nqubits
4
>>> len(q)
4
>>> q.dimension
4
>>> q.qubit_values
(0, 1, 0, 1)
```

We can flip the value of an individual qubit:

```python
>>> q.flip(1)
|0111>
```

We can take the dagger of a Qubit to get a bra:

```python
>>> from sympy.physics.quantum.dagger import Dagger
>>> Dagger(q)
<0101|
>>> type(Dagger(q))
<class 'sympy.physics.quantum.qubit.QubitBra'>
```

Inner products work as expected:
```python
>>> ip = Dagger(q)*q
>>> ip
<0101|0101>
>>> ip.doit()
1
```

class sympy.physics.quantum.qubit.QubitBra(*args, **kwargs)

A multi-qubit bra in the computational (z) basis.

We use the normal convention that the least significant qubit is on the right, so |00001> has a 1 in the least significant qubit.

Parameters:
values : list, str
The qubit values as a list of ints ([0,0,1,1,1]) or a string ('011').

See also:

Qubit (page 1921)
Examples using qubits

sympy.physics.quantum.qubit.matrix_to_density(mat)

Works by finding the eigenvectors and eigenvalues of the matrix. We know we can decompose rho by doing: \sum(EigenVal*|Eigenvect><Eigenvect|)

sympy.physics.quantum.qubit.matrix_to_qubit(matrix)

Convert from the matrix repr. to a sum of Qubit objects.

Parameters:
matrix : Matrix, numpy.matrix, scipy.sparse
The matrix to build the Qubit representation of. This works with SymPy matrices, numpy matrices and scipy.sparse sparse matrices.

Examples

Represent a state and then go back to its qubit form:

```python
>>> from sympy.physics.quantum.qubit import matrix_to_qubit, Qubit
>>> from sympy.physics.quantum.represent import represent
>>> q = Qubit('01')
>>> matrix_to_qubit(represent(q))
|01>
```
sympy.physics.quantum.qubit.measure_all(qubit, format='sympy', normalize=True)

Perform an ensemble measurement of all qubits.

Parameters:
qubit : Qubit, Add
The qubit to measure. This can be any Qubit or a linear combination of them.

format : str
The format of the intermediate matrices to use. Possible values are ('sympy', 'numpy', 'scipy.sparse'). Currently only 'sympy' is implemented.

**Returns**

**result** : list

A list that consists of primitive states and their probabilities.

**Examples**

```python
>>> from sympy.physics.quantum.qubit import Qubit, measure_all
>>> from sympy.physics.quantum.gate import H
>>> from sympy.physics.quantum.qapply import qapply

>>> c = H(0)*H(1)*Qubit('00')
>>> c
H(0)*H(1)*|00>
>>> q = qapply(c)
>>> measure_all(q)
[(|00>, 1/4), (|01>, 1/4), (|10>, 1/4), (|11>, 1/4)]
```

**sympy.physics.quantum.qubit.measure_all_oneshot(qubit, format='sympy')**

Perform a oneshot ensemble measurement on all qubits.

A oneshot measurement is equivalent to performing a measurement on a quantum system. This type of measurement does not return the probabilities like an ensemble measurement does, but rather returns one of the possible resulting states. The exact state that is returned is determined by picking a state randomly according to the ensemble probabilities.

**Parameters**

**qubits** : Qubit

The qubit to measure. This can be any Qubit or a linear combination of them.

**format** : str

The format of the intermediate matrices to use. Possible values are ('sympy', 'numpy', 'scipy.sparse'). Currently only 'sympy' is implemented.

**Returns**

**result** : Qubit

The qubit that the system collapsed to upon measurement.

**sympy.physics.quantum.qubit.measure_partial(qubit, bits, format='sympy', normalize=True)**

Perform a partial ensemble measure on the specified qubits.

**Parameters**

**qubits** : Qubit

The qubit to measure. This can be any Qubit or a linear combination of them.
**bits** : tuple

The qubits to measure.

**format** : str

The format of the intermediate matrices to use. Possible values are ('sympy', 'numpy', 'scipy.sparse'). Currently only 'sympy' is implemented.

**Returns**

**result** : list

A list that consists of primitive states and their probabilities.

**Examples**

```python
>>> from sympy.physics.quantum.qubit import Qubit, measure_partial
>>> from sympy.physics.quantum.gate import H
>>> from sympy.physics.quantum.qapply import qapply

>>> c = H(0)*H(1)*Qubit('00')
>>> c
H(0)*H(1)*|00>
>>> q = qapply(c)
>>> measure_partial(q, (0,))
[(sqrt(2)*|00>/2 + sqrt(2)*|10>/2, 1/2), (sqrt(2)*|01>/2 + sqrt(2)*|11>/2, 1/2)]
```

**sympy.physics.quantum.qubit.measure_partial_oneshot(qubit, bits, format='sympy')**

Perform a partial oneshot measurement on the specified qubits.

A oneshot measurement is equivalent to performing a measurement on a quantum system. This type of measurement does not return the probabilities like an ensemble measurement does, but rather returns one of the possible resulting states. The exact state that is returned is determined by picking a state randomly according to the ensemble probabilities.

**Parameters**

qubits : Qubit

The qubit to measure. This can be any Qubit or a linear combination of them.

**bits** : tuple

The qubits to measure.

**format** : str

The format of the intermediate matrices to use. Possible values are ('sympy', 'numpy', 'scipy.sparse'). Currently only 'sympy' is implemented.

**Returns**

**result** : Qubit

The qubit that the system collapsed to upon measurement.
sympy.physics.quantum.qubit.qubit_to_matrix(qubit, format='sympy')
Converts an Add/Mul of Qubit objects into it's matrix representation
This function is the inverse of matrix_to_qubit and is a shorthand for
represent(qubit).

Shor’s Algorithm

Shor’s algorithm and helper functions.
Todo:
• Get the CMod gate working again using the new Gate API.
• Fix everything.
• Update docstrings and reformat.
class sympy.physics.quantum.shor.CMod(*args, **kwargs)
A controlled mod gate.
This is black box controlled Mod function for use by shor’s algorithm. TODO: implement
a decompose property that returns how to do this in terms of elementary gates
property N
N is the type of modular arithmetic we are doing.
property a
Base of the controlled mod function.
property t
Size of 1/2 input register. First 1/2 holds output.
sympy.physics.quantum.shor.period_find(a, N)
Finds the period of a in modulo N arithmetic
This is quantum part of Shor’s algorithm. It takes two registers, puts first in superposition
of states with Hadamards so: |k>|0> with k being all possible choices. It then does
a controlled mod and a QFT to determine the order of a.
sympy.physics.quantum.shor.shor(N)
This function implements Shor’s factoring algorithm on the Integer N
The algorithm starts by picking a random number (a) and seeing if it is coprime with N.
If it is not, then the gcd of the two numbers is a factor and we are done. Otherwise, it
begins the period finding subroutine which finds the period of a in modulo N arithmetic.
This period, if even, can be used to calculate factors by taking a**(r/2)-1 and a**(r/2)+1.
These values are returned.
Analytic Solutions

Particle in a Box

1D quantum particle in a box.

class sympy.physics.quantum.piab.PIABBra(*args, **kwargs)
    Particle in a box eigenbra.

class sympy.physics.quantum.piab.PIABHamiltonian(*args, **kwargs)
    Particle in a box Hamiltonian operator.

class sympy.physics.quantum.piab.PIABKet(*args, **kwargs)
    Particle in a box eigenket.

Optics Module

Abstract

Contains docstrings of Physics-Optics module

Gaussian Optics

Gaussian optics.
The module implements:

- Ray transfer matrices for geometrical and gaussian optics.
  See RayTransferMatrix, GeometricRay and BeamParameter
- Conjugation relations for geometrical and gaussian optics.
  See geometric_conj*, gauss_conj and conjugate_gauss_beams

The conventions for the distances are as follows:

class sympy.physics.optics.gaussoptBeamParameter(waven, z, z_r=None, w=None, n=1)

Representation for a gaussian ray in the Ray Transfer Matrix formalism.

Parameters

- waven: the wavelength,
- z: the distance to waist, and
- w: the waist, or
\(z_r\): the rayleigh range.
\(n\): the refractive index of medium.

Examples

```python
>>> from sympy.physics.optics import BeamParameter
>>> p = BeamParameter(530e-9, 1, w=1e-3)
>>> p.q
1 + 1.88679245283019*I*pi
```

```python
>>> p.q.n()  
1.0 + 5.92753330865999*I
>>> p.w_0.n()  
0.00100000000000000
>>> p.z_r.n()  
5.92753330865999
```

```python
>>> from sympy.physics.optics import FreeSpace
>>> fs = FreeSpace(10)
>>> p1 = fs*p
>>> p1.w.n()  
0.00101413072159615
>>> p1.w.n()  
0.00210803120913829
```

See also:

RayTransferMatrix (page 1932)

References

[R679], [R680]

property divergence
Half of the total angular spread.

Examples

```python
>>> from sympy.physics.optics import BeamParameter
>>> p = BeamParameter(530e-9, 1, w=1e-3)
>>> p.divergence
0.00053/pi
```

property gouy
The Gouy phase.
Examples

```python
>>> from sympy.physics.optics import BeamParameter
>>> p = BeamParameter(530e-9, 1, w=1e-3)
>>> p.gouy
atan(0.53/pi)
```

**property q**

The complex parameter representing the beam.

Examples

```python
>>> from sympy.physics.optics import BeamParameter
>>> p = BeamParameter(530e-9, 1, w=1e-3)
>>> p.q
1 + 1.88679245283019*I*pi
```

**property radius**

The radius of curvature of the phase front.

Examples

```python
>>> from sympy.physics.optics import BeamParameter
>>> p = BeamParameter(530e-9, 1, w=1e-3)
>>> p.radius
1 + 3.55998576005696*pi**2
```

**property w**

The radius of the beam w(z), at any position z along the beam. The beam radius at 1/e^2 intensity (axial value).

Examples

```python
>>> from sympy.physics.optics import BeamParameter
>>> p = BeamParameter(530e-9, 1, w=1e-3)
>>> p.w
0.001*sqrt(0.2809/pi**2 + 1)
```

See also:

- `w_0 (page 1928)`
  The minimal radius of beam.

**property w_0**

The minimal radius of beam at 1/e^2 intensity (peak value).
Examples

```python
>>> from sympy.physics.optics import BeamParameter
>>> p = BeamParameter(530e-9, 1, w=1e-3)
>>> p.w_0
0.00100000000000000
```

**See also:**

`w` *(page 1928)*

the beam radius at $1/e^2$ intensity (axial value).

**property waist_approximation_limit**

The minimal waist for which the gauss beam approximation is valid.

**Explanation**

The gauss beam is a solution to the paraxial equation. For curvatures that are too great it is not a valid approximation.

Examples

```python
>>> from sympy.physics.optics import BeamParameter
>>> p = BeamParameter(530e-9, 1, w=1e-3)
>>> p.waist_approximation_limit
1.06e-6/pi
```

class sympy.physics.optics.gaussopt.CurvedMirror(R)

Ray Transfer Matrix for reflection from curved surface.

**Parameters**

- `R` : radius of curvature (positive for concave)

Examples

```python
>>> from sympy.physics.optics import CurvedMirror
>>> from sympy import symbols
>>> R = symbols('R')
>>> CurvedMirror(R)
Matrix([[1, 0],
        [-2/R, 1]])
```

**See also:**

`RayTransferMatrix` *(page 1932)*

class sympy.physics.optics.gaussopt.CurvedRefraction(R, n1, n2)

Ray Transfer Matrix for refraction on curved interface.
Parameters

R :
    Radius of curvature (positive for concave).

n1 :
    Refractive index of one medium.

n2 :
    Refractive index of other medium.

Examples

```py
>>> from sympy.physics.optics import CurvedRefraction
>>> from sympy import symbols
>>> R, n1, n2 = symbols('R n1 n2')
>>> CurvedRefraction(R, n1, n2)
Matrix([[1, 0],
        [(n1 - n2)/(R*n2), n1/n2]])
```

See also:

`RayTransferMatrix` (page 1932)

**class** sympy.physics.optics.gaussopt.FlatMirror

Ray Transfer Matrix for reflection.

Examples

```py
>>> from sympy.physics.optics import FlatMirror
>>> FlatMirror()
Matrix([[1, 0],
        [0, 1]])
```

See also:

`RayTransferMatrix` (page 1932)

**class** sympy.physics.optics.gaussopt.FlatRefraction(n1, n2)

Ray Transfer Matrix for refraction.

Parameters

n1 :
    Refractive index of one medium.

n2 :
    Refractive index of other medium.
### Examples

```python
>>> from sympy.physics.optics import FlatRefraction
>>> from sympy import symbols
>>> n1, n2 = symbols('n1 n2')
>>> FlatRefraction(n1, n2)
Matrix([[1, 0],
        [0, n1/n2]])
```

See also:
RayTransferMatrix (page 1932)

```python
class sympy.physics.optics.gaussopt.FreeSpace(d)
    Ray Transfer Matrix for free space.

    Parameters
    distance
```

### Examples

```python
>>> from sympy.physics.optics import FreeSpace
>>> from sympy import symbols, Matrix
>>> d, h, angle = symbols('d, h, angle')
>>> FreeSpace(d)
Matrix([[1, d],
        [0, 1]])
```

See also:
RayTransferMatrix (page 1932)

```python
class sympy.physics.optics.gaussopt.GeometricRay(*args)
    Representation for a geometric ray in the Ray Transfer Matrix formalism.

    Parameters
    h : height, and
    angle : angle, or
    matrix : a 2x1 matrix (Matrix(2, 1, [height, angle]))
```

### Examples

```python
>>> from sympy.physics.optics import GeometricRay, FreeSpace
>>> from sympy import symbols, Matrix
>>> d, h, angle = symbols('d, h, angle')
>>> GeometricRay(h, angle)
Matrix([[h],
        [angle]])
```
>>> FreeSpace(d)*GeometricRay(h, angle)
Matrix([angle*d + h],
       [ angle])

>>> GeometricRay( Matrix( ((h,), (angle,)) ) )
Matrix([ h],
       [angle])

See also:
RayTransferMatrix (page 1932)

property angle
The angle with the optical axis.

Examples

```python
>>> from sympy.physics.optics import GeometricRay
>>> from sympy import symbols
>>> h, angle = symbols('h, angle')
>>> gRay = GeometricRay(h, angle)
>>> gRay.angle
angle
```

property height
The distance from the optical axis.

Examples

```python
>>> from sympy.physics.optics import GeometricRay
>>> from sympy import symbols
>>> h, angle = symbols('h, angle')
>>> gRay = GeometricRay(h, angle)
>>> gRay.height
h
```

class sympy.physics.optics.gaussopt.RayTransferMatrix(*args)
Base class for a Ray Transfer Matrix.

It should be used if there is not already a more specific subclass mentioned in See Also.

Parameters
parameters :
A, B, C and D or 2x2 matrix (Matrix(2, 2, [A, B, C, D]))
Examples

```python
>>> from sympy.physics.optics import RayTransferMatrix, ThinLens
>>> from sympy import Symbol, Matrix

>>> mat = RayTransferMatrix(1, 2, 3, 4)
>>> mat
Matrix([[1, 2],
        [3, 4]])

>>> RayTransferMatrix(Matrix([[1, 2], [3, 4]]))
Matrix([[1, 2],
        [3, 4]])

>>> mat.A
1

>>> f = Symbol('f')
>>> lens = ThinLens(f)
>>> lens
Matrix([[1, 0],
        [-1/f, 1]])

>>> lens.C
-1/f
```

References

[R681]

property A

The A parameter of the Matrix.
```python
>>> from sympy.physics.optics import RayTransferMatrix
>>> mat = RayTransferMatrix(1, 2, 3, 4)
```

**Examples**

```
>>> from sympy.physics.optics import RayTransferMatrix
>>> mat = RayTransferMatrix(1, 2, 3, 4)
>>> mat.A
```

**property B**
The B parameter of the Matrix.

```
>>> from sympy.physics.optics import RayTransferMatrix
>>> mat = RayTransferMatrix(1, 2, 3, 4)
>>> mat.B
```

**property C**
The C parameter of the Matrix.

```
>>> from sympy.physics.optics import RayTransferMatrix
>>> mat = RayTransferMatrix(1, 2, 3, 4)
>>> mat.C
```

**property D**
The D parameter of the Matrix.

```
>>> from sympy.physics.optics import RayTransferMatrix
>>> mat = RayTransferMatrix(1, 2, 3, 4)
>>> mat.D
```

```python
class sympy.physics.optics.gaussopt.ThinLens(f)
Ray Transfer Matrix for a thin lens.

Parameters
f:
The focal distance.
```
Examples

```python
>>> from sympy.physics.optics import ThinLens
>>> from sympy import symbols
>>> f = symbols('f')
>>> ThinLens(f)
Matrix([[-1/f, 1],
         [ 1, 0]])
```

`sympy.physics.optics.gaussopt.conjugate_gauss_beams(wavelen, waist_in, waist_out, **kwargs)`

Find the optical setup conjugating the object/image waists.

Parameters

- **wavelen**
  The wavelength of the beam.

- **waist_in and waist_out**
  The waists to be conjugated.

- **f**
  The focal distance of the element used in the conjugation.

Returns

A tuple containing `(s_in, s_out, f)`

- **s_in**
  The distance before the optical element.

- **s_out**
  The distance after the optical element.

- **f**
  The focal distance of the optical element.

Examples

```python
>>> from sympy.physics.optics import conjugate_gauss_beams
>>> from sympy import symbols, factor
>>> l, w_i, w_o, f = symbols('l w_i w_o f')

>>> conjugate_gauss_beams(l, w_i, w_o, f=f)[0]
f*(1 - sqrt(w_i**2/w_o**2 - pi**2*w_i**4/(f**2*l**2)))

>>> factor(conjugate_gauss_beams(l, w_i, w_o, f=f)[1])
f*w_o**2*(w_i**2/w_o**2 - sqrt(w_i**2/w_o**2 - pi**2*w_i**4/(f**2*l**2)))/w_i**2
```
Conjugation relation for gaussian beams.

**Parameters**

- **s_in**:
  
The distance to optical element from the waist.

- **z_r_in**:
  
The rayleigh range of the incident beam.

- **f**:
  
The focal length of the optical element.

**Returns**

- a tuple containing (s_out, z_r_out, m)

  - **s_out**:
    
The distance between the new waist and the optical element.

  - **z_r_out**:
    
The rayleigh range of the emergent beam.

  - **m**:
    
The ration between the new and the old waists.

**Examples**

```python
from sympy.physics.optics import gaussian_conj
from sympy import symbols

s_in, z_r_in, f = symbols('s_in z_r_in f')

gaussian_conj(s_in, z_r_in, f)[0]
1/(-1/(s_in + z_r_in**2/(-f + s_in)) + 1/f)

gaussian_conj(s_in, z_r_in, f)[1]
z_r_in/(1 - s_in**2/f**2 + z_r_in**2/f**2)

gaussian_conj(s_in, z_r_in, f)[2]
1/sqrt(1 - s_in**2/f**2 + z_r_in**2/f**2)
```

Conjugation relation for geometrical beams under paraxial conditions.
**Explanation**

Takes the distances to the optical element and returns the needed focal distance.

**Examples**

```
>>> from sympy.physics.optics import geometric_conj_ab
>>> from sympy import symbols
>>> a, b = symbols('a b')
>>> geometric_conj_ab(a, b)
a*b/(a + b)
```

**See also:**

`geometric_conj_ab` (page 1936), `geometric_conj_bf` (page 1937)

**Explanation**

Takes the object distance (for geometric_conj_af) or the image distance (for geometric_conj_bf) to the optical element and the focal distance. Then it returns the other distance needed for conjugation.

**Examples**

```
>>> from sympy.physics.optics.gaussopt import geometric_conj_af, geometric_conj_bf
>>> from sympy import symbols
>>> a, b, f = symbols('a b f')
>>> geometric_conj_af(a, f)
a*f/(a - f)
>>> geometric_conj_bf(b, f)
b*f/(b - f)
```

**See also:**

`geometric_conj_ab` (page 1936)

sympy.physics.optics.gaussopt.geometric_conj_bf(a, f)

Conjugation relation for geometrical beams under paraxial conditions.
Explanation

Takes the object distance (for geometric_conj_af) or the image distance (for geometric_conj_bf) to the optical element and the focal distance. Then it returns the other distance needed for conjugation.

Examples

```python
>>> from sympy.physics.optics.gaussopt import geometric_conj_af,
   geometric_conj_bf
>>> from sympy import symbols
>>> a, b, f = symbols('a b f')
>>> geometric_conj_af(a, f)
a*f/(a - f)
>>> geometric_conj_bf(b, f)
b*f/(b - f)
```

See also:

`geometric_conj_ab` (page 1936)

sympy.physics.optics.gaussopt.**rayleigh2waist**(*z_r*, *wavelen*)

Calculate the waist from the rayleigh range of a gaussian beam.

Examples

```python
>>> from sympy.physics.optics import rayleigh2waist
>>> from sympy import symbols
>>> z_r, wavelen = symbols('z_r wavelen')
>>> rayleigh2waist(z_r, wavelen)
sqrt(wavelen*z_r)/sqrt(pi)
```

See also:

`waist2rayleigh` (page 1938), **BeamParameter** (page 1926)

sympy.physics.optics.gaussopt.**waist2rayleigh**(*w*, *wavelen*, *n*=1)

Calculate the rayleigh range from the waist of a gaussian beam.

Examples

```python
>>> from sympy.physics.optics import waist2rayleigh
>>> from sympy import symbols
>>> w, wavelen = symbols('w wavelen')
>>> waist2rayleigh(w, wavelen)
pi*w**2/wavelen
```

See also:

`rayleigh2waist` (page 1938), **BeamParameter** (page 1926)
Medium

Contains

- Medium

class sympy.physics.optics.medium.Medium(name, permittivity=None, permeability=None, n=None)

This class represents an optical medium. The prime reason to implement this is to facilitate refraction, Fermat’s principle, etc.

Parameters

- name: string
  The display name of the Medium.

- permittivity: Sympifyable
  Electric permittivity of the space.

- permeability: Sympifyable
  Magnetic permeability of the space.

- n: Sympifyable
  Index of refraction of the medium.

Explanation

An optical medium is a material through which electromagnetic waves propagate. The permittivity and permeability of the medium define how electromagnetic waves propagate in it.

Examples

>>> from sympy.abc import epsilon, mu
>>> from sympy.physics.optics import Medium
>>> m1 = Medium('m1')
>>> m2 = Medium('m2', epsilon, mu)
>>> m1.intrinsic_impedance
149896229*pi*kilogram*meter**2/(1250000*ampere**2*second**3)
>>> m2.refractive_index
299792458*meter*sqrt(epsilon*mu)/second
property refractive_index
Returns refractive index of the medium.

Examples

```python
>>> from sympy.physics.optics import Medium
>>> m = Medium('m')
>>> m.refractive_index
1
```

property speed
Returns speed of the electromagnetic wave travelling in the medium.

Examples

```python
>>> from sympy.physics.optics import Medium
>>> m = Medium('m')
>>> m.speed
299792458*meter/second
>>> m2 = Medium('m2', n=1)
>>> m.speed == m2.speed
True
```

Polarization

The module implements routines to model the polarization of optical fields and can be used to calculate the effects of polarization optical elements on the fields.

- Jones vectors.
- Stokes vectors.
- Jones matrices.
- Mueller matrices.

Examples

We calculate a generic Jones vector:

```python
>>> from sympy import symbols, pprint, zeros, simplify
>>> from sympy.physics.optics.polarization import (jones_vector, stokes_vector, half_wave_retarder, polarizing_beam_splitter, jones_2_stokes)
```
>>> psi, chi, p, I0 = symbols("psi, chi, p, I0", real=True)
>>> x0 = jones_vector(psi, chi)
>>> pprint(x0, use_unicode=True)
\[
\begin{bmatrix}
-i \sin(\chi) \sin(\psi) + \cos(\chi) \cos(\psi) \\
i \sin(\chi) \cos(\psi) + \sin(\psi) \cos(\chi)
\end{bmatrix}
\]

And the more general Stokes vector:

>>> s0 = stokes_vector(psi, chi, p, I0)
>>> pprint(s0, use_unicode=True)
\[
\begin{bmatrix}
I_0 \\
I_0 \cdot p \cdot \cos(2 \cdot \chi) \cdot \cos(2 \cdot \psi) \\
I_0 \cdot p \cdot \sin(2 \cdot \psi) \cdot \cos(2 \cdot \chi) \\
I_0 \cdot p \cdot \sin(2 \cdot \chi)
\end{bmatrix}
\]

We calculate how the Jones vector is modified by a half-wave plate:

>>> alpha = symbols("alpha", real=True)
>>> HWP = half_wave_retarder(alpha)
>>> x1 = simplify(HWP*x0)

We calculate the very common operation of passing a beam through a half-wave plate and then through a polarizing beam-splitter. We do this by putting this Jones vector as the first entry of a two-Jones-vector state that is transformed by a 4x4 Jones matrix modelling the polarizing beam-splitter to get the transmitted and reflected Jones vectors:

>>> PBS = polarizing_beam_splitter()
>>> X1 = zeros(4, 1)
>>> X1[2, :] = x1
>>> X2 = PBS*X1
>>> transmitted_port = X2[2, :]
>>> reflected_port = X2[2:, :]

This allows us to calculate how the power in both ports depends on the initial polarization:

>>> transmitted_power = jones_2_stokes(transmitted_port)[0]
>>> reflected_power = jones_2_stokes(reflected_port)[0]
>>> print(transmitted_power)
\[
\cos(-2 \cdot \alpha + \chi + \psi)^2/2 + \cos(2 \cdot \alpha + \chi - \psi)^2/2
\]

>>> print(reflected_power)
\[
\sin(-2 \cdot \alpha + \chi + \psi)^2/2 + \sin(2 \cdot \alpha + \chi - \psi)^2/2
\]

Please see the description of the individual functions for further details and examples.
References

sympy.physics.optics.polarization.half_wave_retarder(theta)
A half-wave retarder Jones matrix at angle theta.

Parameters
theta : numeric type or SymPy Symbol
The angle of the fast axis relative to the horizontal plane.

Returns
SymPy Matrix
A Jones matrix representing the retarder.

Examples

A generic half-wave plate.

>>> from sympy import pprint, symbols
>>> from sympy.physics.optics.polarization import half_wave_retarder
>>> theta = symbols("theta", real=True)
>>> HWP = half_wave_retarder(theta)
>>> pprint(HWP, use_unicode=True)
\[
\begin{pmatrix}
2 & 2 \\
-i \cdot (-\sin(\theta) + \cos(\theta)) & -2 \cdot i \cdot \sin(\theta) \cdot \cos(\theta) \\
-2 \cdot i \cdot \sin(\theta) \cdot \cos(\theta) & -i \cdot (\sin(\theta) - \cos(\theta))
\end{pmatrix}
\]

sympy.physics.optics.polarization.jones_2_stokes(e)
Return the Stokes vector for a Jones vector e.

Parameters
e : SymPy Matrix
A Jones vector.

Returns
SymPy Matrix
A Jones vector.

Examples

The axes on the Poincaré sphere.

>>> from sympy import pprint, pi
>>> from sympy.physics.optics.polarization import jones_vector
>>> from sympy.physics.optics.polarization import jones_2_stokes
>>> H = jones_vector(0, 0)
>>> V = jones_vector(pi/2, 0)
>>> D = jones_vector(pi/4, 0)
>>> A = jones_vector(-pi/4, 0)
sympy.physics.optics.polarization.jones_vector(psi, chi)
A Jones vector corresponding to a polarization ellipse with psi tilt, and chi circularity.

**Parameters**
- **psi**: numeric type or SymPy Symbol
  - The tilt of the polarization relative to the x axis.
- **chi**: numeric type or SymPy Symbol
  - The angle adjacent to the major axis of the polarization ellipse.

**Returns**
- **Matrix**: A Jones vector.

**Examples**

The axes on the Poincaré sphere.

```python
>>> from sympy import pprint, symbols, pi
>>> from sympy.physics.optics.polarization import jones_vector
>>> psi, chi = symbols("psi, chi", real=True)
```

A general Jones vector.

```python
>>> pprint(jones_vector(psi, chi), use_unicode=True)
[-i⋅sin(χ)⋅sin(ψ) + cos(χ)⋅cos(ψ)]
[i⋅sin(χ)⋅cos(ψ) + sin(ψ)⋅cos(χ)]
```

Horizontal polarization.

```python
>>> pprint(jones_vector(0, 0), use_unicode=True)
[1]
[0]
```

Vertical polarization.
>>> pprint(jones_vector(pi/2, 0), use_unicode=True)

\[
\begin{bmatrix}
0 \\
1 
\end{bmatrix}
\]

Diagonal polarization.

>>> pprint(jones_vector(pi/4, 0), use_unicode=True)

\[
\begin{bmatrix}
\frac{\sqrt{2}}{2} \\
\frac{\sqrt{2}}{2} \\
\frac{-\sqrt{2}}{2} \\
\frac{\sqrt{2}}{2} \\
\end{bmatrix}
\]

Anti-diagonal polarization.

>>> pprint(jones_vector(-pi/4, 0), use_unicode=True)

\[
\begin{bmatrix}
\frac{\sqrt{2}}{2} \\
\frac{-\sqrt{2}}{2} \\
\frac{\sqrt{2} \cdot i}{2} \\
\frac{-\sqrt{2} \cdot i}{2} \\
\end{bmatrix}
\]

Right-hand circular polarization.

>>> pprint(jones_vector(0, pi/4), use_unicode=True)

\[
\begin{bmatrix}
\frac{\sqrt{2}}{2} \\
\frac{\sqrt{2} \cdot i}{2} \\
\frac{\sqrt{2}}{2} \\
\frac{-\sqrt{2}}{2} \\
\end{bmatrix}
\]

Left-hand circular polarization.

```python
sympy.physics.optics.polarization.linear_polarizer(theta=0)
```

A linear polarizer Jones matrix with transmission axis at an angle theta.
**Parameters**

**theta**: numeric type or SymPy Symbol

The angle of the transmission axis relative to the horizontal plane.

**Returns**

SymPy Matrix

A Jones matrix representing the polarizer.

**Examples**

A generic polarizer.

```python
>>> from sympy import pprint, symbols

>>> from sympy.physics.optics.polarization import linear_polarizer

>>> theta = symbols("theta", real=True)

>>> J = linear_polarizer(theta)

>>> pprint(J, use_unicode=True)

\[
\begin{bmatrix}
2 & \cos(\theta) \cdot \sin(\theta) \\
\sin(\theta) \cdot \cos(\theta) & 2
\end{bmatrix}
\]

```

**sympy.physics.optics.polarization.mueller_matrix(J)**

The Mueller matrix corresponding to Jones matrix J.

**Parameters**

**J**: SymPy Matrix

A Jones matrix.

**Returns**

SymPy Matrix

The corresponding Mueller matrix.

**Examples**

Generic optical components.

```python
>>> from sympy import pprint, symbols

>>> from sympy.physics.optics.polarization import (mueller_matrix,
... linear_polarizer, half_wave_retarder, quarter_wave_retarder)

>>> theta = symbols("theta", real=True)

```

A linear_polarizer

```python
>>> pprint(mueller_matrix(linear_polarizer(theta)), use_unicode=True)

\[
\begin{bmatrix}
1/2 & \cos(2\cdot \theta) & \sin(2\cdot \theta) \\
2 & 2 & 0
\end{bmatrix}
\]
```

(continues on next page)
A half-wave plate

```python
>>> pprint(mueller_matrix(half_wave_retarder(theta)), use_unicode=True)
```

A quarter-wave plate

```python
>>> pprint(mueller_matrix(quarter_wave_retarder(theta)), use_unicode=True)
```

`sympy.physics.optics.polarization.phase_retarder(theta=0, delta=0)`

A phase retarder Jones matrix with retardance `delta` at angle `theta`.

**Parameters**

- `theta` : numeric type or SymPy Symbol
  
  The angle of the fast axis relative to the horizontal plane.

- `delta` : numeric type or SymPy Symbol
  
  The phase difference between the fast and slow axes of the transmitted light.
Returns
SymPy Matrix:
A Jones matrix representing the retarder.

Examples
A generic retarder.

```python
from sympy import pprint, symbols
from sympy.physics.optics.polarization import phase_retarder
theta, delta = symbols("theta, delta", real=True)
R = phase_retarder(theta, delta)
pprint(R, use_unicode=True)
```

```
⎡ -i⋅δ -i⋅δ ⎤
⎢ ───── ─────⎥
⎢⎛ i⋅δ 2 2 ⎞ 2 ⎛ i⋅δ⎞ 2 ⎥
⎢⎝e ⋅sin (θ) + cos (θ)⎠⋅e ⎝1 - e ⎠⋅e ⋅sin(θ)⋅cos(θ)⎥
⎢ ⎥
⎢ -i⋅δ -i⋅δ ⎥
⎢ ───── ─────⎥
⎢⎛ i⋅δ⎞ 2 ⎛ i⋅δ 2 2 ⎞ 2 ⎥
⎢⎝1 - e ⎠⋅e ⋅sin(θ)⋅cos(θ) ⎝e ⋅cos (θ) + sin (θ)⎠⋅e ⎦
```

```
sympy.physics.optics.polarization.polarizing_beam_splitter(Tp=1, Rs=1, Ts=0, Rp=0, phia=0, phib=0)
```

A polarizing beam splitter Jones matrix at angle \( \theta \).

Parameters

- **J**: SymPy Matrix
  A Jones matrix.

- **Tp** : numeric type or SymPy Symbol
  The transmissivity of the P-polarized component.

- **Rs** : numeric type or SymPy Symbol
  The reflectivity of the S-polarized component.

- **Ts** : numeric type or SymPy Symbol
  The transmissivity of the S-polarized component.

- **Rp** : numeric type or SymPy Symbol
  The reflectivity of the P-polarized component.

- **phia** : numeric type or SymPy Symbol
  The phase difference between transmitted and reflected component for output mode a.

- **phib** : numeric type or SymPy Symbol
  The phase difference between transmitted and reflected component for output mode b.
Returns

SymPy Matrix

A 4x4 matrix representing the PBS. This matrix acts on a 4x1 vector whose first two entries are the Jones vector on one of the PBS ports, and the last two entries the Jones vector on the other port.

Examples

Generic polarizing beam-splitter.

```python
>>> from sympy import pprint, symbols
>>> from sympy.physics.optics.polarization import polarizing_beam_splitter
>>> Ts, Rs, Tp, Rp = symbols("Ts, Rs, Tp, Rp", positive=True)
>>> phia, phib = symbols("phi_a, phi_b", real=True)
>>> PBS = polarizing_beam_splitter(Tp, Rs, Ts, Rp, phia, phib)
>>> pprint(PBS, use_unicode=False)
[ ____ ____ ]

[ [ ]
[I*\ / Rp \ / 0 \ / \ / Tp \ / 0 \ ]
[ ]
[ ]
[ 0 -I*\ / Rs \ / e \ / 0 \ / \ / Ts \ ]
```

sympy.physics.optics.polarization.quarter_wave_retarder(theta)

A quarter-wave retarder Jones matrix at angle theta.

Parameters

theta : numeric type or SymPy Symbol

The angle of the fast axis relative to the horizontal plane.

Returns

SymPy Matrix

A Jones matrix representing the retarder.

Examples

A generic quarter-wave plate.

```python
>>> from sympy import pprint, symbols
>>> from sympy.physics.optics.polarization import quarter_wave_retarder
>>> theta= symbols("theta", real=True)
>>> QWP = quarter_wave_retarder(theta)
>>> pprint(QWP, use_unicode=True)
⎡ -i⋅π -i⋅π ⎤
⎢ ───── ───── ⎥
1948 Chapter5. APIReference (continues on next page)
SymPy.physics.optics.polarization.reflective_filter(R)
A reflective filter Jones matrix with reflectance R.

**Parameters**
- **R**: numeric type or SymPy Symbol
  The reflectance of the filter.

**Returns**
- SymPy Matrix
  A Jones matrix representing the filter.

**Examples**

A generic filter.

```python
>>> from sympy import pprint, symbols
>>> from sympy.physics.optics.polarization import reflective_filter
>>> R = symbols("R", real=True)
>>> pprint(reflective_filter(R), use_unicode=True)
⎡√R 0 ⎤
⎢     ⎥
⎣0 -√R⎦
```

SymPy.physics.optics.polarization.stokes_vector(psi, chi, p=1, I=1)
A Stokes vector corresponding to a polarization ellipse with psi tilt, and chi circularity.

**Parameters**
- **psi**: numeric type or SymPy Symbol
  The tilt of the polarization relative to the x axis.
- **chi**: numeric type or SymPy Symbol
  The angle adjacent to the mayor axis of the polarization ellipse.
- **p**: numeric type or SymPy Symbol
  The degree of polarization.
- **I**: numeric type or SymPy Symbol
  The intensity of the field.

**Returns**
- Matrix
  A Stokes vector.
**Examples**

The axes on the Poincaré sphere.

```python
>>> from sympy import pprint, symbols, pi
>>> from sympy.physics.optics.polarization import stokes_vector
>>> psi, chi, p, I = symbols("psi, chi, p, I", real=True)
>>> pprint(stokes_vector(psi, chi, p, I), use_unicode=True)
```

```
[   I  ]
| I\cdot p\cdot \cos(2\cdot \chi)\cdot \cos(2\cdot \psi) |
| I\cdot p\cdot \sin(2\cdot \psi)\cdot \cos(2\cdot \chi) |
|     I\cdot p\cdot \sin(2\cdot \chi)  |
```

Horizontal polarization

```python
>>> pprint(stokes_vector(0, 0), use_unicode=True)
```

```
[1  |
 | 1 |
 | 0 |
 | 0 |
```

Vertical polarization

```python
>>> pprint(stokes_vector(pi/2, 0), use_unicode=True)
```

```
[1  |
 | -1|
 | 0 |
 | 0 |
```

Diagonal polarization

```python
>>> pprint(stokes_vector(pi/4, 0), use_unicode=True)
```

```
[1  |
 | 0 |
 | 1 |
 | 0 |
```

Anti-diagonal polarization
Right-hand circular polarization

$$\begin{bmatrix}
1 \\
0 \\
-1 \\
0
\end{bmatrix}$$

Left-hand circular polarization

$$\begin{bmatrix}
1 \\
0 \\
0 \\

\end{bmatrix}$$

Unpolarized light

$$\begin{bmatrix}
1 \\
0 \\
0 \\
0
\end{bmatrix}$$

sympy.physics.optics.polarization.transmissive_filter(T)

An attenuator Jones matrix with transmittance T.

**Parameters**

- **T**: numeric type or SymPy Symbol

  The transmittance of the attenuator.

**Returns**

SymPy Matrix

A Jones matrix representing the filter.
Examples

A generic filter.

```python
>>> from sympy import pprint, symbols
>>> from sympy.physics.optics.polarization import transmissive_filter
>>> T = symbols("T", real=True)
>>> NDF = transmissive_filter(T)
>>> pprint(NDF, use_unicode=True)
⎡√T  0⎤
⎢     ⎥
⎣0   √T⎦
```

Utilities

Contains

- `refraction_angle`
- `fresnel_coefficients`
- `deviation`
- `brewster_angle`
- `critical_angle`
- `lens_makers_formula`
- `mirror_formula`
- `lens_formula`
- `hyperfocal_distance`
- `transverse_magnification`

```python
sympy.physics.optics.utils.brewster_angle(medium1, medium2)
```

This function calculates the Brewster’s angle of incidence to Medium 2 from Medium 1 in radians.

**Parameters**

- `medium 1` : Medium or sympifiable
  - Refractive index of Medium 1
- `medium 2` : Medium or sympifiable
  - Refractive index of Medium 1
**Examples**

```python
>>> from sympy.physics.optics import brewster_angle
>>> brewster_angle(1, 1.33)
0.926093295503462
```

```
sympy.physics.optics.utils.critical_angle(medium1, medium2)

This function calculates the critical angle of incidence (marking the onset of total internal) to Medium 2 from Medium 1 in radians.

**Parameters**

- medium 1 : Medium or sympifiable
  - Refractive index of Medium 1.
- medium 2 : Medium or sympifiable
  - Refractive index of Medium 1.

**Examples**

```python
>>> from sympy.physics.optics import critical_angle
>>> critical_angle(1.33, 1)
0.850908514477849
```

```
sympy.physics.optics.utils.deviation(incident, medium1, medium2, normal=None, plane=None)

This function calculates the angle of deviation of a ray due to refraction at planar surface.

**Parameters**

- incident : Matrix, Ray3D, sequence or float
  - Incident vector or angle of incidence
- medium1 : sympy.physics.optics.medium.Medium or sympifiable
  - Medium 1 or its refractive index
- medium2 : sympy.physics.optics.medium.Medium or sympifiable
  - Medium 2 or its refractive index
- normal : Matrix, Ray3D, or sequence
  - Normal vector
- plane : Plane
  - Plane of separation of the two media.

**Returns**

angular deviation between incident and refracted rays
Examples

```python
>>> from sympy.physics.optics import deviation
>>> from sympy.geometry import Point3D, Ray3D, Plane
>>> from sympy.matrices import Matrix
>>> from sympy import symbols

>>> n1, n2 = symbols('n1, n2')

>>> n = Matrix([0, 0, 1])
>>> P = Plane(Point3D(0, 0, 0), normal_vector=[0, 0, 1])
>>> r1 = Ray3D(Point3D(-1, -1, 1), Point3D(0, 0, 0))

>>> deviation(r1, 1, 1, n)
0

>>> deviation(r1, n1, n2, plane=P)
-acos(-sqrt(-2*n1**2/(3*n2**2) + 1)) + acos(-sqrt(3)/3)

>>> round(deviation(0.1, 1.2, 1.5), 5)
-0.02005
```

sympy.physics.optics.utils.fresnel_coefficients(angle_of_incidence, medium1, medium2)

This function uses Fresnel equations to calculate reflection and transmission coefficients. Those are obtained for both polarisations when the electric field vector is in the plane of incidence (labelled 'p') and when the electric field vector is perpendicular to the plane of incidence (labelled 's'). There are four real coefficients unless the incident ray reflects in total internal in which case there are two complex ones. Angle of incidence is the angle between the incident ray and the surface normal. medium1 and medium2 can be Medium or any sympifiable object.

**Parameters**

- `angle_of_incidence` : sympifiable
- `medium1` : Medium or sympifiable
  - Medium 1 or its refractive index
- `medium2` : Medium or sympifiable
  - Medium 2 or its refractive index

**Returns**

Returns a list with four real Fresnel coefficients:

- [reflection p (TM), reflection s (TE),
  transmission p (TM), transmission s (TE)]

If the ray is undergoes total internal reflection then returns a list of two complex Fresnel coefficients:

- [reflection p (TM), reflection s (TE)]
Examples

```python
>>> from sympy.physics.optics import fresnel_coefficients
>>> fresnel_coefficients(0.3, 1, 2)
[0.317843553417859, -0.348645229818821, 0.658921776708929, 0.651354770181179]
>>> fresnel_coefficients(0.6, 2, 1)
[-0.235625382192159 - 0.971843958291041*I, 0.816477005968898 - 0.577377951366403*I]
```

References

[R686] sympy.physics.optics.utils.hyperfocal_distance($f, N, c$)

**Parameters**

- **f**: sympifiable
  - Focal length of a given lens.
- **N**: sympifiable
  - F-number of a given lens.
- **c**: sympifiable
  - Circle of Confusion (CoC) of a given image format.

**Example**

```python
>>> from sympy.physics.optics import hyperfocal_distance
>>> round(hyperfocal_distance(f = 0.5, N = 8, c = 0.0033), 2)
9.47
```

sympy.physics.optics.utils.lens_formula($focal\_length=None, u=None, v=None$)

This function provides one of the three parameters when two of them are supplied. This is valid only for paraxial rays.

**Parameters**

- **focal_length**: sympifiable
  - Focal length of the mirror.
- **u**: sympifiable
  - Distance of object from the optical center on the principal axis.
- **v**: sympifiable
  - Distance of the image from the optical center on the principal axis.
Examples

```python
def from sympy.physics.optics import lens_formula
def from sympy.abs import f, u, v
def lens_formula(focal_length=f, u=u)
def lens_formula(focal_length=f, v=v)
def lens_formula(u=u, v=v)
```

`sympy.physics.optics.utils.lens_makers_formula(n_lens, n_surr, r1, r2, d=0)`

This function calculates focal length of a lens. It follows cartesian sign convention.

**Parameters**
- **n_lens**: Medium or sympifiable
  Index of refraction of lens.
- **n_surr**: Medium or sympifiable
  Index of reflection of surrounding.
- **r1**: sympifiable
  Radius of curvature of first surface.
- **r2**: sympifiable
  Radius of curvature of second surface.
- **d**: sympifiable, optional
  Thickness of lens, default value is 0.

**Examples**

```python
def from sympy.physics.optics import lens_makers_formula
def from sympy import S
def lens_makers_formula(1.33, 1, 10, -10)
def lens_makers_formula(1.2, 1, 10, S.Infinity)
def lens_makers_formula(1.33, 1, 10, -10, d=1)
```

`sympy.physics.optics.utils.mirror_formula(focal_length=None, u=None, v=None)`

This function provides one of the three parameters when two of them are supplied. This is valid only for paraxial rays.

**Parameters**
- **focal_length**: sympifiable
  Focal length of the mirror.
- **u**: sympifiable
  Distance of object from the pole on the principal axis.
v : sympifiable

Distance of the image from the pole on the principal axis.

Examples

```python
>>> from sympy.physics.optics import mirror_formula
>>> from sympy.abc import f, u, v
>>> mirror_formula(focal_length=f, u=u)
f*u/(-f + u)
>>> mirror_formula(focal_length=f, v=v)
f*v/(-f + v)
>>> mirror_formula(u=u, v=v)
u*v/(u + v)
```

sympy.physics.optics.utils.refraction_angle(incident, medium1, medium2,
normal=None, plane=None)

This function calculates transmitted vector after refraction at planar surface. medium1 and medium2 can be Medium or any sympifiable object. If incident is a number then treated as angle of incidence (in radians) in which case refraction angle is returned.

If incident is an object of Ray3D, normal also has to be an instance of Ray3D in order to get the output as a Ray3D. Please note that if plane of separation is not provided and normal is an instance of Ray3D, normal will be assumed to be intersecting incident ray at the plane of separation. This will not be the case when normal is a Matrix or any other sequence. If incident is an instance of Ray3D and plane has not been provided and normal is not Ray3D, output will be a Matrix.

Parameters

- incident : Matrix, Ray3D, sequence or a number
  Incident vector or angle of incidence
- medium1 : sympy.physics.optics.medium.Medium or sympifiable
  Medium 1 or its refractive index
- medium2 : sympy.physics.optics.medium.Medium or sympifiable
  Medium 2 or its refractive index
- normal : Matrix, Ray3D, or sequence
  Normal vector
- plane : Plane
  Plane of separation of the two media.

Returns

Returns an angle of refraction or a refracted ray depending on inputs.
Examples

```python
>>> from sympy.physics.optics import refraction_angle
>>> from sympy.geometry import Point3D, Ray3D, Plane
>>> from sympy.matrices import Matrix
>>> from sympy import symbols, pi

>>> n = Matrix([0, 0, 1])
>>> P = Plane(Point3D(0, 0, 0), normal_vector=[0, 0, 1])
>>> r1 = Ray3D(Point3D(-1, -1, 1), Point3D(0, 0, 0))
>>> refraction_angle(r1, 1, 1, n)
Matrix([[1], [1], [-1]])

>>> refraction_angle(r1, 1, 1, plane=P)
Ray3D(Point3D(0, 0, 0), Point3D(1/3, 1/3, -sqrt(3)/3))
```

With different index of refraction of the two media

```python
>>> n1, n2 = symbols('n1, n2')

>>> refraction_angle(r1, n1, n2, n)
Matrix([[n1/n2], [n1/n2], [-sqrt(3)*sqrt(-2*n1**2/(3*n2**2) + 1)]]),

>>> refraction_angle(r1, n1, n2, plane=P)
Ray3D(Point3D(0, 0, 0), Point3D(n1/n2, n1/n2, -sqrt(3)*sqrt(-2*n1**2/(3*n2**2) + 1)))

>>> round(refraction_angle(pi/6, 1.2, 1.5), 5)
0.41152
```

`sympy.physics.optics.utils.transverse_magnification(si, so)`

Calculates the transverse magnification, which is the ratio of the image size to the object size.

**Parameters**

- **so**: sympifiable
  - Lens-object distance.

- **si**: sympifiable
  - Lens-image distance.

**Example**

```python
>>> from sympy.physics.optics import transverse_magnification

>>> transverse_magnification(30, 15)
-2
```
Waves

This module has all the classes and functions related to waves in optics.

Contains
- TWave

class sympy.physics.optics.waves.TWave(amplitude, frequency=None, phase=0, time_period=None, n=n)

This is a simple transverse sine wave travelling in a one-dimensional space. Basic properties are required at the time of creation of the object, but they can be changed later with respective methods provided.

Raises
- ValueError: When neither frequency nor time period is provided or they are not consistent.
- TypeError: When anything other than TWave objects is added.

Explanation

It is represented as $A \times \cos(k \times x - \omega \times t + \phi)$, where $A$ is the amplitude, $\omega$ is the angular frequency, $k$ is the wavenumber (spatial frequency), $x$ is a spatial variable to represent the position on the dimension on which the wave propagates, and $\phi$ is the phase angle of the wave.

Arguments

amplitude
  [Sympifyable] Amplitude of the wave.

frequency
  [Sympifyable] Frequency of the wave.

phase
  [Sympifyable] Phase angle of the wave.

time_period
  [Sympifyable] Time period of the wave.

n
  [Sympifyable] Refractive index of the medium.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.optics import TWave
>>> A1, phi1, A2, phi2, f = symbols('A1, phi1, A2, phi2, f')
>>> w1 = TWave(A1, f, phi1)
>>> w2 = TWave(A2, f, phi2)
>>> w3 = w1 + w2  # Superposition of two waves
>>> w3
```
(continues on next page)
property amplitude

Returns the amplitude of the wave.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.optics import TWave
>>> A, phi, f = symbols('A, phi, f')
>>> w = TWave(A, f, phi)
>>> w.amplitude
A
```

property angular_velocity

Returns the angular velocity of the wave, in radians per second.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.optics import TWave
>>> A, phi, f = symbols('A, phi, f')
>>> w = TWave(A, f, phi)
>>> w.angular_velocity
2*pi*f
```

property frequency

Returns the frequency of the wave, in cycles per second.
Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.optics import TWave
>>> A, phi, f = symbols('A, phi, f')
>>> w = TWave(A, f, phi)
>>> w.frequency
f
```

**property n**

Returns the refractive index of the medium

**property phase**

Returns the phase angle of the wave, in radians.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.optics import TWave
>>> A, phi, f = symbols('A, phi, f')
>>> w = TWave(A, f, phi)
>>> w.phase
phi
```

**property speed**

Returns the propagation speed of the wave, in meters per second. It is dependent on the propagation medium.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.optics import TWave
>>> A, phi, f = symbols('A, phi, f')
>>> w = TWave(A, f, phi)
>>> w.speed
299792458*meter/(second*n)
```

**property time_period**

Returns the temporal period of the wave, in seconds per cycle.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.optics import TWave
>>> A, phi, f = symbols('A, phi, f')
>>> w = TWave(A, f, phi)
>>> w.time_period
1/f
```
property wavelength

Returns the wavelength (spatial period) of the wave, in meters per cycle. It depends on the medium of the wave.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.optics import TWave
>>> A, phi, f = symbols('A, phi, f')
>>> w = TWave(A, f, phi)
>>> w.wavelength
299792458*meter/(second*f*n)
```

property wavenumber

Returns the wavenumber of the wave, in radians per meter.

Examples

```python
>>> from sympy import symbols
>>> from sympy.physics.optics import TWave
>>> A, phi, f = symbols('A, phi, f')
>>> w = TWave(A, f, phi)
>>> w.wavenumber
pi*second*f*n/(149896229*meter)
```

Control Module

Abstract

Contains docstrings of Physics-Control module

Control

Currently, `sympy.physics.control` (page 1962) is able to deal with LTI (Linear, time-invariant) systems. The TransferFunction class is used to represent Continuous-time Transfer functions in the Laplace domain; where Transfer functions are input to output representations of dynamic systems. The additive property is used for transfer functions in the Parallel class, and the multiplicative property is used for transfer functions in the Series class. Also, there is a Feedback class which is used to represent negative feedback interconnection between two input/output systems. MIMO systems are also supported with TransferFunctionMatrix as the base class for representing one. MIMO Series, MIMO Parallel and MIMO Feedback are MIMO equivalent of Series, Parallel and Feedback classes.

The advantage of this symbolic Control system package is that the solutions obtained from it are highly accurate and do not rely on numerical methods to approximate the solutions. Symbolic solutions obtained are also in a compact form that can be used for further analysis.
Control API

lti

class sympy.physics.control.lti.TransferFunction(num, den, var)
A class for representing LTI (Linear, time-invariant) systems that can be strictly described by ratio of polynomials in the Laplace transform complex variable. The arguments are num, den, and var, where num and den are numerator and denominator polynomials of the TransferFunction respectively, and the third argument is a complex variable of the Laplace transform used by these polynomials of the transfer function. num and den can be either polynomials or numbers, whereas var has to be a Symbol (page 1028).

Parameters
num : Expr, Number
  The numerator polynomial of the transfer function.

den : Expr, Number
  The denominator polynomial of the transfer function.

var : Symbol
  Complex variable of the Laplace transform used by the polynomials of the transfer function.

Raises
TypeError
  When var is not a Symbol or when num or den is not a number or a polynomial.

ValueError
  When den is zero.

Explanation

Generally, a dynamical system representing a physical model can be described in terms of Linear Ordinary Differential Equations like -

\[ b_m y^{(m)} + b_{m-1} y^{(m-1)} + \cdots + b_1 y^{(1)} + b_0 y = a_n x^{(n)} + a_{n-1} x^{(n-1)} + \cdots + a_1 x^{(1)} + a_0 x \]

Here, \( x \) is the input signal and \( y \) is the output signal and superscript on both is the order of derivative (not exponent). Derivative is taken with respect to the independent variable, \( t \). Also, generally \( m \) is greater than \( n \).

It is not feasible to analyse the properties of such systems in their native form therefore, we use mathematical tools like Laplace transform to get a better perspective. Taking the Laplace transform of both the sides in the equation (at zero initial conditions), we get -

\[ L[b_m y^{(m)} + b_{m-1} y^{(m-1)} + \cdots + b_1 y^{(1)} + b_0 y] = L[a_n x^{(n)} + a_{n-1} x^{(n-1)} + \cdots + a_1 x^{(1)} + a_0 x] \]

Using the linearity property of Laplace transform and also considering zero initial conditions (i.e. \( y(0^-) = 0, y'(0^-) = 0 \) and so on), the equation above gets translated to -

\[ b_m L[y^{(m)}] + \cdots + b_1 L[y^{(1)}] + b_0 L[y] = a_n L[x^{(n)}] + \cdots + a_1 L[x^{(1)}] + a_0 L[x] \]

Now, applying Derivative property of Laplace transform,
Here, the superscript on $s$ is **exponent**. Note that the zero initial conditions assumption, mentioned above, is very important and cannot be ignored otherwise the dynamical system cannot be considered time-independent and the simplified equation above cannot be reached.

Collecting $L[y]$ and $L[x]$ terms from both the sides and taking the ratio $\frac{L[y]}{L[x]}$, we get the typical rational form of transfer function.

The numerator of the transfer function is, therefore, the Laplace transform of the output signal (the signals are represented as functions of time) and similarly, the denominator of the transfer function is the Laplace transform of the input signal. It is also a convention to denote the input and output signal’s Laplace transform with capital alphabets like shown below.

$$H(s) = \frac{Y(s)}{X(s)} = \frac{L\{y(t)\}}{L\{x(t)\}}$$

$s$, also known as complex frequency, is a complex variable in the Laplace domain. It corresponds to the equivalent variable $t$, in the time domain. Transfer functions are sometimes also referred to as the Laplace transform of the system’s impulse response. Transfer function, $H$, is represented as a rational function in $s$ like,

$$H(s) = \frac{a_n s^n + a_{n-1} s^{n-1} + \ldots + a_1 s + a_0}{b_m s^m + b_{m-1} s^{m-1} + \ldots + b_1 s + b_0}$$

**Examples**

```python
>>> from sympy.abc import s, p, a
>>> from sympy.physics.control.lti import TransferFunction
>>> tf1 = TransferFunction(s + a, s**2 + s + 1, s)
>>> tf1
TransferFunction(a + s, s**2 + s + 1, s)
>>> tf1.num
a + s
>>> tf1.den
s**2 + s + 1
>>> tf1.var
s
>>> tf1.args
(a + s, s**2 + s + 1, s)
```

Any complex variable can be used for var.

```python
>>> tf2 = TransferFunction(a*p**3 - a*p**2 + p*s, p + a**2, p)
>>> tf2
TransferFunction(a*p**3 - a*p**2 + p*s, a**2 + p, p)
>>> tf3 = TransferFunction((p + 3)*(p - 1), (p - 1)*(p + 5), p)
>>> tf3
TransferFunction((p - 1)*(p + 3), (p - 1)*(p + 5), p)
```

To negate a transfer function the `-` operator can be prepended:

```python
>>> tf4 = TransferFunction(-a + s, p**2 + s, p)
>>> -tf4
```

(continues on next page)
You can use a float or an integer (or other constants) as numerator and denominator:

```python
>>> tf6 = TransferFunction(1/2, 4, s)
>>> tf6.num
0.5
>>> tf6.den
4
>>> tf6.var
s
>>> tf6.args
(0.5, 4, s)
```

You can take the integer power of a transfer function using the ** operator:

```python
>>> tf7 = TransferFunction(s + a, s - a, s)
>>> tf7**3
TransferFunction((a + s)**3, (-a + s)**3, s)
>>> tf7**0
TransferFunction(1, 1, s)
>>> tf8 = TransferFunction(p + 4, p - 3, p)
>>> tf8**-1
TransferFunction(p - 3, p + 4, p)
```

Addition, subtraction, and multiplication of transfer functions can form unevaluated Series or Parallel objects.

```python
>>> tf9 = TransferFunction(s + 1, s**2 + s + 1, s)
>>> tf10 = TransferFunction(s - p, s + 3, s)
>>> tf11 = TransferFunction(4*s**2 + 2*s - 4, s - 1, s)
>>> tf12 = TransferFunction(1 - s, s**2 + 4, s)
>>> tf9 + tf10
Parallel(TransferFunction(s + 1, s**2 + s + 1, s), TransferFunction(-p + s, s + 3, s))
>>> tf10 - tf11
Parallel(TransferFunction(-p + s, s + 3, s), TransferFunction(-4*s**2 - 2*s + 4, s - 1, s))
>>> tf9 * tf10
Series(TransferFunction(s + 1, s**2 + s + 1, s), TransferFunction(-p + s, s + 3, s))
>>> tf10 - (tf9 + tf12)
Parallel(TransferFunction(-p + s, s + 3, s), TransferFunction(-s - 1, -s**2 + s + 1, s), TransferFunction(s - 1, s**2 + 4, s))
>>> tf10 - (tf9 * tf12)
Parallel(TransferFunction(-p + s, s + 3, s), Series(TransferFunction(-1, -1, s), TransferFunction(s + 1, s**2 + s + 1, s), TransferFunction(1 - s, s**2 + 4, s)))
>>> tf11 * tf10 * tf9
Series(TransferFunction(4*s**2 + 2*s - 4, s - 1, s), TransferFunction(-p, p, s))
```

(continues on next page)
These unevaluated Series or Parallel objects can convert into the resultant transfer function using .doit() method or by .rewrite(TransferFunction).

References

[R675], [R676]

dc_gain()

Computes the gain of the response as the frequency approaches zero.

The DC gain is infinite for systems with pure integrators.

Examples

```python
>>> from sympy.abc import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction
>>> tf1 = TransferFunction(s + 3, s**2 - 9, s)
>>> tf1.dc_gain()
-1/3
>>> tf2 = TransferFunction(p**2, p - 3 + p**3, p)
>>> tf2.dc_gain()
0
>>> tf3 = TransferFunction(a*p**2 - b, s + b, s)
>>> tf3.dc_gain()
(a*p**2 - b)/b
>>> tf4 = TransferFunction(1, s, s)
>>> tf4.dc_gain()
oo
```
property den

Returns the denominator polynomial of the transfer function.

Examples

```python
>>> from sympy import s, p
>>> from sympy.physics.control.lti import TransferFunction
>>> G1 = TransferFunction(s + 4, p**3 - 2*p + 4, s)
>>> G1.den
p**3 - 2*p + 4
>>> G2 = TransferFunction(3, 4, s)
>>> G2.den
4
```

expand()

Returns the transfer function with numerator and denominator in expanded form.

Examples

```python
>>> from sympy import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction
>>> G1 = TransferFunction((a - s)**2, (s**2 + a)**2, s)
>>> G1.expand()
TransferFunction(a**2 - 2*a*s + s**2, a**2 + 2*a*s**2 + s**4, s)
>>> G2 = TransferFunction((p + 3*b)*(p - b), (p - b)*(p + 2*b), p)
>>> G2.expand()
TransferFunction(-3*b**2 + 2*b*p + p**2, -2*b**2 + b*p + p**2, p)
```

classmethod from_rational_expression(expr, var=None)

Creates a new TransferFunction efficiently from a rational expression.

Parameters

expr : Expr, Number
    The rational expression representing the TransferFunction.

var : Symbol, optional
    Complex variable of the Laplace transform used by the polynomials of the transfer function.

Raises

ValueError
    When expr is of type Number and optional parameter var is not passed.
    When expr has more than one variables and an optional parameter var is not passed.

ZeroDivisionError
    When denominator of expr is zero or it has ComplexInfinity in its numerator.
Examples

```python
>>> from sympy import s, p, a
>>> expr1 = (s + 5)/(3*s**2 + 2*s + 1)
>>> tf1 = TransferFunction.from_rational_expression(expr1)
>>> tf1
TransferFunction(s + 5, 3*s**2 + 2*s + 1, s)

>>> expr2 = (a*p**3 - a*p**2 + p*s)/(p + a**2)  # Expr with more than one variables
>>> tf2 = TransferFunction.from_rational_expression(expr2, p)
>>> tf2
TransferFunction(a*p**3 - a*p**2 + p*s, a**2 + p, p)
```

In case of conflict between two or more variables in an expression, SymPy will raise a `ValueError`, if var is not passed by the user.

```python
>>> tf = TransferFunction.from_rational_expression((a + a*s)/(s**2 + s + 1))
Traceback (most recent call last):
  ... ValueError: Conflicting values found for positional argument `var` (\{a, s\}). Specify it manually.

This can be corrected by specifying the var parameter manually.

```python
>>> tf = TransferFunction.from_rational_expression((a + a*s)/(s**2 + s + 1), s)
>>> tf
TransferFunction(a*s + a, s**2 + s + 1, s)
```

`var` also need to be specified when `expr` is a `Number`

```python
>>> tf3 = TransferFunction.from_rational_expression(10, s)
>>> tf3
TransferFunction(10, 1, s)
```

**property is_biproper**

Returns True if degree of the numerator polynomial is equal to degree of the denominator polynomial, else False.

Examples

```python
>>> from sympy import s, p, a, b
>>> tf1 = TransferFunction(a*p**2 + b*s, s + p, s)
>>> tf1.is_biproper
True
>>> tf2 = TransferFunction(p**2, p + a, p)
>>> tf2.is_biproper
False
```
property is_proper
Returns True if degree of the numerator polynomial is less than or equal to degree of the denominator polynomial, else False.

Examples

```python
>>> from sympy import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction
>>> tf1 = TransferFunction(b*s**2 + p**2 - a*p + s, b - p**2, s)
>>> tf1.is_proper
False
>>> tf2 = TransferFunction(p**2 - 4*p, p**3 + 3*p + 2, p)
>>> tf2.is_proper
True
```

is_stable()
Returns True if the transfer function is asymptotically stable; else False.
This would not check the marginal or conditional stability of the system.

Examples

```python
>>> from sympy import s, p, a
>>> from sympy import symbols
>>> from sympy.physics.control.lti import TransferFunction
>>> q, r = symbols('q, r', negative=True)
>>> tf1 = TransferFunction((1 - s)**2, (s + 1)**2, s)
>>> tf1.is_stable()
True
>>> tf2 = TransferFunction((1 - p)**2, (s**2 + 1)**2, s)
>>> tf2.is_stable()
False
>>> tf3 = TransferFunction(4, q*s - r, s)
>>> tf3.is_stable()
False
>>> tf4 = TransferFunction(p + 1, a*p - s**2, p)
>>> tf4.is_stable() is None # Not enough info about the symbols to determine stability
True
```

property is_strictly_proper
Returns True if degree of the numerator polynomial is strictly less than degree of the denominator polynomial, else False.
Examples

```python
>>> from sympy.abc import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction
>>> tf1 = TransferFunction(a*p**2 + b*s, s - p, s)
>>> tf1.is_strictly_proper
False
>>> tf2 = TransferFunction(s**3 - 2, s**4 + 5*s + 6, s)
>>> tf2.is_strictly_proper
True
```

**property num**

Returns the numerator polynomial of the transfer function.

Examples

```python
>>> from sympy.abc import s, p
>>> from sympy.physics.control.lti import TransferFunction
>>> G1 = TransferFunction(s**2 + p*s + 3, s - 4, s)
>>> G1.num
p*s + s**2 + 3
>>> G2 = TransferFunction((p + 5)*(p - 3), (p - 3)*(p + 1), p)
>>> G2.num
(p - 3)*(p + 5)
```

**poles()**

Returns the poles of a transfer function.

Examples

```python
>>> from sympy.abc import s, p, a
>>> from sympy.physics.control.lti import TransferFunction
>>> tf1 = TransferFunction((p + 3)*(p - 1), (p - 1)*(p + 5), p)
>>> tf1.poles()
[-5, 1]
>>> tf2 = TransferFunction((1 - s)**2, (s**2 + 1)**2, s)
>>> tf2.poles()
[I, I, -I, -I]
>>> tf3 = TransferFunction(s**2, a*s + p, s)
>>> tf3.poles()
[-p/a]
```

**to_expr()**

Converts a TransferFunction object to SymPy Expr.
Examples

```python
>>> from sympy import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction
>>> from sympy import Expr

>>> tf1 = TransferFunction(s, a*s**2 + 1, s)
>>> tf1.to_expr()
s/(a*s**2 + 1)

>>> isinstance(_, Expr)
True

>>> tf2 = TransferFunction(1, (p + 3*b)*(b - p), p)
>>> tf2.to_expr()
1/((b - p)*3*b + p))

>>> tf3 = TransferFunction((s - 2)*(s - 3), (s - 1)*(s - 2)*(s - 3), s)
>>> tf3.to_expr()
((s - 3)*(s - 2))/(((s - 3)*(s - 2)*(s - 1)))
```

**property var**

Returns the complex variable of the Laplace transform used by the polynomials of the transfer function.

Examples

```python
>>> from sympy import s, p, a
>>> from sympy.physics.control.lti import TransferFunction

>>> G1 = TransferFunction(p**2 + 2*p + 4, p - 6, p)
>>> G1.var
p

>>> G2 = TransferFunction(0, s - 5, s)
>>> G2.var
s
```

**zeros()**

Returns the zeros of a transfer function.

Examples

```python
>>> from sympy import s, p, a
>>> from sympy.physics.control.lti import TransferFunction

>>> tf1 = TransferFunction((p + 3)*(p - 1), (p - 1)*(p + 5), p)
>>> tf1.zeros()
[-3, 1]

>>> tf2 = TransferFunction((1 - s)**2, (s**2 + 1)**2, s)
>>> tf2.zeros()
[1, 1]

>>> tf3 = TransferFunction(s**2, a*s + p, s)
>>> tf3.zeros()
[0, 0]
```
class sympy.physics.control.lti.Series(*args, evaluate=False)

A class for representing a series configuration of SISO systems.

Parameters

- **args**: SISOLinearTimeInvariant
  
  SISO systems in a series configuration.

- **evaluate**: Boolean, Keyword
  
  When passed True, returns the equivalent Series(*args).doit().
  Set to False by default.

Raises

- **ValueError**
  
  When no argument is passed.

- **TypeError**
  
  Any of the passed *args has unsupported type

A combination of SISO and MIMO systems is passed. There should be homogeneity in the type of systems passed, SISO in this case.

Examples

```python
>>> from sympy.abc import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction, Series,
    Parallel
>>> tf1 = TransferFunction(a*p**2 + b*s, -p + s, s)
>>> tf2 = TransferFunction(s**3 - 2, s**4 + 5*s + 6, s)
>>> tf3 = TransferFunction(p**2, p + s, s)
>>> S1 = Series(tf1, tf2)
>>> S1
Series(TransferFunction(a*p**2 + b*s, -p + s, s), TransferFunction(s**3 - 2, s**4 + 5*s + 6, s))
>>> S1.var
s
>>> S2 = Series(tf2, Parallel(tf3, -tf1))
>>> S2
Series(TransferFunction(s**3 - 2, s**4 + 5*s + 6, s),
    Parallel(TransferFunction(p**2, p + s, s), TransferFunction(-a*p**2 -
    -b*s, -p + s, s)))
>>> S2.var
s
>>> S3 = Series(Parallel(tf1, tf2), Parallel(tf2, tf3))
>>> S3
Series(Parallel(TransferFunction(a*p**2 + b*s, -p + s, s),
    TransferFunction(s**3 - 2, s**4 + 5*s + 6, s)),
    Parallel(TransferFunction(s**3 - 2, s**4 + 5*s + 6, s),
    TransferFunction(p**2, p + s, s)))
>>> S3.var
s
```
You can get the resultant transfer function by using `.doit()` method:

```python
>>> S3 = Series(tf1, tf2, -tf3)
>>> S3.doit()
TransferFunction(-p**2*(s**3 - 2)*(a*p**2 + b*s), (-p + s)*(p + s)*(s**4 + 5*s + 6), s)

>>> S4 = Series(tf2, Parallel(tf1, -tf3))
>>> S4.doit()
TransferFunction(((s**3 - 2)*(-p**2*(-p + s) + (p + s)*(a*p**2 + b*s)), (-p + s)*(p + s)*(s**4 + 5*s + 6), s)
```

**Notes**

All the transfer functions should use the same complex variable `var` of the Laplace transform.

**See also:**

**doit(**hints**)**

Returns the resultant transfer function obtained after evaluating the transfer functions in series configuration.

**Examples**

```python
>>> from sympy.abc import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction, Series
>>> tf1 = TransferFunction(a*p**2 + b*s, s - p, s)
>>> tf2 = TransferFunction(s**3 - 2, s**4 + 5*s + 6, s)
>>> Series(tf2, tf1).doit()
TransferFunction((s**3 - 2)*(a*p**2 + b*s), (-p + s)*(s**4 + 5*s + 6), s)

>>> Series(-tf1, -tf2).doit()
TransferFunction((2 - s**3)*(-a*p**2 - b*s), (-p + s)*(s**4 + 5*s + 6), s)
```

**property is_biproper**

Returns True if degree of the numerator polynomial of the resultant transfer function is equal to degree of the denominator polynomial of the same, else False.
Examples

```python
>>> from sympy.abc import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction, Series
>>> tf1 = TransferFunction(a*p**2 + b*s, s - p, s)
>>> tf2 = TransferFunction(p, s**2, s)
>>> tf3 = TransferFunction(s**2, 1, s)
>>> S1 = Series(tf1, -tf2)
>>> S1.is_biproper
False
>>> S2 = Series(tf2, tf3)
>>> S2.is_biproper
True
```

**property is_proper**

Returns True if degree of the numerator polynomial of the resultant transfer function is less than or equal to degree of the denominator polynomial of the same, else False.

Examples

```python
>>> from sympy.abc import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction, Series
>>> tf1 = TransferFunction(b*s**2 + p**2 - a*p + s, b - p**2, s)
>>> tf2 = TransferFunction(p**2 - 4*p, p**3 + 3*s + 2, s)
>>> tf3 = TransferFunction(s, s**2 + s + 1, s)
>>> S1 = Series(-tf2, tf1)
>>> S1.is_proper
False
>>> S2 = Series(tf1, tf2, tf3)
>>> S2.is_proper
True
```

**property is_strictly_proper**

Returns True if degree of the numerator polynomial of the resultant transfer function is strictly less than degree of the denominator polynomial of the same, else False.

Examples

```python
>>> from sympy.abc import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction, Series
>>> tf1 = TransferFunction(a*p**2 + b*s, s - p, s)
>>> tf2 = TransferFunction(s**2 - 2, s**2 + 5*s + 6, s)
>>> tf3 = TransferFunction(1, s**2 + s + 1, s)
>>> S1 = Series(tf1, tf2)
>>> S1.is_strictly_proper
False
>>> S2 = Series(tf1, tf2, tf3)
>>> S2.is_strictly_proper
True
```
to_expr()
Returns the equivalent Expr object.

property var
Returns the complex variable used by all the transfer functions.

Examples

```python
>>> from sympy.abc import p
>>> from sympy.physics.control.lti import TransferFunction, Series,
    Parallel
>>> G1 = TransferFunction(p**2 + 2*p + 4, p - 6, p)
>>> G2 = TransferFunction(p, 4 - p, p)
>>> G3 = TransferFunction(0, p**4 - 1, p)
>>> Series(G1, G2).var
p
>>> Series(-G3, Parallel(G1, G2)).var
p
```

class sympy.physics.control.lti.Parallel(*args, evaluate=False)
A class for representing a parallel configuration of SISO systems.

Parameters
- **args**: SISOLinearTimeInvariant
  SISO systems in a parallel arrangement.
- **evaluate**: Boolean, Keyword
  When passed True, returns the equivalent Parallel(*args).doit().
  Set to False by default.

Raises
- **ValueError**
  When no argument is passed.
  var attribute is not same for every system.
- **TypeError**
  Any of the passed *args has unsupported type
  A combination of SISO and MIMO systems is passed. There should be homogeneity in the type of systems passed.

Examples

```python
>>> from sympy.abc import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction, Parallel,
    Series
>>> tf1 = TransferFunction(a*p**2 + b*s, s - p, s)
>>> tf2 = TransferFunction(s**3 - 2, s**4 + 5*s + 6, s)
>>> tf3 = TransferFunction(p**2, p + s, s)
>>> P1 = Parallel(tf1, tf2)
```
You can get the resultant transfer function by using .doit() method:

```python
>>> Parallel(tf1, tf2, -tf3).doit()
TransferFunction(-p**2*(-p + s)*(s**4 + 5*s + 6) + (-p + s)*(p +
   s)*(s**3 - 2) + (p + s)*(a*p**2 + b*s)*(s**4 + 5*s + 6), (-p + s)*(p +
   s)*(s**4 + 5*s + 6), s)
```

**Notes**

All the transfer functions should use the same complex variable \( \text{var} \) of the Laplace transform.

**See also:**

**doit(****hints**

Returns the resultant transfer function obtained after evaluating the transfer functions in parallel configuration.
Examples

```python
>>> from sympy import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction, Parallel
>>> tf1 = TransferFunction(a*p**2 + b*s, s - p, s)
>>> tf2 = TransferFunction(s**3 - 2, s**4 + 5*s + 6, s)
>>> Parallel(tf2, tf1).doit()
TransferFunction((-p + s)*(s**3 - 2) + (a*p**2 + b*s)*(s**4 + 5*s + 6), (-p + s)*(s**4 + 5*s + 6), s)
```

property is_biproper

Returns True if degree of the numerator polynomial of the resultant transfer function is equal to degree of the denominator polynomial of the same, else False.

Examples

```python
>>> from sympy import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction, Parallel
>>> tf1 = TransferFunction(b*s**2 + p**2 + a*p + s, b - p**2, s)
>>> tf2 = TransferFunction(p**2 + 4*p, p**3 + 3*s + 2, s)
>>> tf3 = TransferFunction(s, s**2 + s + 1, s)
>>> P1 = Parallel(-tf2, tf1)
>>> P1.is_biproper
True
>>> P2 = Parallel(tf2, tf3)
>>> P2.is_biproper
False
```

property is_proper

Returns True if degree of the numerator polynomial of the resultant transfer function is less than or equal to degree of the denominator polynomial of the same, else False.

Examples

```python
>>> from sympy import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction, Parallel
>>> tf1 = TransferFunction(b*s**2 + p**2 + a*p + s, b - p**2, s)
>>> tf2 = TransferFunction(p**2 + 4*p, p**3 + 3*s + 2, s)
>>> tf3 = TransferFunction(s, s**2 + s + 1, s)
>>> P1 = Parallel(-tf2, tf1)
>>> P1.is_proper
False
>>> P2 = Parallel(tf2, tf3)
>>> P2.is_proper
True
```
property is_strictly_proper
Returns True if degree of the numerator polynomial of the resultant transfer function
is strictly less than degree of the denominator polynomial of the same, else False.

Examples
```python
>>> from sympy.abc import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction, Parallel
>>> tf1 = TransferFunction(a*p**2 + b*s, s - p, s)
>>> tf2 = TransferFunction(s**3 - 2, s**4 + 5*s + 6, s)
>>> tf3 = TransferFunction(s, s**2 + s + 1, s)
>>> P1 = Parallel(tf1, tf2)
>>> P1.is_strictly_proper
False
>>> P2 = Parallel(tf2, tf3)
>>> P2.is_strictly_proper
True
```

to_expr()
Returns the equivalent Expr object.

property var
Returns the complex variable used by all the transfer functions.

Examples
```python
>>> from sympy.abc import p
>>> from sympy.physics.control.lti import TransferFunction, Parallel,
... Series
>>> G1 = TransferFunction(p**2 + 2*p + 4, p - 6, p)
>>> G2 = TransferFunction(p, 4 - p, p)
>>> G3 = TransferFunction(0, p**4 - 1, p)
>>> Parallel(G1, G2).var
p
>>> Parallel(-G3, Series(G1, G2)).var
p
```

class sympy.physics.control.lti.Feedback(sys1, sys2=None, sign=-1)
A class for representing closed-loop feedback interconnection between two SISO input/output systems.

The first argument, sys1, is the feedforward part of the closed-loop system or in simple words, the dynamical model representing the process to be controlled. The second argument, sys2, is the feedback system and controls the feedback signal to sys1. Both sys1 and sys2 can either be Series or TransferFunction objects.

Parameters
- **sys1** : Series, TransferFunction
  - The feedforward path system.
- **sys2** : Series, TransferFunction, optional
The feedback path system (often a feedback controller). It is the
model sitting on the feedback path.
If not specified explicitly, the sys2 is assumed to be unit (1.0) transfer
function.

**sign** : int, optional

The sign of feedback. Can either be 1 (for positive feedback) or -1
(for negative feedback). Default value is 1.

**Raises**

**ValueError**

When sys1 and sys2 are not using the same complex variable of the
Laplace transform.
When a combination of sys1 and sys2 yields zero denominator.

**TypeError**

When either sys1 or sys2 is not a Series or a TransferFunction
object.

**Examples**

```
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunction, Feedback
>>> plant = TransferFunction(3*s**2 + 7*s - 3, s**2 - 4*s + 2, s)
>>> controller = TransferFunction(5*s - 10, s + 7, s)
>>> F1 = Feedback(plant, controller)
>>> F1
Feedback(TransferFunction(3*s**2 + 7*s - 3, s**2 - 4*s + 2, s),
             →TransferFunction(5*s - 10, s + 7, s), -1)
```

You can get the feedforward and feedback path systems by using .sys1 and .sys2 re-
spectively.

```
>>> F1.sys1
TransferFunction(3*s**2 + 7*s - 3, s**2 - 4*s + 2, s)
>>> F1.sys2
TransferFunction(5*s - 10, s + 7, s)
```

You can get the resultant closed loop transfer function obtained by negative feedback
interconnection using .doit() method.

```
>>> F1.doit()
TransferFunction((s + 7)*(s**2 - 4*s + 2)*(3*s**2 + 7*s - 3), ((s +
             →7)*(s**2 - 4*s + 2) + (5*s - 10)*(3*s**2 + 7*s - 3))*(s**2 - 4*s + 2),
             →s)
>>> G = TransferFunction(2*s**2 + 5*s + 1, s**2 + 2*s + 3, s)
```

(continues on next page)
```
>>> C = TransferFunction(5*s + 10, s + 10, s)
>>> F2 = Feedback(G*C, TransferFunction(1, 1, s))
>>> F2.doit()
TransferFunction((s + 10)*(5*s + 10)*(s**2 + 2*s + 3)*(2*s**2 + 5*s + 1),
                (s + 10)*(s + 10)*(s**2 + 2*s + 3) + (5*s + 10)*(2*s**2 + 5*s + 1),
                (s**2 + 2*s + 3), s)
```

To negate a Feedback object, the - operator can be prepended:

```
>>> -F1
Feedback(TransferFunction(-3*s**2 - 7*s + 3, s**2 - 4*s + 2, s),
         TransferFunction(10 - 5*s, s + 7, s), -1)
>>> -F2
Feedback(Series(TransferFunction(-1, 1, s), TransferFunction(2*s**2 + 5*s + 1, s**2 + 2*s + 3, s), TransferFunction(5*s + 10, s + 10, s)),
         TransferFunction(-1, 1, s), -1)
```

See also:

- `MIMOFeedback` (page 1999), `Series` (page 1971), `Parallel` (page 1975)

`doit(cancel=False, expand=False, **hints)`

Returns the resultant transfer function obtained by the feedback interconnection.

**Examples**

```
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunction, Feedback
>>> plant = TransferFunction(3*s**2 + 7*s - 3, s**2 - 4*s + 2, s)
>>> controller = TransferFunction(5*s - 10, s + 7, s)
>>> F1 = Feedback(plant, controller)
>>> F1.doit()
TransferFunction((s + 7)*(s**2 - 4*s + 2)*(3*s**2 + 7*s - 3), ((s + 7)*(s**2 - 4*s + 2) + (5*s - 10)*(3*s**2 + 7*s - 3))*(s**2 - 4*s + 2), s)
>>> G = TransferFunction(2*s**2 + 5*s + 1, s**2 + 2*s + 3, s)
>>> F2 = Feedback(G, TransferFunction(1, 1, s))
>>> F2.doit()
TransferFunction((s**2 + 2*s + 3)*(2*s**2 + 5*s + 1), (s**2 + 2*s +
                 3)*(3*s**2 + 7*s + 4), s)
```

Use kwarg `expand=True` to expand the resultant transfer function. Use `cancel=True` to cancel out the common terms in numerator and denominator.

```
>>> F2.doit(cancel=True, expand=True)
TransferFunction(2*s**2 + 5*s + 1, 3*s**2 + 7*s + 4, s)
>>> F2.doit(expand=True)
TransferFunction(2*s**4 + 9*s**3 + 17*s**2 + 17*s + 3, 3*s**4 +
                 13*s**3 + 27*s**2 + 29*s + 12, s)
```

**property sensitivity**

Returns the sensitivity function of the feedback loop.
Sensitivity of a Feedback system is the ratio of change in the open loop gain to the change in the closed loop gain.

**Note:** This method would not return the complementary sensitivity function.

### Examples

```python
>>> from sympy.abc import p
>>> from sympy.physics.control.lti import TransferFunction, Feedback
>>> C = TransferFunction(5*p + 10, p + 10, p)
>>> P = TransferFunction(1 - p, p + 2, p)
>>> F_1 = Feedback(P, C)
>>> F_1.sensitivity
1/((1 - p)*(5*p + 10)/((p + 2)*(p + 10)) + 1)
```

**property sign**

Returns the type of MIMO Feedback model. 1 for Positive and -1 for Negative.

**property sys1**

Returns the feedforward system of the feedback interconnection.

### Examples

```python
>>> from sympy.abc import s, p
>>> from sympy.physics.control.lti import TransferFunction, Feedback
>>> plant = TransferFunction(3*s**2 + 7*s - 3, s**2 - 4*s + 2, s)
>>> controller = TransferFunction(5*s - 10, s + 7, s)
>>> F1 = Feedback(plant, controller)
>>> F1.sys1
TransferFunction(3*s**2 + 7*s - 3, s**2 - 4*s + 2, s)
>>> G = TransferFunction(2*s**2 + 5*s + 1, p**2 + 2*p + 3, p)
>>> C = TransferFunction(5*p + 10, p + 10, p)
>>> P = TransferFunction(1 - s, p + 2, p)
>>> F2 = Feedback(TransferFunction(1, 1, p), G*C*P)
>>> F2.sys1
TransferFunction(1, 1, p)
```

**property sys2**

Returns the feedback controller of the feedback interconnection.
Examples

```python
>>> from sympy import s, p
>>> from sympy.physics.control.lti import TransferFunction, Feedback
>>> plant = TransferFunction(3*s**2 + 7*s - 3, s**2 - 4*s + 2, s)
>>> controller = TransferFunction(5*s - 10, s + 7, s)
>>> F1 = Feedback(plant, controller)
>>> F1
TransferFunction(5*s - 10, s + 7, s)

>>> G = TransferFunction(2*s**2 + 5*s + 1, p**2 + 2*p + 3, p)
>>> C = TransferFunction(5*p + 10, p + 10, p)
>>> P = TransferFunction(1 - s, p + 2, p)
>>> F2 = Feedback(TransferFunction(1, 1, p), G*C*P)
>>> F2
Series(TransferFunction(2*s**2 + 5*s + 1, p**2 + 2*p + 3, p),
      TransferFunction(5*p + 10, p + 10, p), TransferFunction(1 - s, p + 2, p))
```

**property var**

Returns the complex variable of the Laplace transform used by all the transfer functions involved in the feedback interconnection.

Examples

```python
>>> from sympy import s, p
>>> from sympy.physics.control.lti import TransferFunction, Feedback
>>> plant = TransferFunction(3*s**2 + 7*s - 3, s**2 - 4*s + 2, s)
>>> controller = TransferFunction(5*s - 10, s + 7, s)
>>> F1 = Feedback(plant, controller)
>>> F1.var
s

>>> G = TransferFunction(2*s**2 + 5*s + 1, p**2 + 2*p + 3, p)
>>> C = TransferFunction(5*p + 10, p + 10, p)
>>> P = TransferFunction(1 - s, p + 2, p)
>>> F2 = Feedback(TransferFunction(1, 1, p), G*C*P)
>>> F2.var
p
```

**class sympy.physics.control.lti.TransferFunctionMatrix(arg)**

A class for representing the MIMO (multiple-input and multiple-output) generalization of the SISO (single-input and single-output) transfer function.

It is a matrix of transfer functions (TransferFunction, SISO-Series or SISO-Parallel). There is only one argument, arg which is also the compulsory argument. arg is expected to be strictly of the type list of lists which holds the transfer functions or reducible to transfer functions.

**Parameters**

- **arg**: Nested List (strictly).

Users are expected to input a nested list of TransferFunction, Series and/or Parallel objects.
Examples

Note: `pprint()` can be used for better visualization of `TransferFunctionMatrix` objects.

```python
>>> from sympy.abc import s, p, a
>>> from sympy import pprint
>>> from sympy.physics.control.lti import TransferFunction,
    TransferFunctionMatrix, Series, Parallel
>>> tf_1 = TransferFunction(s + a, s**2 + s + 1, s)
>>> tf_2 = TransferFunction(p**4 - 3*p + 2, s + p, s)
>>> tf_3 = TransferFunction(3, s + 2, s)
>>> tf_4 = TransferFunction(-a + p, 9*s - 9, s)
>>> tfm_1 = TransferFunctionMatrix([[tf_1], [tf_2], [tf_3]])
>>> tfm_1
TransferFunctionMatrix(((TransferFunction(a + s, s**2 + s + 1, s),), (TransferFunction(p**4 - 3*p + 2, p + s, s),), (TransferFunction(3, s + 2, s),)))
>>> tfm_1.var
s
>>> tfm_1.num_inputs
1
>>> tfm_1.num_outputs
3
>>> tfm_1.shape
(3, 1)
>>> tfm_1.args
(((TransferFunction(a + s, s**2 + s + 1, s),), (TransferFunction(p**4 - 3*p + 2, p + s, s),), (TransferFunction(3, s + 2, s),)),)
>>> tfm_2 = TransferFunctionMatrix([[tf_1, -tf_3], [tf_2, -tf_1], [tf_3, -tf_2]])
>>> tfm_2
TransferFunctionMatrix(((TransferFunction(a + s, s**2 + s + 1, s),), (TransferFunction(p**4 - 3*p + 2, p + s, s),), (TransferFunction(3, s + 2, s),)),)
>>> pprint(tfm_2, use_unicode=False)  # pretty-printing for better visualization
\[
\begin{bmatrix}
  a + s & -3 \\
  2 & s + 2 \\
  s + s + 1 & \\
  4 & \\
  p - 3*p + 2 & -a - s \\
  p + s & 2 \\
  s + s + 1 & \\
  4 & \\
  3 & - p + 3*p - 2
\end{bmatrix}
\]
(continues on next page)
TransferFunctionMatrix can be transposed, if user wants to switch the input and output transfer functions

```python
>>> tfm_2.transpose()
TransferFunctionMatrix(((TransferFunction(a + s, s**2 + s + 1, s), TransferFunction(p**4 - 3*p + 2, p + s, s), TransferFunction(3, s + 2, s)), (TransferFunction(-3, s + 2, s), TransferFunction(-a - s, s**2 + s + 1, s), TransferFunction(-p**4 + 3*p - 2, p + s, s))))
```
To access the `TransferFunction` at any index in the `TransferFunctionMatrix`, use the index notation.

```python
tfm_3[1, 0]  # gives the TransferFunction present at 2nd Row and 1st Col. Similar to that in Matrix classes
```

```python
TransferFunction(5, s*(s**2 + 2), s)
```

```python
tfm_3[0, 0]  # gives the TransferFunction present at 1st Row and 1st Col.
```

```python
TransferFunction(5, s, s)
```

```python
tfm_3[:, 0]  # gives the first column
```

```python
(TransferFunction(5, s, s), TransferFunction(5*s, s*(s**2 + 2), s)),)
```

```python
>>> pprint(_, use_unicode=False)
[ 5
 [ - ]
 [ s ]
 [ 5]
[--------]
[ / 2 \]
[5*\s + 2]/{t}
```

```python
tfm_3[0, :]  # gives the first row
```

```python
TransferFunctionMatrix(((TransferFunction(5, s, s),), TransferFunction(5*s, s*(s**2 + 2), s)),))
```

```python
>>> pprint(_, use_unicode=False)
[5 5*s ]
[- -------]
[ s 2 ]
[ s + 2]{t}
```

To negate a transfer function matrix, - operator can be prepended:

```python
tfm_4 = TransferFunctionMatrix([[tf_2], [-tf_1], [tf_3]])
```

```python
TransferFunctionMatrix(((TransferFunction(-p**4 + 3*p - 2, p + s, s),), TransferFunction(a + s, s**2 + s + 1, s), TransferFunction(-3, s + 2, s),))
```

```python
tfm_5 = TransferFunctionMatrix([[tf_1, tf_2], [tf_3, -tf_1]])
```

```python
TransferFunctionMatrix(((TransferFunction(-a - s, s**2 + s + 1, s), TransferFunction(-p**4 + 3*p - 2, p + s, s), TransferFunction(-3, s + 2, s), TransferFunction(a + s, s**2 + s + 1, s))),)
```

`subs()` returns the `TransferFunctionMatrix` object with the value substituted in the expression. This will not mutate your original `TransferFunctionMatrix`.

```python
tfm_2.subs(p, 2)  # substituting p everywhere in tfm_2 with 2.
```

```python
TransferFunctionMatrix(((TransferFunction(a + s, s**2 + s + 1, s), TransferFunction(-3, s + 2, s), TransferFunction(12, s + 2, s), TransferFunction(3, s + 2, s)),)
```

(continues on next page)
```
>>> pprint(_, use_unicode=False)
[ a + s  -3 ]
[--- ----- ]
[ 2 s + 2 ]
[ s + s + 1 ]
[s + s + 1]
[ 12 -a - s]
[ ----- --------- ]
[ s + 2 2 ]
[ s + s + 1 ]
[ 3 -12 ]
[ ----- ----- ]
[ 12 -a - s]
[ ------- ---------- ]
[ s + 2 2 ]
[s + s + 1]
```

```
>>> pprint(_, use_unicode=False)
[ a + s  -3 ]
[--- ----- ]
[ 2 s + 2 ]
[ s + s + 1 ]
[s + s + 1]
[ 4 -3*p + 2 -a - s]
[--------- --------- ]
[ p+s 2 ]
[ s + s + 1 ]
[ 4 ]
[ 3 -p + 3*p - 2]
[ ----- --------- ]
[ s + 2 p + s ]
```

```
>>> print(subs()) also supports multiple substitutions.
```

```
>>> tfm_2.subs({p: 2, a: 1})
TransferFunctionMatrix([(TransferFunction(s + 1, s**2 + s + 1, s), TransferFunction(-3, s + 2, s)), (TransferFunction(12, s + 2, s), TransferFunction(-s - 1, s**2 + s + 1, s)), (TransferFunction(3, s + 2, s), TransferFunction(-12, s + 2, s))])
```

```
>>> pprint(_, use_unicode=False)
[ s + 1  -3 ]
[--------- ----- ]
[ 2 s + 2 ]
[s + s + 1 ]
[ 12 -s - 1 ]
[ ------- --------- ]
[ s + 2 2 ]
[ s + s + 1 ]
[ 3 -12 ]
```

(continues on next page)
Users can reduce the Series and Parallel elements of the matrix to TransferFunction by using \texttt{doit()}.

\begin{verbatim}
>>> tfm_6 = TransferFunctionMatrix([[Series(tf_3, tf_4), Parallel(tf_3, tf_4)]])
>>> tfm_6
TransferFunctionMatrix(( (Series(TransferFunction(3, s + 2, s),  #
  TransferFunction(-a + p, 9*s - 9, s)), Parallel(TransferFunction(3, s,  #
  + 2, s), TransferFunction(-a + p, 9*s - 9, s))),))
>>> pprint(tfm_6, use_unicode=False)
[ -a + p  3 ]
[-------*----- ------- + ------]
[9*s - 9 s + 2 9*s - 9 s + 2]{t}

>>> tfm_6.doit()
TransferFunctionMatrix(( (TransferFunction(-3*a + 3*p, (s + 2)*(9*s - 9),  #
  s), TransferFunction(27*s + (-a + p)*(s + 2) - 27, (s + 2)*(9*s - 9),  #
  s)),))
>>> pprint(_, use_unicode=False)
[ -3*a + 3*p  27*s + (-a + p)*(s + 2) - 27]
[----------------- ----------------------------]
[(s + 2)*(9*s - 9) (s + 2)*(9*s - 9)]{t}

>>> tf_9 = TransferFunction(1, s, s)
>>> tf_10 = TransferFunction(1, s**2, s)
>>> tfm_7 = TransferFunctionMatrix([[Series(tf_9, tf_10), tf_9], [tf_10,  #
  Parallel(tf_9, tf_10)]]))
>>> tfm_7
TransferFunctionMatrix(( (Series(TransferFunction(1, s, s),  #
  TransferFunction(1, s**2, s)), TransferFunction(1, s, s)),  #
  (TransferFunction(1, s**2, s), Parallel(TransferFunction(1, s, s),  #
  TransferFunction(1, s**2, s))))))
>>> pprint(tfm_7, use_unicode=False)
[ 1 1 ]
[---- - ]
[ 2 s ]
[s*s ]

[ 1 1 1]
[ -- -- + -]
[ 2 2 s]
[s s s ]{t}

>>> tfm_7.doit()
TransferFunctionMatrix(( (TransferFunction(1, s**3, s),  #
  TransferFunction(1, s, s)), (TransferFunction(1, s**2, s),  #
  TransferFunction(s**2 + s, s**3, s))))
>>> pprint(_, use_unicode=False)
[ 1 1 ]
[ - - - ]
[ 3 s ]
[s s ]
\end{verbatim}
Addition, subtraction, and multiplication of transfer function matrices can form unevaluated Series or Parallel objects.

- For addition and subtraction: All the transfer function matrices must have the same shape.

- For multiplication (C = A * B): The number of inputs of the first transfer function matrix (A) must be equal to the number of outputs of the second transfer function matrix (B).

Also, use pretty-printing (pprint) to analyse better.

```python
>>> tfm_8 = TransferFunctionMatrix([[tf_3], [tf_2], [-tf_1]])
>>> tfm_9 = TransferFunctionMatrix([[tf_3]])
>>> tfm_10 = TransferFunctionMatrix([[tf_1], [tf_2], [tf_4]])
>>> tfm_11 = TransferFunctionMatrix([[tf_4], [-tf_1]])
>>> tfm_12 = TransferFunctionMatrix([[tf_4, -tf_1, tf_3], [-tf_2, -tf_4, -tf_3]])
>>> tfm_8 + tfm_10
MIMOParallel(TransferFunctionMatrix(((TransferFunction(3, s + 2, s),), (TransferFunction(p**4 - 3*p + 2, p + s, s),), (TransferFunction(-a - s, s**2 + s + 1, s),)), TransferFunctionMatrix(((TransferFunction(a + s),), (TransferFunction(-a + p, 9*s - 9, s),), (TransferFunction(-3, s + 2, s),)))), TransferFunctionMatrix(((TransferFunction(-a - s, s**2 + s + 1, s),), (TransferFunction(-p**4 + 3*p - 2, p + s, s),), (TransferFunction(-3, s + 2, s),)))))
```

```python
>>> pprint(_, use_unicode=False)
[ 3 ] [ a + s ]
[ ---- ] [ --------- ]
[ s + 2 ] [ 2 ]
[ 4 ]
[ p - 3*p + 2 ] [ 4 ]
[ ------------ ] + [ p - 3*p + 2 ]
[ p + s ] [ --------- ]
[ ] [ p + s ]
[ -a - s ] [ ]
[ ---------- ] [ -a + p ]
[ 2 ] [ ------- ]
[ s + s + 1 ]{t} [ 9*s - 9 ]{t}
```

```python
>>> -tfm_10 - tfm_8
MIMOParallel(TransferFunctionMatrix(((TransferFunction(-a - s, s**2 + s + 1, s),), (TransferFunction(-p**4 + 3*p - 2, p + s, s),), (TransferFunction(-a - s, s**2 + s + 1, s),)), TransferFunctionMatrix(((TransferFunction(p + s),), (TransferFunction(-a + p, 9*s - 9, s),), (TransferFunction(-3, s + 2, s),)))), TransferFunctionMatrix(((TransferFunction(-a - s, s**2 + s + 1, s),), (TransferFunction(-p**4 + 3*p - 2, p + s, s),), (TransferFunction(-3, s + 2, s),)))))
```

```python
>>> pprint(_, use_unicode=False)
[ -a - s ] [ -3 ]
```

(continues on next page)
\[
\begin{bmatrix}
\frac{-3}{s + 2} & \frac{3}{s + s + 1} & \frac{4}{s + 2} \\
\frac{4}{p + 3p - 2} & \frac{a - p}{s + s + 1} & \frac{-3}{s + 2}
\end{bmatrix}
\times
\begin{bmatrix}
\frac{-p^4 + 3p - 2}{p + s} & \frac{a - p}{9s - 9} & \frac{-3}{s + 2} \\
\frac{-a - s}{s^2 + s + 1} & \frac{-a + p}{9s - 9} & \frac{3}{s + 2}
\end{bmatrix}
\times
\begin{bmatrix}
\frac{p + 3p - 2}{s + 2} & \frac{a - p}{s + s + 1} & \frac{-3}{s + 2}
\end{bmatrix}
\]
These unevaluated Series or Parallel objects can convert into the resultant transfer function matrix using .doit() method or by .rewrite(TransferFunctionMatrix).

See also:

TransferFunction (page 1963), MIMOSeries (page 1994), MIMOParallel (page 1997), Feedback (page 1978)

elem_poles()
Returns the poles of each element of the TransferFunctionMatrix.

**Note:** Actual poles of a MIMO system are NOT the poles of individual elements.

**Examples**

```python
>>> from sympy import s
>>> from sympy.physics.control.lti import TransferFunction, TransferFunctionMatrix
>>> tf_1 = TransferFunction(3, (s + 1), s)
>>> tf_2 = TransferFunction(s + 6, (s + 1)*(s + 2), s)
>>> tf_3 = TransferFunction(s + 3, s**2 + 3*s + 2, s)
>>> tf_4 = TransferFunction(s + 2, s**2 + 5*s - 10, s)
>>> tfm_1 = TransferFunctionMatrix([[tf_1, tf_2], [tf_3, tf_4]])
>>> tfm_1
TransferFunctionMatrix(((TransferFunction(3, s + 1, s), TransferFunction(s + 6, (s + 1)*(s + 2), s)), (TransferFunction(s + 3, s**2 + 3*s + 2, s), TransferFunction(s + 2, s**2 + 5*s - 10, s))))
>>> tfm_1.poles()
[[[-1], [-2, -1]], [[-2, -1], [-5/2 + sqrt(65)/2, -sqrt(65)/2 - 5/2]]]

See also:

elem_zeros (page 1991)

elem_zeros()

Returns the zeros of each element of the TransferFunctionMatrix.

**Note:** Actual zeros of a MIMO system are NOT the zeros of individual elements.

**Examples**

```python
>>> from sympy import s
>>> from sympy.physics.control.lti import TransferFunction, TransferFunctionMatrix
>>> tf_1 = TransferFunction(3, (s + 1), s)
>>> tf_2 = TransferFunction(s + 6, (s + 1)*(s + 2), s)
>>> tf_3 = TransferFunction(s + 3, s**2 + 3*s + 2, s)
>>> tf_4 = TransferFunction(s**2 - 9*s + 20, s**2 + 5*s - 10, s)
>>> tfm_1 = TransferFunctionMatrix([[tf_1, tf_2], [tf_3, tf_4]])
>>> tfm_1
TransferFunctionMatrix(((TransferFunction(3, s + 1, s), TransferFunction(s + 6, (s + 1)*(s + 2), s)), (TransferFunction(s + 3, s**2 + 3*s + 2, s), TransferFunction(s**2 - 9*s + 20, s**2 + 5*s - 10, s))))
>>> tfm_1.zeros()
[[[], [-6]], [[-3], [4, 5]]]
```
**See also:**

*elem_poles (page 1990)*

**expand(****hints***)
Expands the transfer function matrix

**classmethod from_Matrix(matrix, var)**
Creates a new `TransferFunctionMatrix` efficiently from a SymPy Matrix of Expr objects.

**Parameters**

- **matrix**: `ImmutableMatrix` having `Expr/Number` elements.
- **var**: `Symbol`

Complex variable of the Laplace transform which will be used by the all the `TransferFunction` objects in the `TransferFunctionMatrix`.

**Examples**

```python
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunctionMatrix
>>> from sympy import Matrix, pprint

>>> M = Matrix([[s, 1/s], [1/(s+1), s]])
>>> M_tf = TransferFunctionMatrix.from_Matrix(M, s)
>>> pprint(M_tf, use_unicode=False)
\[
\begin{bmatrix}
  s & 1 \\
  - & - \\
  1 & s \\
  - & - \\
  [s + 1] & 1 \\
\end{bmatrix}
\]

>>> M_tf.elem_poles()
[[[]], [[0]]]
>>> M_tf.elem_zeros()
[[[0], []], [[]], [[], [0]]]
```

**property num_inputs**

Returns the number of inputs of the system.

**Examples**

```python
>>> from sympy.abc import s, p
>>> from sympy.physics.control.lti import TransferFunction, TransferFunctionMatrix

>>> G1 = TransferFunction(s + 3, s**2 - 3, s)
>>> G2 = TransferFunction(4, s**2, s)
>>> G3 = TransferFunction(p**2 + s**2, p - 3, s)
>>> tfm_1 = TransferFunctionMatrix([[G2, -G1, G3], [-G2, -G1, -G3]])
>>> tfm_1.num_inputs
3
```
See also:

num_outputs (page 1993)

**property num_outputs**

Returns the number of outputs of the system.

**Examples**

```python
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunctionMatrix
>>> from sympy import Matrix

>>> M_1 = Matrix([[s], [1/s]])
>>> TFM = TransferFunctionMatrix.from_Matrix(M_1, s)
>>> print(TFM)
TransferFunctionMatrix(((TransferFunction(s, 1, s),),
                          (TransferFunction(1, s, s),)))
>>> TFM.num_outputs
2
```

See also:

num_inputs (page 1992)

**property shape**

Returns the shape of the transfer function matrix, that is, (# of outputs, # of inputs).

**Examples**

```python
>>> from sympy.abc import s, p
>>> from sympy.physics.control.lti import TransferFunction, TransferFunctionMatrix

>>> tf1 = TransferFunction(p**2 - 1, s**4 + s**3 - p, p)
>>> tf2 = TransferFunction(1 - p, p**2 - 3*p + 7, p)
>>> tf3 = TransferFunction(3, 4, p)
>>> tfm1 = TransferFunctionMatrix([[tf1, -tf2]])
>>> tfm1.shape
(1, 2)
>>> tfm2 = TransferFunctionMatrix([[-tf2, tf3], [tf1, -tf1]])
>>> tfm2.shape
(2, 2)
```

**transpose()**

Returns the transpose of the TransferFunctionMatrix (switched input and output layers).

**property var**

Returns the complex variable used by all the transfer functions or Series/Parallel objects in a transfer function matrix.

5.8. Topics 1993
Examples

```python
>>> from sympy import p, s
>>> from sympy.physics.control.lti import TransferFunction,
                   TransferFunctionMatrix, Series, Parallel
>>> G1 = TransferFunction(p**2 + 2*p + 4, p - 6, p)
>>> G2 = TransferFunction(p, 4 - p, p)
>>> G3 = TransferFunction(0, p**4 - 1, p)
>>> G4 = TransferFunction(s + 1, s**2 + s + 1, s)
>>> S1 = Series(G1, G2)
>>> S2 = Series(-G3, Parallel(G2, -G1))
>>> tfm1 = TransferFunctionMatrix([[G1], [G2], [G3]])
>>> tfm1.var
p
>>> tfm2 = TransferFunctionMatrix([[-S1, -S2], [S1, S2]])
>>> tfm2.var
p
>>> tfm3 = TransferFunctionMatrix([[G4]])
>>> tfm3.var
s
```

class sympy.physics.control.lti.MIMOSeries(*args, evaluate=False)

A class for representing a series configuration of MIMO systems.

**Parameters**

args: MIMOLinearTimeInvariant

MIMO systems in a series configuration.

evaluate : Boolean, Keyword

When passed True, returns the equivalent MIMOSeries(*args).
doit(). Set to False by default.

**Raises**

ValueError

When no argument is passed.

var attribute is not same for every system.

num_outputs of the MIMO system is not equal to the num_inputs of its adjacent MIMO system. (Matrix multiplication constraint, basically)

TypeError

Any of the passed *args has unsupported type

A combination of SISO and MIMO systems is passed. There should be homogeneity in the type of systems passed, MIMO in this case.
Examples

```python
>>> from sympy.physics.control.lti import MIMOSeries,
    TransferFunctionMatrix
>>> from sympy import Matrix, pprint

mat_a = Matrix([[5*s], [5]]) # 2 Outputs 1 Input
mat_b = Matrix([[5, 1/(6*s**2)]]) # 1 Output 2 Inputs
mat_c = Matrix([[1, s], [5/s, 1]]) # 2 Outputs 2 Inputs

from sympy import s

>>> tfm_a = TransferFunctionMatrix.from_Matrix(mat_a, s)
>>> tfm_b = TransferFunctionMatrix.from_Matrix(mat_b, s)
>>> tfm_c = TransferFunctionMatrix.from_Matrix(mat_c, s)

>>> MIMOSeries(tfm_c, tfm_b, tfm_a)
MIMOSeries(TransferFunctionMatrix(((TransferFunction(1, 1, s),
    TransferFunction(s, 1, s)), (TransferFunction(5, s, s),
    TransferFunction(1, 1, s)))),
    TransferFunctionMatrix(((TransferFunction(5, 1, s), TransferFunction(1,
    6*s**2, s)),), TransferFunctionMatrix(((TransferFunction(5*s, 1, s),
    ...), (TransferFunction(5, 1, s),))))

>>> pprint(_, use_unicode=False) # For Better Visualization
\[
\begin{aligned}
[5*s] &

\]
[150*s + 25] &
[150*s + 5] &
\begin{array}{c}
3 \\
2
\end{array}
\]
[6 s] &
[6 s] \{t\}
\]
```

5.8. Topics 1995
Notes

All the transfer function matrices should use the same complex variable \texttt{var} of the Laplace transform.

\texttt{MIMOSeries(A, B)} is not equivalent to \texttt{A*B}. It is always in the reverse order, that is \texttt{B*A}.

See also:

\texttt{Series} (page 1971), \texttt{MIMOParallel} (page 1997)

\texttt{doit(cancel=False, **kwargs)}

Returns the resultant transfer function matrix obtained after evaluating the MIMO systems arranged in a series configuration.

Examples

```python
>>> from sympy.abc import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction, MIMOSeries, TransferFunctionMatrix
>>> tf1 = TransferFunction(a*p**2 + b*s, s - p, s)
>>> tf2 = TransferFunction(s**3 - 2, s**4 + 5*s + 6, s)
>>> tfm1 = TransferFunctionMatrix([[tf1, tf2], [tf2, tf2]])
>>> tfm2 = TransferFunctionMatrix([[tf2, tf1], [tf1, tf1]])
>>> MIMOSeries(tfm2, tfm1).doit()

\begin{verbatim}
TransferFunctionMatrix(((TransferFunction(2*(-p + s)*(s**3 - 2)*(a*p**2 + b*s)*(s**4 + 5*s + 6), (-p + s)**2*(s**4 + 5*s + 6)**2, s), TransferFunction((-p + s)**2*(s**3 - 2)*(a*p**2 + b*s) + (-p + s)**3*(s**4 + 5*s + 6), (-p + s)**3*(s**4 + 5*s + 6)**2, s)), (TransferFunction((-p + s)*(s**3 - 2)**2*(s**4 + 5*s + 6) + (-s)**3*(s**4 + 5*s + 6)**2, (-p + s)**3*(s**4 + 5*s + 6), (-p + s)**3*(s**4 + 5*s + 6))
\end{verbatim}
```

\texttt{property num_inputs}

Returns the number of input signals of the series system.

\texttt{property num_outputs}

Returns the number of output signals of the series system.

\texttt{property shape}

Returns the shape of the equivalent MIMO system.

\texttt{property var}

Returns the complex variable used by all the transfer functions.
Examples

```python
>>> from sympy import p
>>> from sympy.physics.control.lti import TransferFunction, MIMOSeries, TransferFunctionMatrix
>>> G1 = TransferFunction(p**2 + 2*p + 4, p - 6, p)
>>> G2 = TransferFunction(p, 4 - p, p)
>>> G3 = TransferFunction(0, p**2 - 1, p)
>>> tfm_1 = TransferFunctionMatrix([[G1, G2, G3]])
>>> tfm_2 = TransferFunctionMatrix([[G1], [G2], [G3]])
>>> MIMOSeries(tfm_2, tfm_1).var
```

class sympy.physics.control.lti.MIMOParallel(*args, evaluate=False)
A class for representing a parallel configuration of MIMO systems.

Parameters

**args** : MIMOLinearTimeInvariant
MIMO Systems in a parallel arrangement.

**evaluate** : Boolean, Keyword
When passed True, returns the equivalent MIMOParallel(*args). doit(). Set to False by default.

Raises

**ValueError**
When no argument is passed.
var attribute is not same for every system.
All MIMO systems passed do not have same shape.

**TypeError**
Any of the passed *args has unsupported type
A combination of SISO and MIMO systems is passed. There should be homogeneity in the type of systems passed, MIMO in this case.

Examples

```python
>>> from sympy import s
>>> from sympy.physics.control.lti import TransferFunctionMatrix, MIMOParallel
>>> from sympy import Matrix, pprint
>>> expr_1 = 1/s
>>> expr_2 = s/(s**2-1)
>>> expr_3 = (2 + s)/(s**2 - 1)
>>> expr_4 = 5
>>> tfm_a = TransferFunctionMatrix.from_Matrix(Matrix([[expr_1, expr_2], [expr_3, expr_4]]), s)
>>> tfm_b = TransferFunctionMatrix.from_Matrix(Matrix([[expr_2, expr_1], [expr_4, expr_3]]), s)
>>> tfm_c = TransferFunctionMatrix.from_Matrix(Matrix([[expr_3, expr_4], [expr_1, expr_2]]), s)
```
(continues on next page)
All the transfer function matrices should use the same complex variable \( \text{var} \) of the Laplace transform.

See also:

Parallel (page 1975), MIMOSeries (page 1994)

doit(**hints)

Returns the resultant transfer function matrix obtained after evaluating the MIMO systems arranged in a parallel configuration.
Examples

```python
>>> from sympy import s, p, a, b
>>> from sympy.physics.control.lti import TransferFunction, MIMOParallel, TransferFunctionMatrix
>>> tf1 = TransferFunction(a*p**2 + b*s, s - p, s)
>>> tf2 = TransferFunction(s**3 - 2, s**4 + 5*s + 6, s)
>>> tfm_1 = TransferFunctionMatrix([[tf1, tf2], [tf2, tf1]])
>>> tfm_2 = TransferFunctionMatrix([[tf2, tf1], [tf1, tf2]])
>>> MIMOParallel(tfm_1, tfm_2).doit()
```

```python
property num_inputs
Returns the number of input signals of the parallel system.

property num_outputs
Returns the number of output signals of the parallel system.

property shape
Returns the shape of the equivalent MIMO system.

property var
Returns the complex variable used by all the systems.
```

Examples

```python
>>> from sympy import p
>>> from sympy.physics.control.lti import TransferFunction, MIMOParallel
>>> G1 = TransferFunction(p**2 + 2*p + 4, p - 6, p)
>>> G2 = TransferFunction(p, 4 - p, p)
>>> G3 = TransferFunction(0, p**4 - 1, p)
>>> G4 = TransferFunction(p**2, p**2 - 1, p)
>>> tfm_a = TransferFunctionMatrix([[G1, G2], [G3, G4]])
>>> tfm_b = TransferFunctionMatrix([[G2, G1], [G4, G3]])
>>> MIMOParallel(tfm_a, tfm_b).var
```

class sympy.physics.control.lti.MIMOFeedback(sys1, sys2, sign=-1)
A class for representing closed-loop feedback interconnection between two MIMO input/output systems.

Parameters

- **sys1**: MIMOSeries, TransferFunctionMatrix
  The MIMO system placed on the feedforward path.
- **sys2**: MIMOSeries, TransferFunctionMatrix
```
The system placed on the feedback path (often a feedback controller).

**sign** : int, optional

The sign of feedback. Can either be 1 (for positive feedback) or -1 (for negative feedback). Default value is -1.

**Raises**

**ValueError**

When `sys1` and `sys2` are not using the same complex variable of the Laplace transform.

Forward path model should have an equal number of inputs/outputs to the feedback path outputs/inputs.

When product of `sys1` and `sys2` is not a square matrix.

When the equivalent MIMO system is not invertible.

**TypeError**

When either `sys1` or `sys2` is not a MIMOSeries or a TransferFunctionMatrix object.

**Examples**

```python
>>> from sympy import Matrix, pprint
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunctionMatrix,
>>> MIMOFeedback
>>> plant_mat = Matrix([[1, 1/s], [0, 1]])
>>> controller_mat = Matrix([[10, 0], [0, 10]])  # Constant Gain
>>> plant = TransferFunctionMatrix.from_Matrix(plant_mat, s)
>>> controller = TransferFunctionMatrix.from_Matrix(controller_mat, s)
>>> feedback = MIMOFeedback(plant, controller)  # Negative Feedback
>>> (default)
>>> pprint(feedback, use_unicode=False)
/  [1 1]  [10 0 ] \-1 [1 1]  \\
| [- -]  [- - ] | [- -]  |
| [1 s] [1 1 ] | [1 s]  |
|I + [ ] *[ ] | *[ ]  |
| [0 1 ] [0 10] | [0 1 ]  |
| [- -]  [- -- ] | [- -]  |
\ [1 1]{t} [1 1 ]{t}/ [1 1]{t}
```

To get the equivalent system matrix, use either `doit` or `rewrite` method.

```python
>>> pprint(feedback.doit(), use_unicode=False)
[1  1 ]
[-- ------]
[11 121*s]
[ ]
[0  1 ]
[- -- ]
[1 11 ]{t}
```
To negate the MIMOFeedback object, use `-` operator.

```python
>>> neg_feedback = -feedback
```

```python
>>> pprint(neg_feedback.doit(), use_unicode=False)
[-1 -1 ]
[---- ----]  
[ 1 121*s]  
[ 0 -1 ]
[ - ---- ]  
[ 1 11 ]
```

See also:

- `Feedback` (page 1978)
- `MIMOSeries` (page 1994)
- `MIMOParallel` (page 1997)

`doit(cancel=True, expand=False, **hints)`

Returns the resultant transfer function matrix obtained by the feedback interconnection.

**Examples**

```python
>>> from sympy import pprint
>>> from sympy.abc import s

>>> from sympy.physics.control.lti import TransferFunction, TransferFunctionMatrix, MIMOFeedback

>>> tf1 = TransferFunction(s, 1 - s, s)
>>> tf2 = TransferFunction(1, s, s)
>>> tf3 = TransferFunction(5, 1, s)
>>> tf4 = TransferFunction(s - 1, s, s)
>>> tf5 = TransferFunction(0, 1, s)

>>> sys1 = TransferFunctionMatrix([[tf1, tf2], [tf3, tf4]])
>>> sys2 = TransferFunctionMatrix([[tf3, tf5], [tf5, tf5]])

>>> F_1 = MIMOFeedback(sys1, sys2, 1)

>>> pprint(F_1, use_unicode=False)
/ [ s 1 ] [5 0] \-1 [ s 1 ]
| [----- -] [1 1] | [----- -]  
| [1 - s s ] [1 1] | [1 - s s ]  
| I - [ ] *[ ] | *[ ]
| [ 5 s - 1] [0 0] | [ 5 s - 1]
| [ - -----] [ - ] | [ - -----]
\ [ 1 s ]

>>> pprint(F_1.doit(), use_unicode=False)
[ -s s - 1 ]
[-------- ------------ ]
[6*s - 1 s*(6*s - 1) ]
[ [5*s - 5 (s - 1)*(6*s + 24)]
[-------- ------------ ]
[6*s - 1 s*(6*s - 1) ]
```

If the user wants the resultant `TransferFunctionMatrix` object without canceling the common factors then the `cancel` kwarg should be passed `False`.

5.8. Topics 2001
If the user wants the expanded form of the resultant transfer function matrix, the `expand` kwarg should be passed as `True`.

```python
>>> pprint(F_1.doit(expand=True), use_unicode=False)
[    -s  s - 1 ]
[------- -------- ]
[6*s - 1 2    ]
[            ]
[            ]
[6*s - s    ]
[            ]
[2           ]
[            ]
[5*s - 5 6*s + 18*s - 24]
[------- -------- ]
[6*s - 1 2    ]
[            ]
[            ]
[ 6*s - s    ]{t}
```

**property sensitivity**

Returns the sensitivity function matrix of the feedback loop.

Sensitivity of a closed-loop system is the ratio of change in the open loop gain to the change in the closed loop gain.

**Note:** This method would not return the complementary sensitivity function.

**Examples**

```python
>>> from sympy import pprint
>>> from sympy.abc import p
>>> from sympy.physics.control.lti import TransferFunction,
... TransferFunctionMatrix, MIMOFeedback
>>> tf1 = TransferFunction(p, 1 - p, p)
>>> tf2 = TransferFunction(1, p, p)
>>> tf3 = TransferFunction(1, 1, p)
```
```python
>> sys1 = TransferFunctionMatrix([[tf1, tf2], [tf2, tf1]])
>> sys2 = TransferFunctionMatrix([[tf1, tf3], [tf3, tf2]])
>> F_1 = MIMOFeedback(sys1, sys2, 1)  # Positive feedback
>> F_2 = MIMOFeedback(sys1, sys2)    # Negative feedback
>> pprint(F_1.sensitivity, use_unicode=False)
[ 4 3 2 5 4 2 ]
[- p + 3*p - 4*p + 3*p - 1 p - 2*p + 3*p - 3*p + 1 ]
[-------------------- -----------------------------]
[ 4 3 2 5 4 3 2 ]
[ p + 3*p - 8*p + 8*p - 3 p + 3*p - 8*p + 8*p - 3*p ]
[-------------------- ]
[ 4 3 2 3 2 ]
[ p - p - p + p 3*p - 6*p + 4*p - 1 ]
[-------------------------- ]
[ 4 3 2 4 3 2 ]
[ p + 3*p - 8*p + 8*p - 3 p + 3*p - 8*p + 8*p - 3 ]
```
property sys2

Returns the feedback controller of the MIMO feedback interconnection.

Examples

```python
>>> from sympy import pprint
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunction, TransferFunctionMatrix, MIMOFeedback
>>> tf1 = TransferFunction(s**2, s**3 - s + 1, s)
>>> tf2 = TransferFunction(1, s, s)
>>> tf3 = TransferFunction(1, 1, s)
>>> sys1 = TransferFunctionMatrix([[tf1, tf2], [tf2, tf1]])
>>> sys2 = TransferFunctionMatrix([[tf1, tf3], [tf3, tf2]])
>>> F_1 = MIMOFeedback(sys1, sys2)
>>> F_1.sys2
TransferFunctionMatrix((TransferFunction(s**2, s**3 - s + 1, s), TransferFunction(1, 1, s)), (TransferFunction(1, 1, s), TransferFunction(1, s, s)))
```

property var

Returns the complex variable of the Laplace transform used by all the transfer functions involved in the MIMO feedback loop.
Examples

```python
>>> from sympy.abc import p
>>> from sympy.physics.control.lti import TransferFunction,
    TransferFunctionMatrix, MIMOFeedback
>>> tf1 = TransferFunction(p, 1 - p, p)
>>> tf2 = TransferFunction(1, p, p)
>>> tf3 = TransferFunction(1, 1, p)
>>> sys1 = TransferFunctionMatrix([[tf1, tf2], [tf2, tf1]])
>>> sys2 = TransferFunctionMatrix([[tf1, tf3], [tf3, tf2]])
>>> F_1 = MIMOFeedback(sys1, sys2, 1)  # Positive feedback
```

`sympy.physics.control.lti.bilinear(tf, sample_per)`

Returns falling coefficients of H(z) from numerator and denominator. Where H(z) is the corresponding discretized transfer function, discretized with the bilinear transform method. H(z) is obtained from the continuous transfer function H(s) by substituting s(z) = 2/T * (z-1)/(z+1) into H(s), where T is the sample period. Coefficients are falling, i.e. H(z) = (az+b)/(cz+d) is returned as [a, b], [c, d].

Examples

```python
>>> from sympy.physics.control.lti import TransferFunction, bilinear
>>> from sympy.abc import s, L, R, T
>>> tf = TransferFunction(1, s*L + R, s)
>>> numZ, denZ = bilinear(tf, T)
>>> numZ
[T, T]
>>> denZ
```

`sympy.physics.control.lti.backward_diff(tf, sample_per)`

Returns falling coefficients of H(z) from numerator and denominator. Where H(z) is the corresponding discretized transfer function, discretized with the backward difference transform method. H(z) is obtained from the continuous transfer function H(s) by substituting s(z) = (z-1)/(T*z) into H(s), where T is the sample period. Coefficients are falling, i.e. H(z) = (az+b)/(cz+d) is returned as [a, b], [c, d].

Examples

```python
>>> from sympy.physics.control.lti import TransferFunction, backward_diff
>>> from sympy.abc import s, L, R, T
>>> tf = TransferFunction(1, s*L + R, s)
>>> numZ, denZ = backward_diff(tf, T)
>>> numZ
[T, 0]
>>> denZ
[L + R*T, -L]
```
Control System Plots

This module contains plotting functions for some of the common plots used in control system. Matplotlib will be required as an external dependency if the user wants the plots. To get only the numerical data of the plots, NumPy will be required as external dependency.

Pole-Zero Plot

control_plots.pole_zero_plot(pole_color='blue', pole_markersize=10, zero_color='orange', zero_markersize=7, grid=True, show_axes=True, show=True, **kwargs)

Returns the Pole-Zero plot (also known as PZ Plot or PZ Map) of a system.

A Pole-Zero plot is a graphical representation of a system’s poles and zeros. It is plotted on a complex plane, with circular markers representing the system’s zeros and ‘x’ shaped markers representing the system’s poles.

Parameters

- system : SISOLinearTimelInvariant type systems
  The system for which the pole-zero plot is to be computed.
- pole_color : str, tuple, optional
  The color of the pole points on the plot. Default color is blue. The color can be provided as a matplotlib color string, or a 3-tuple of floats each in the 0-1 range.
- pole_markersize : Number, optional
  The size of the markers used to mark the poles in the plot. Default pole markersize is 10.
- zero_color : str, tuple, optional
  The color of the zero points on the plot. Default color is orange. The color can be provided as a matplotlib color string, or a 3-tuple of floats each in the 0-1 range.
- zero_markersize : Number, optional
  The size of the markers used to mark the zeros in the plot. Default zero markersize is 7.
- grid : boolean, optional
  If True, the plot will have a grid. Defaults to True.
- show_axes : boolean, optional
  If True, the coordinate axes will be shown. Defaults to False.
- show : boolean, optional
  If True, the plot will be displayed otherwise the equivalent matplotlib plot object will be returned. Defaults to True.
Examples

```python
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunction
>>> from sympy.physics.control.control_plots import pole_zero_plot
>>> tf1 = TransferFunction(s**2 + 1, s**4 + 4*s**3 + 6*s**2 + 5*s + 2, s)
>>> pole_zero_plot(tf1)
```

Poles and Zeros of \( \frac{s^2 + 1}{s^4 + 4s^3 + 6s^2 + 5s + 2} \)

See also:

`pole_zero_numerical_data` (page 2007)

References

[R671]

control_plots.pole_zero_numerical_data()

Returns the numerical data of poles and zeros of the system. It is internally used by pole_zero_plot to get the data for plotting poles and zeros. Users can use this data to further analyse the dynamics of the system or plot using a different backend/plotting-module.

**Parameters**

- `system`: SISOLinearTimeInvariant
The system for which the pole-zero data is to be computed.

**Returns**

tuple : (zeros, poles)

** Raises **

NotImplementedError

   When a SISO LTI system is not passed.
   When time delay terms are present in the system.

ValueError

   When more than one free symbol is present in the system. The only variable in the transfer function should be the variable of the Laplace transform.

**Examples**

```python
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunction
>>> from sympy.physics.control.control_plots import pole_zero_numerical_data
>>> tf1 = TransferFunction(s**2 + 1, s**4 + 4*s**3 + 6*s**2 + 5*s + 2, s)
>>> pole_zero_numerical_data(tf1)
([-0.+1.j 0.-1.j], [-2. +0.j -0.5+0.8660254j -0.5-0.8660254j -1. +0.j])
```

**See also:**

pole_zero_plot (page 206)

**Bode Plot**

control_plots.bode_plot(initial_exp=-5, final_exp=5, grid=True, show_axes=False, show=True, freq_unit='rad/sec', phase_unit='rad', **kwargs)

Returns the Bode phase and magnitude plots of a continuous-time system.

**Parameters**

- **system** : SISOLinearTimelInvariant type
  The LTI SISO system for which the Bode Plot is to be computed.

- **initial_exp** : Number, optional
  The initial exponent of 10 of the semilog plot. Defaults to -5.

- **final_exp** : Number, optional
  The final exponent of 10 of the semilog plot. Defaults to 5.

- **show** : boolean, optional
  If True, the plot will be displayed otherwise the equivalent matplotlib plot object will be returned. Defaults to True.
**Examples**

```python
>>> from sympy import s
>>> from sympy.physics.control.lti import TransferFunction
>>> from sympy.physics.control.control_plots import bode_plot
>>> tf1 = TransferFunction(1*s**2 + 0.1*s + 7.5, 1*s**4 + 0.12*s**3 + 9*s**2, s)
>>> bode_plot(tf1, initial_exp=0.2, final_exp=0.7)
```

See also:

- `bode_magnitude_plot` (page 2009), `bode_phase_plot` (page 2009)
- `control_plots.bode_magnitude_plot(initial_exp=-5, final_exp=5, color='b',
  show_axes=False, grid=True, show=True,
  freq_unit='rad/sec', **kwargs)`

  Returns the Bode magnitude plot of a continuous-time system.

  See `bode_plot` for all the parameters.

- `control_plots.bode_phase_plot(initial_exp=-5, final_exp=5, color='b', show_axes=False,
  grid=True, show=True, freq_unit='rad/sec',
  phase_unit='rad', **kwargs)`

  Returns the Bode phase plot of a continuous-time system.

  See `bode_plot` for all the parameters.

- `control_plots.bode_magnitude_numerical_data(initial_exp=-5, final_exp=5,
  freq_unit='rad/sec', **kwargs)`

  Returns the numerical data of the Bode magnitude plot of the system. It is internally
  used by `bode_magnitude_plot` to get the data for plotting Bode magnitude plot. Users
  can use this data to further analyse the dynamics of the system or plot using a different
  backend/plotting-module.

**Parameters**

- **system** : SISOLinearTimeInvariant
Bode Plot of \( \frac{s^2 + 0.1s + 7.5}{s^4 + 0.12s^3 + 9s^2} \)
The system for which the data is to be computed.

**initial_exp** : Number, optional
The initial exponent of 10 of the semilog plot. Defaults to -5.

**final_exp** : Number, optional
The final exponent of 10 of the semilog plot. Defaults to 5.

**freq_unit** : string, optional
User can choose between 'rad/sec' (radians/second) and 'Hz' (Hertz) as frequency units.

**Returns**

**tuple** : (x, y)

x = x-axis values of the Bode magnitude plot. y = y-axis values of the Bode magnitude plot.

**Raises**

NotImplementedError
When a SISO LTI system is not passed.
When time delay terms are present in the system.

ValueError
When more than one free symbol is present in the system. The only variable in the transfer function should be the variable of the Laplace transform.
When incorrect frequency units are given as input.

**Examples**

```python
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunction
>>> from sympy.physics.control.control_plots import bode_magnitude_numerical_data
>>> tf1 = TransferFunction(s**2 + 1, s**4 + 4*s**3 + 6*s**2 + 5*s + 2, s)
>>> bode_magnitude_numerical_data(tf1)
([[1e-05, 1.5148378120533502e-05,..., 68437.36188804005, 100000.0],
  [-6.020599914256786, -6.0205999155219505,..., -193.4117304087953, -200.00000000000000260573]]
```

See also:

- `bode_magnitude_plot` (page 2009), `bode_phase_numerical_data` (page 211)

control_plots.bode_phase_numerical_data(initial_exp=-5, final_exp=5,
freq_unit='rad/sec', phase_unit='rad',
**kwargs)

Returns the numerical data of the Bode phase plot of the system. It is internally used by bode_phase_plot to get the data for plotting Bode phase plot. Users can use this data to further analyse the dynamics of the system or plot using a different backend/plotting-module.
Parameters

- **system**: SISOLinearTimeInvariant
  The system for which the Bode phase plot data is to be computed.
- **initial_exp**: Number, optional
  The initial exponent of 10 of the semilog plot. Defaults to -5.
- **final_exp**: Number, optional
  The final exponent of 10 of the semilog plot. Defaults to 5.
- **freq_unit**: string, optional
  User can choose between 'rad/sec' (radians/second) and 'Hz' (Hertz) as frequency units.
- **phase_unit**: string, optional
  User can choose between 'rad' (radians) and 'deg' (degree) as phase units.

Returns

- **tuple**: (x, y)
  x = x-axis values of the Bode phase plot. y = y-axis values of the Bode phase plot.

Raises

- **NotImplementedError**
  When a SISO LTI system is not passed.
  When time delay terms are present in the system.
- **ValueError**
  When more than one free symbol is present in the system. The only variable in the transfer function should be the variable of the Laplace transform.
  When incorrect frequency or phase units are given as input.

Examples

```python
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunction
>>> from sympy.physics.control.control_plots import bode_phase_numerical_data
>>> tf1 = TransferFunction(s**2 + 1, s**4 + 4*s**3 + 6*s**2 + 5*s + 2, s)
>>> bode_phase_numerical_data(tf1)
([1e-05, 1.4472354033813751e-05, 2.035581932165858e-05,..., 47577.
 →3248186011, 67884.09326036123, 100000.0],
[-2.5000000000291665e-05, -3.6180885085e-05, -5.08895483066e-05,...,-3.
 →1415085799262523, -3.14155265358979])
```

Impulse-Response Plot

control_plots.impulse_response_plot(color='b', prec=8, lower_limit=0, upper_limit=10, show_axes=False, grid=True, show=True, **kwargs)

Returns the unit impulse response (Input is the Dirac-Delta Function) of a continuous-time system.

Parameters

- `system`: SISOLinearTimeInvariant type
  The LTI SISO system for which the Impulse Response is to be computed.
- `color`: str, tuple, optional
  The color of the line. Default is Blue.
- `show`: boolean, optional
  If True, the plot will be displayed otherwise the equivalent matplotlib plot object will be returned. Defaults to True.
- `lower_limit`: Number, optional
  The lower limit of the plot range. Defaults to 0.
- `upper_limit`: Number, optional
  The upper limit of the plot range. Defaults to 10.
- `prec`: int, optional
  The decimal point precision for the point coordinate values. Defaults to 8.
- `show_axes`: boolean, optional
  If True, the coordinate axes will be shown. Defaults to False.
- `grid`: boolean, optional
  If True, the plot will have a grid. Defaults to True.

Examples

```python
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunction
>>> from sympy.physics.control.control_plots import impulse_response_plot
>>> tf1 = TransferFunction(8*s**2 + 18*s + 32, s**3 + 6*s**2 + 14*s + 24, s)
>>> impulse_response_plot(tf1)
```

See also:

`step_response_plot` (page 2016), `ramp_response_plot` (page 2019)
Impulse Response of \( \frac{8s^2 + 18s + 32}{s^3 + 6s^2 + 14s + 24} \)
control_plots.impulse_response_numerical_data(prec=8, lower_limit=0, upper_limit=10, **kwargs)

Returns the numerical values of the points in the impulse response plot of a SISO continuous-time system. By default, adaptive sampling is used. If the user wants to instead get an uniformly sampled response, then adaptive kwarg should be passed False and nb_of_points must be passed as additional kwargs. Refer to the parameters of class sympy.plotting.plot.LineOver1DRangeSeries (page 2950) for more details.

Parameters

- **system**: SISOLinearTimeInvariant
  - The system for which the impulse response data is to be computed.
- **prec**: int, optional
  - The decimal point precision for the point coordinate values. Defaults to 8.
- **lower_limit**: Number, optional
  - The lower limit of the plot range. Defaults to 0.
- **upper_limit**: Number, optional
  - The upper limit of the plot range. Defaults to 10.
- **kwargs**:
  - Additional keyword arguments are passed to the underlying sympy.plotting.plot.LineOver1DRangeSeries (page 2950) class.

Returns

- **tuple**: (x, y)
  - x = Time-axis values of the points in the impulse response. NumPy array.
  - y = Amplitude-axis values of the points in the impulse response. NumPy array.

Raises

- **NotImplementedError**
  - When a SISO LTI system is not passed.
  - When time delay terms are present in the system.
- **ValueError**
  - When more than one free symbol is present in the system. The only variable in the transfer function should be the variable of the Laplace transform.
  - When lower_limit parameter is less than 0.
Examples

```python
>>> from sympy import s
>>> from sympy.physics.control.lti import TransferFunction
>>> from sympy.physics.control.control_plots import impulse_response_numerical_data
>>> tf1 = TransferFunction(s, s**2 + 5*s + 8, s)
>>> impulse_response_numerical_data(tf1)
([0.0, 0.06616480200395854,... , 9.854500743565858, 10.0],

**Step-Response Plot**

`control_plots.step_response_plot(color='b', prec=8, lower_limit=0, upper_limit=10, show_axes=False, grid=True, show=True, **kwargs)`

Returns the unit step response of a continuous-time system. It is the response of the system when the input signal is a step function.

**Parameters**

- `system` : SISOLinearTimeInvariant type
  The LTI SISO system for which the Step Response is to be computed.
- `color` : str, tuple, optional
  The color of the line. Default is Blue.
- `show` : boolean, optional
  If True, the plot will be displayed otherwise the equivalent matplotlib plot object will be returned. Defaults to True.
- `lower_limit` : Number, optional
  The lower limit of the plot range. Defaults to 0.
- `upper_limit` : Number, optional
  The upper limit of the plot range. Defaults to 10.
- `prec` : int, optional
  The decimal point precision for the point coordinate values. Defaults to 8.
- `show_axes` : boolean, optional
  If True, the coordinate axes will be shown. Defaults to False.
- `grid` : boolean, optional
  If True, the plot will have a grid. Defaults to True.
Examples

```python
from sympy.abc import s
from sympy.physics.control.lti import TransferFunction
from sympy.physics.control.control_plots import step_response_plot

tf1 = TransferFunction(8*s**2 + 18*s + 32, s**3 + 6*s**2 + 14*s + 24, s)
step_response_plot(tf1)
```

References

[R673]

control_plots.step_response_numerical_data(\(prec=8, \text{lower\_limit}=0, \text{upper\_limit}=10, \text{**kwargs}\))

Returns the numerical values of the points in the step response plot of a SISO continuous-time system. By default, adaptive sampling is used. If the user wants to instead get an uniformly sampled response, then adaptive kwarg should be passed False and
nb_of_points must be passed as additional kwargs. Refer to the parameters of class `sympy.plotting.plot.LineOver1DRangeSeries` (page 2950) for more details.

**Parameters**

- **system**: SISOLinearTimeInvariant
  
  The system for which the unit step response data is to be computed.

- **prec**: int, optional
  
  The decimal point precision for the point coordinate values. Defaults to 8.

- **lower_limit**: Number, optional
  
  The lower limit of the plot range. Defaults to 0.

- **upper_limit**: Number, optional
  
  The upper limit of the plot range. Defaults to 10.

- **kwargs**: Additional keyword arguments are passed to the underlying `sympy.plotting.plot.LineOver1DRangeSeries` class.

**Returns**

- **tuple**: (x, y)
  
  x = Time-axis values of the points in the step response. NumPy array.
  
  y = Amplitude-axis values of the points in the step response. NumPy array.

**Raises**

- **NotImplementedError**
  
  When a SISO LTI system is not passed.
  
  When time delay terms are present in the system.

- **ValueError**
  
  When more than one free symbol is present in the system. The only variable in the transfer function should be the variable of the Laplace transform.
  
  When lower_limit parameter is less than 0.

**Examples**

```python
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunction
>>> from sympy.physics.control.control_plots import step_response_numerical_data
>>> tf1 = TransferFunction(s, s**2 + 5*s + 8, s)
>>> step_response_numerical_data(tf1)
([0.0, 0.025413462339411542, 0.0484508722725343, ... , 9.670250533855183, 9.844291913708725, 10.0], [0.0, 0.023844582399907256, 0.042894276802320226, ..., 6.828770759094287e-12, 6.456457160755703e-12])
```

Ramp-Response Plot

control_plots.ramp_response_plot(slope=1, color='b', prec=8, lower_limit=0, upper_limit=10, show_axes=False, grid=True, show=True, **kwargs)

Returns the ramp response of a continuous-time system.

Ramp function is defined as the straight line passing through origin \( f(x) = mx \). The slope of the ramp function can be varied by the user and the default value is 1.

**Parameters**

- **system** : SISOLinearTimeInvariant type
  The LTI SISO system for which the Ramp Response is to be computed.

- **slope** : Number, optional
  The slope of the input ramp function. Defaults to 1.

- **color** : str, tuple, optional
  The color of the line. Default is Blue.

- **show** : boolean, optional
  If True, the plot will be displayed otherwise the equivalent matplotlib plot object will be returned. Defaults to True.

- **lower_limit** : Number, optional
  The lower limit of the plot range. Defaults to 0.

- **upper_limit** : Number, optional
  The upper limit of the plot range. Defaults to 10.

- **prec** : int, optional
  The decimal point precision for the point coordinate values. Defaults to 8.

- **show_axes** : boolean, optional
  If True, the coordinate axes will be shown. Defaults to False.

- **grid** : boolean, optional
  If True, the plot will have a grid. Defaults to True.
Examples

```python
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunction
>>> from sympy.physics.control.control_plots import ramp_response_plot
>>> tf1 = TransferFunction(s, (s+4)*(s+8), s)
>>> ramp_response_plot(tf1, upper_limit=2)
```

Ramp Response of \(\frac{s}{(s+4)(s+8)}\) [Slope = 1]

[R674]

calculus.control_plots.ramp_response_numerical_data(slope=1, prec=8, lower_limit=0, upper_limit=10, **kwargs)

Returns the numerical values of the points in the ramp response plot of a SISO continuous-time system. By default, adaptive sampling is used. If the user wants to instead get an uniformly sampled response, then adaptive kwarg should be passed False and nb_of_points must be passed as additional kwargs. Refer to the parameters of class `sympy.plotting.plot.LineOver1DRangeSeries` (page 2950) for more details.
Parameters

- **system**: SISOLinearTimeInvariant
  The system for which the ramp response data is to be computed.
- **slope**: Number, optional
  The slope of the input ramp function. Defaults to 1.
- **prec**: int, optional
  The decimal point precision for the point coordinate values. Defaults to 8.
- **lower_limit**: Number, optional
  The lower limit of the plot range. Defaults to 0.
- **upper_limit**: Number, optional
  The upper limit of the plot range. Defaults to 10.
- **kwargs**: Additional keyword arguments are passed to the underlying sympy.plotting.plot.LineOver1DRangeSeries (page 2950) class.

Returns

- **tuple**: (x, y)
  x = Time-axis values of the points in the ramp response plot. NumPy array. y = Amplitude-axis values of the points in the ramp response plot. NumPy array.

Raises

- **NotImplementedError**
  When a SISO LTI system is not passed.
  When time delay terms are present in the system.
- **ValueError**
  When more than one free symbol is present in the system. The only variable in the transfer function should be the variable of the Laplace transform.
  When lower_limit parameter is less than 0.
  When slope is negative.

Examples

```python
>>> from sympy.abc import s
>>> from sympy.physics.control.lti import TransferFunction
>>> from sympy.physics.control.control_plots import ramp_response_numerical_data
>>> tf1 = TransferFunction(s, s**2 + 5*s + 8, s)

```
Continuum Mechanics

Abstract

Contains docstrings for methods in continuum mechanics module.

Beam

Beam (Docstrings)

This module can be used to solve 2D beam bending problems with singularity functions in mechanics.

```python
class sympy.physics.continuum_mechanics.beam.Beam(length, elastic_modulus, second_moment, area=A, variable=x, base_char='C')
```

A Beam is a structural element that is capable of withstanding load primarily by resisting against bending. Beams are characterized by their cross sectional profile (Second moment of area), their length and their material.

**Note:** A consistent sign convention must be used while solving a beam bending problem; the results will automatically follow the chosen sign convention. However, the chosen sign convention must respect the rule that, on the positive side of beam’s axis (in respect to current section), a loading force giving positive shear yields a negative moment, as below (the curved arrow shows the positive moment and rotation):
Examples

There is a beam of length 4 meters. A constant distributed load of 6 N/m is applied from half of the beam till the end. There are two simple supports below the beam, one at the starting point and another at the ending point of the beam. The deflection of the beam at the end is restricted.

Using the sign convention of downwards forces being positive.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols, Piecewise

>>> E, I = symbols('E, I')
>>> R1, R2 = symbols('R1, R2')

>>> b = Beam(4, E, I)

>>> b.apply_load(R1, 0, -1)
>>> b.apply_load(6, 2, 0)
>>> b.apply_load(R2, 4, -1)

>>> b.bc_deflection = [(0, 0), (4, 0)]

>>> b.boundary_conditions
{'deflection': [(0, 0), (4, 0)], 'slope': []}

>>> b.load
R1*SingularityFunction(x, 0, -1) + R2*SingularityFunction(x, 4, -1) +
   6*SingularityFunction(x, 2, 0)

>>> b.solve_for_reaction_loads(R1, R2)
```
Calculate the support reactions for a fully symbolic beam of length \( L \). There are two simple supports below the beam, one at the starting point and another at the ending point of the beam. The deflection of the beam at the end is restricted. The beam is loaded with:

- a downward point load \( P_1 \) applied at \( L/4 \)
- an upward point load \( P_2 \) applied at \( L/8 \)
- a counterclockwise moment \( M_1 \) applied at \( L/2 \)
- a clockwise moment \( M_2 \) applied at \( 3L/4 \)
- a distributed constant load \( q_1 \), applied downward, starting from \( L/2 \) up to \( 3L/4 \)
- a distributed constant load \( q_2 \), applied upward, starting from \( 3L/4 \) up to \( L \)

No assumptions are needed for symbolic loads. However, defining a positive length will help the algorithm to compute the solution.

```python
>>> E, I = symbols('E, I')
>>> L = symbols('L', positive=True)
>>> P1, P2, M1, M2, q1, q2 = symbols('P1, P2, M1, M2, q1, q2')
>>> R1, R2 = symbols('R1, R2')
>>> b = Beam(L, E, I)
>>> b.apply_load(R1, 0, -1)
>>> b.apply_load(R2, L, -1)
>>> b.apply_load(P1, L/4, -1)
>>> b.apply_load(-P2, L/8, -1)
>>> b.apply_load(M1, L/2, -2)
>>> b.apply_load(-M2, 3*L/4, -2)
>>> b.apply_load(q1, L/2, 0, 3*L/4)
>>> b.apply_load(-q2, 3*L/4, 0, L)
>>> b.bc_deflection = [(0, 0), (L, 0)]
>>> b.solve_for_reaction_loads(R1, R2)
>>> print(b.reaction_loads[R1])
(-3*L**2*q1 + L**2*q2 - 24*L*P1 + 28*L*P2 - 32*M1 + 32*M2)/(32*L)
```
>>> print(breaction_loads[R2])
-5\*L^2q1 + 7\*L^2q2 - 8\*Lp1 + 4\*Lp2 + 32\*m1 - 32\*m2)/(32\*L)

**property applied_loads**

Returns a list of all loads applied on the beam object. Each load in the list is a tuple of form (value, start, order, end).

**Examples**

There is a beam of length 4 meters. A moment of magnitude 3 Nm is applied in the clockwise direction at the starting point of the beam. A pointload of magnitude 4 N is applied from the top of the beam at 2 meters from the starting point. Another pointload of magnitude 5 N is applied at same position.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> E, I = symbols('E, I')
>>> b = Beam(4, E, I)
>>> b.apply_load(-3, 0, -2)
>>> b.apply_load(4, 2, -1)
>>> b.apply_load(5, 2, -1)
>>> b.load
-3*SingularityFunction(x, 0, -2) + 9*SingularityFunction(x, 2, -1)
>>> b.applied_loads
[(-3, 0, -2, None), (4, 2, -1, None), (5, 2, -1, None)]
```

**apply_load** *(value, start, order, end=None)*

This method adds up the loads given to a particular beam object.

**Parameters**

- **value**: Sympifyable
  
The value inserted should have the units [Force/(Distance**(n+1))] where n is the order of applied load. Units for applied loads:
  
  - For moments, unit = kN*m
  - For point loads, unit = kN
  - For constant distributed load, unit = kN/m
  - For ramp loads, unit = kN/m/m
  - For parabolic ramp loads, unit = kN/m/m/m
  - ... so on.

  **start**: Sympifyable
  
The starting point of the applied load. For point moments and point forces this is the location of application.

  **order**: Integer
  
The order of the applied load.
  
  - For moments, order = -2

5.8. Topics
• For point loads, order = -1
• For constant distributed load, order = 0
• For ramp loads, order = 1
• For parabolic ramp loads, order = 2
• ... so on.

**end**: Symplifiable, optional

An optional argument that can be used if the load has an end point within the length of the beam.

**Examples**

There is a beam of length 4 meters. A moment of magnitude 3 Nm is applied in the clockwise direction at the starting point of the beam. A point load of magnitude 4 N is applied from the top of the beam at 2 meters from the starting point and a parabolic ramp load of magnitude 2 N/m is applied below the beam starting from 2 meters to 3 meters away from the starting point of the beam.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> E, I = symbols('E, I')
>>> b = Beam(4, E, I)
>>> b.apply_load(-3, 0, -2)
>>> b.apply_load(4, 2, -1)
>>> b.apply_load(-2, 2, 2, end=3)
>>> b.load
-3*SingularityFunction(x, 0, -2) + 4*SingularityFunction(x, 2, -1) - 2*SingularityFunction(x, 2, 2) + 2*SingularityFunction(x, 3, 0) + 4*SingularityFunction(x, 3, 1) + 2*SingularityFunction(x, 3, 2)
```

**apply_support**(loc, type='fixed')

This method applies support to a particular beam object.

**Parameters**

- **loc**: Symplifiable
  
  Location of point at which support is applied.

- **type**: String
  
  Determines type of Beam support applied. To apply support structure with - zero degree of freedom, type = “fixed” - one degree of freedom, type = “pin” - two degrees of freedom, type = “roller”
Examples

There is a beam of length 30 meters. A moment of magnitude 120 Nm is applied in the clockwise direction at the end of the beam. A point load of magnitude 8 N is applied from the top of the beam at the starting point. There are two simple supports below the beam. One at the end and another one at a distance of 10 meters from the start. The deflection is restricted at both the supports.

Using the sign convention of upward forces and clockwise moment being positive.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> E, I = symbols('E, I')
>>> b = Beam(30, E, I)
>>> b.apply_support(10, 'roller')
>>> b.apply_load(-8, 0, -1)
>>> b.apply_load(120, 30, -2)
>>> R_10, R_30 = symbols('R_10, R_30')
>>> b.solve_for_reaction_loads(R_10, R_30)
>>> b.load
-8*SingularityFunction(x, 0, -1) + 6*SingularityFunction(x, 10, -1) + 120*SingularityFunction(x, 30, -2) + 2*SingularityFunction(x, 30, -1)
>>> b.slope()
(-4*SingularityFunction(x, 0, 2) + 3*SingularityFunction(x, 10, 2) + 120*SingularityFunction(x, 30, 1) + SingularityFunction(x, 30, 2) + 4000/3)/(E*I)
```

property area

Cross-sectional area of the Beam.

bending_moment()

Returns a Singularity Function expression which represents the bending moment curve of the Beam object.

Examples

There is a beam of length 30 meters. A moment of magnitude 120 Nm is applied in the clockwise direction at the end of the beam. A point load of magnitude 8 N is applied from the top of the beam at the starting point. There are two simple supports below the beam. One at the end and another one at a distance of 10 meters from the start. The deflection is restricted at both the supports.

Using the sign convention of upward forces and clockwise moment being positive.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> E, I = symbols('E, I')
>>> R1, R2 = symbols('R1, R2')
>>> b = Beam(30, E, I)
>>> b.apply_load(-8, 0, -1)
>>> b.apply_load(R1, 10, -1)
```
property boundary_conditions

Returns a dictionary of boundary conditions applied on the beam. The dictionary has three keywords namely moment, slope and deflection. The value of each keyword is a list of tuple, where each tuple contains location and value of a boundary condition in the format (location, value).

Examples

There is a beam of length 4 meters. The bending moment at 0 should be 4 and at 4 it should be 0. The slope of the beam should be 1 at 0. The deflection should be 2 at 0.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> E, I = symbols('E, I')
>>> b = Beam(4, E, I)
>>> b.bc_deflection = [(0, 2)]
>>> b.bc_slope = [(0, 1)]
>>> b.boundary_conditions
{'deflection': [(0, 2)], 'slope': [(0, 1)]}
```

Here the deflection of the beam should be 2 at 0. Similarly, the slope of the beam should be 1 at 0.

property cross_section

Cross-section of the beam

deflection()

Returns a Singularity Function expression which represents the elastic curve or deflection of the Beam object.

Examples

There is a beam of length 30 meters. A moment of magnitude 120 Nm is applied in the clockwise direction at the end of the beam. A pointload of magnitude 8 N is applied from the top of the beam at the starting point. There are two simple supports below the beam. One at the end and another one at a distance of 10 meters from the start. The deflection is restricted at both the supports.

Using the sign convention of upward forces and clockwise moment being positive.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
```

>>> E, I = symbols('E, I')
>>> R1, R2 = symbols('R1, R2')
>>> b = Beam(30, E, I)
>>> b.apply_load(-8, 0, -1)
>>> b.apply_load(R1, 10, -1)
>>> b.apply_load(R2, 30, -1)
>>> b.apply_load(120, 30, -2)
>>> b.bc_deflection = [(10, 0), (30, 0)]
>>> b.solve_for_reaction_loads(R1, R2)

\[
\text{deflection} = \left(\frac{4000x}{3} - \frac{4}{3}\text{SingularityFunction}(x, 0, 3) + \text{SingularityFunction}(x, 10, 3)
+ 60\text{SingularityFunction}(x, 30, 2) + \text{SingularityFunction}(x, 30, 3)/3 - 12000\right)/(E*I)
\]

**draw(pictorial=True)**

Returns a plot object representing the beam diagram of the beam.

**Note:** The user must be careful while entering load values. The draw function assumes a sign convention which is used for plotting loads. Given a right handed coordinate system with XYZ coordinates, the beam’s length is assumed to be along the positive X axis. The draw function recognizes positive loads(with n>2) as loads acting along negative Y direction and positive moments acting along positive Z direction.

**Parameters**

**pictorial:** Boolean (default=True)

Setting pictorial=True would simply create a pictorial (scaled) view of the beam diagram not with the exact dimensions. Although setting pictorial=False would create a beam diagram with the exact dimensions on the plot.

**Examples**

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> R1, R2 = symbols('R1, R2')
>>> E, I = symbols('E, I')
>>> b = Beam(50, 20, 30)
>>> b.apply_load(10, 2, -1)
>>> b.apply_load(R1, 10, -1)
>>> b.apply_load(R2, 30, -1)
>>> b.apply_load(90, 5, 0, 23)
>>> b.apply_load(10, 30, 1, 50)
>>> b.apply_support(50, "pin")
>>> b.apply_support(0, "fixed")
>>> b.apply_support(20, "roller")
>>> p = b.draw()
```

(continues on next page)
property elastic_modulus
    Young’s Modulus of the Beam.

property ild_moment
    Returns the I.L.D. moment equation.

property ild_reactions
    Returns the I.L.D. reaction forces in a dictionary.

property ild_shear
    Returns the I.L.D. shear equation.

join(beam, via='fixed')
    This method joins two beams to make a new composite beam system. Passed Beam
class instance is attached to the right end of calling object. This method can be used to form beams having Discontinuous values of Elastic modulus or Second moment.

**Parameters**

beam : Beam class object

The Beam object which would be connected to the right of calling object.

via : String

States the way two Beam object would get connected - For axially fixed Beams, via="fixed" - For Beams connected via hinge, via="hinge"

**Examples**

There is a cantilever beam of length 4 meters. For first 2 meters its moment of inertia is $1.5*I$ and $I$ for the other end. A pointload of magnitude 4 N is applied from the top at its free end.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> E, I = symbols('E, I')
>>> R1, R2 = symbols('R1, R2')
>>> b1 = Beam(2, E, 1.5*I)
>>> b2 = Beam(2, E, I)
>>> b = b1.join(b2, "fixed")
>>> b.apply_load(20, 4, -1)
>>> b.apply_load(R1, 0, -1)
>>> b.apply_load(R2, 0, -2)
>>> b.bc_slope = [(0, 0)]
>>> b.bc_deflection = [(0, 0)]
>>> b.solve_for_reaction_loads(R1, R2)
>>> b.load
80*SingularityFunction(x, 0, -2) - 20*SingularityFunction(x, 0, -1) -
20*SingularityFunction(x, 4, -1)
```

**property length**

Length of the Beam.

**property load**

Returns a Singularity Function expression which represents the load distribution curve of the Beam object.
Examples

There is a beam of length 4 meters. A moment of magnitude 3 Nm is applied in the clockwise direction at the starting point of the beam. A point load of magnitude 4 N is applied from the top of the beam at 2 meters from the starting point and a parabolic ramp load of magnitude 2 N/m is applied below the beam starting from 3 meters away from the starting point of the beam.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> E, I = symbols('E, I')
>>> b = Beam(4, E, I)
>>> b.apply_load(-3, 0, -2)
>>> b.apply_load(4, 2, -1)
>>> b.apply_load(-2, 3, 2)
>>> load
-3*SingularityFunction(x, 0, -2) + 4*SingularityFunction(x, 2, -1) - 2*SingularityFunction(x, 3, 2)
```

**max_bmoment()**

Returns maximum Shear force and its coordinate in the Beam object.

**max_deflection()**

Returns point of max deflection and its corresponding deflection value in a Beam object.

**max_shear_force()**

Returns maximum Shear force and its coordinate in the Beam object.

**plot_bending_moment**(sub=None)

Returns a plot for Bending moment present in the Beam object.

**Parameters**

- **sub**: dictionary
  
  Python dictionary containing Symbols as key and their corresponding values.

Examples

There is a beam of length 8 meters. A constant distributed load of 10 KN/m is applied from half of the beam till the end. There are two simple supports below the beam, one at the starting point and another at the ending point of the beam. A point load of magnitude 5 KN is also applied from top of the beam, at a distance of 4 meters from the starting point. Take E = 200 GPa and I = 400*(10**-6) meter**4.

Using the sign convention of downwards forces being positive.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> R1, R2 = symbols('R1, R2')
>>> b = Beam(8, 200*(10**9), 400*(10**-6))
>>> b.apply_load(5000, 2, -1)
>>> b.apply_load(R1, 0, -1)
```
```python
>>> b.apply_load(R2, 8, -1)
>>> b.apply_load(10000, 4, 0, end=8)
>>> b.bc_deflection = [(0, 0), (8, 0)]
>>> b.solve_for_reaction_loads(R1, R2)
```

```python
Plot object containing:
[0]: cartesian line: 13750*SingularityFunction(x, 0, 1) - 5000*SingularityFunction(x, 2, 1) - 5000*SingularityFunction(x, 4, 2) + 31250*SingularityFunction(x, 8, 1) + 5000*SingularityFunction(x, 8, 2) for x over (0.0, 8.0)
```

**plot_deflection**(subs=None)

Returns a plot for deflection curve of the Beam object.

**Parameters**

- **subs**: dictionary
  
  Python dictionary containing Symbols as key and their corresponding values.

---

5.8. Topics 2033
Examples

There is a beam of length 8 meters. A constant distributed load of 10 KN/m is applied from half of the beam till the end. There are two simple supports below the beam, one at the starting point and another at the ending point of the beam. A point load of magnitude 5 KN is also applied from top of the beam, at a distance of 4 meters from the starting point. Take E = 200 GPa and I = 400*(10**-6) meter**4.

Using the sign convention of downwards forces being positive.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> R1, R2 = symbols('R1, R2')
>>> b = Beam(8, 200*(10**9), 400*(10**-6))
>>> b.apply_load(5000, 2, -1)
>>> b.apply_load(R1, 0, -1)
>>> b.apply_load(R2, 8, -1)
>>> b.apply_load(10000, 4, 0, end=8)
>>> b.bc_deflection = [(0, 0), (8, 0)]
>>> b.solve_for_reaction_loads(R1, R2)
>>> b.plot_deflection()
```

Plot object containing:

[0]: cartesian line: 0.0013854166666667*x - 2.86458333333333e-5*SingularityFunction(x, 0, 3) + 1.04166666666667e-5*SingularityFunction(x, 2, 3) + 5.20833333333333e-6*SingularityFunction(x, 4, 4) - 6.51041666666667e-5*SingularityFunction(x, 8, 3) - 5.20833333333333e-6*SingularityFunction(x, 8, 4) for x over (0.0, 8.0)

plot_ild_moment(subs=None)

Plots the Influence Line Diagram for Moment under the effect of a moving load. This function should be called after calling solve_for_ild_moment().

Parameters

subs: dictionary

Python dictionary containing Symbols as key and their corresponding values.

Examples

There is a beam of length 12 meters. There are two simple supports below the beam, one at the starting point and another at a distance of 8 meters. Plot the I.L.D. for Moment at a distance of 4 meters under the effect of a moving load of magnitude 1kN.

Using the sign convention of downwards forces being positive.

```python
>>> from sympy import symbols
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> E, I = symbols('E, I')
>>> R_0, R_8 = symbols('R_0, R_8')
>>> b = Beam(12, E, I)
```
Deflection

\[ \delta \]

\[ x \]

Deflection
>>> b.apply_support(0, 'roller')
>>> b.apply_support(8, 'roller')
>>> b.solve_for_ild_reactions(1, R_0, R_8)
>>> b.solve_for_ild_moment(4, 1, R_0, R_8)
>>> b.ild_moment
Piecewise((-x/2, x < 4), (x/2 - 4, x > 4))

>>> b.plot_ild_moment()
Plot object containing:
[0]: cartesian line: Piecewise((-x/2, x < 4), (x/2 - 4, x > 4)) for x,
over (0.0, 12.0)

plot_ild_reactions(subs=None)
Plots the Influence Line Diagram of Reaction Forces under the effect of a moving
load. This function should be called after calling solve_for_ild_reactions().

Parameters
subs : dictionary
Python dictionary containing Symbols as key and their corresponding
values.
Examples

There is a beam of length 10 meters. A point load of magnitude 5kN is also applied from top of the beam, at a distance of 4 meters from the starting point. There are two simple supports below the beam, located at the starting point and at a distance of 7 meters from the starting point. Plot the I.L.D. equations for reactions at both support points under the effect of a moving load of magnitude 1kN.

Using the sign convention of downwards forces being positive.

```python
from sympy import symbols
from sympy.physics.continuum_mechanics.beam import Beam

E, I = symbols('E, I')
R_0, R_7 = symbols('R_0, R_7')
b = Beam(10, E, I)
b.apply_support(0, 'roller')
b.apply_support(7, 'roller')
b.apply_load(5, 4, -1)
b.solve_for_ild_reactions(1, R_0, R_7)

b.ild_reactions
{R_0: x/7 - 22/7, R_7: -x/7 - 20/7}
b.plot_ild_reactions()
```

`plot_ild/shear(subs=None)`

Plots the Influence Line Diagram for Shear under the effect of a moving load. This function should be called after calling `solve_for_ild/shear()`.

**Parameters**

- `subs`: dictionary
  
  Python dictionary containing Symbols as key and their corresponding values.

Examples

There is a beam of length 12 meters. There are two simple supports below the beam, one at the starting point and another at a distance of 8 meters. Plot the I.L.D. for Shear at a distance of 4 meters under the effect of a moving load of magnitude 1kN.

Using the sign convention of downwards forces being positive.

```python
from sympy import symbols
from sympy.physics.continuum_mechanics.beam import Beam

E, I = symbols('E, I')
R_0, R_8 = symbols('R_0, R_8')
b = Beam(12, E, I)
b.apply_support(0, 'roller')
b.apply_support(8, 'roller')
b.solve_for_ild_reactions(1, R_0, R_8)
```
```python
>>> b.solve_for_ild_shear(4, 1, R_0, R_8)
>>> b.ild_shear
Piecewise((x/8, x < 4), (x/8 - 1, x > 4))
>>> b.plot_ild_shear()
Plot object containing:
[0]: cartesian line: Piecewise((x/8, x < 4), (x/8 - 1, x > 4)) for x over (0.0, 12.0)
```

### plot_loading_results

**plot_loading_results**(subs=None)

Returns a subplot of Shear Force, Bending Moment, Slope and Deflection of the Beam object.

**Parameters**

- **subs**: dictionary

  Python dictionary containing Symbols as key and their corresponding values.

---

5.8. Topics 2039
Examples

There is a beam of length 8 meters. A constant distributed load of 10 KN/m is applied from half of the beam till the end. There are two simple supports below the beam, one at the starting point and another at the ending point of the beam. A point load of magnitude 5 KN is also applied from top of the beam, at a distance of 4 meters from the starting point. Take $E = 200$ GPa and $I = 400*(10**-6)$ meter$^4$.

Using the sign convention of downwards forces being positive.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols

>>> R1, R2 = symbols('R1, R2')
>>> b = Beam(8, 200*(10**9), 400*(10**6))
>>> b.apply_load(5000, 2, -1)
>>> b.apply_load(R1, 0, -1)
>>> b.apply_load(R2, 8, -1)
>>> b.apply_load(10000, 4, 0, end=8)
>>> b.bc_deflection = [(0, 0), (8, 0)]
>>> b.solve_for_reaction_loads(R1, R2)
>>> axes = b.plot_loading_results()
```

```
plot_shear_force(subs=None)
Returns a plot for Shear force present in the Beam object.
```
Parameters

subs : dictionary

Python dictionary containing Symbols as key and their corresponding values.

Examples

There is a beam of length 8 meters. A constant distributed load of 10 KN/m is applied from half of the beam till the end. There are two simple supports below the beam, one at the starting point and another at the ending point of the beam. A point load of magnitude 5 KN is also applied from top of the beam, at a distance of 4 meters from the starting point. Take $E = 200$ GPa and $I = 400*(10**-6)$ meter**4.

Using the sign convention of downwards forces being positive.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> R1, R2 = symbols('R1, R2')
>>> b = Beam(8, 200*(10**9), 400*(10**-6))
>>> b.apply_load(5000, 2, -1)
>>> b.apply_load(R1, 0, -1)
>>> b.apply_load(R2, 8, -1)
>>> b.apply_load(10000, 4, 0, end=8)
>>> b.bc_deflection = [(0, 0), (8, 0)]
>>> b.solve_for_reaction_loads(R1, R2)
>>> b.plot_shear_force()

Plot object containing:
[0]: cartesian line: 13750*SingularityFunction(x, 0, 0) - 5000*SingularityFunction(x, 2, 0) - 10000*SingularityFunction(x, 4, 1) + 31250*SingularityFunction(x, 8, 0) + 10000*SingularityFunction(x, 8, 1) for x over (0.0, 8.0)

plot_shear_stress(subs=None)

Returns a plot of shear stress present in the beam object.

Parameters

subs : dictionary

Python dictionary containing Symbols as key and their corresponding values.

Examples

There is a beam of length 8 meters and area of cross section 2 square meters. A constant distributed load of 10 KN/m is applied from half of the beam till the end. There are two simple supports below the beam, one at the starting point and another at the ending point of the beam. A point load of magnitude 5 KN is also applied from top of the beam, at a distance of 4 meters from the starting point. Take $E = 200$ GPa and $I = 400*(10**-6)$ meter**4.

Using the sign convention of downwards forces being positive.
```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols

>>> R1, R2 = symbols('R1, R2')

>>> b = Beam(8, 200*(10**9), 400*(10**6), 2)

>>> b.apply_load(5000, 2, -1)
>>> b.apply_load(R1, 0, -1)
>>> b.apply_load(R2, 8, -1)

>>> b.apply_load(10000, 4, 0, end=8)

>>> b.bc_deflection = [(0, 0), (8, 0)]

>>> b.solve_for_reaction_loads(R1, R2)

>>> b.plot_shear_stress()
```

**plot_slope**(subs=None)

Returns a plot for slope of deflection curve of the Beam object.

**Parameters**

*subs*: dictionary
Python dictionary containing Symbols as key and their corresponding values.

Examples

There is a beam of length 8 meters. A constant distributed load of 10 KN/m is applied from half of the beam till the end. There are two simple supports below the beam, one at the starting point and another at the ending point of the beam. A point load of magnitude 5 KN is also applied from top of the beam, at a distance of 4 meters from the starting point. Take E = 200 GPa and I = 400*(10**-6) meter**4.

Using the sign convention of downwards forces being positive.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> R1, R2 = symbols('R1, R2')
>>> b = Beam(8, 200*(10**9), 400*(10**-6))
>>> b.apply_load(5000, 2, -1)
>>> b.apply_load(R1, 0, -1)
>>> b.apply_load(R2, 8, -1)
>>> b.apply_load(10000, 4, 0, end=8)
>>> b.bc_deflection = [(0, 0), (8, 0)]
>>> b.solve_for_reaction_loads(R1, R2)
>>> b.plot_slope()
Plot object containing:
[0]: cartesian line: -8.59375e-5*SingularityFunction(x, 0, 2) + 3.
   -125e-5*SingularityFunction(x, 2, 2)
   + 2.0833333333333*SingularityFunction(x, 4, 3) - 0.
   -0.01953125*SingularityFunction(x, 8, 2)
   - 2.0833333333333*SingularityFunction(x, 8, 3) + 0.
   0.0138541666666667 for x over (0.0, 8.0)
```

point_cflexure()

Returns a Set of point(s) with zero bending moment and where bending moment curve of the beam object changes its sign from negative to positive or vice versa.

Examples

There is a 10 meter long overhanging beam. There are two simple supports below the beam. One at the start and another one at a distance of 6 meters from the start. Point loads of magnitude 10KN and 20KN are applied at 2 meters and 4 meters from start respectively. A Uniformly distribute load of magnitude of magnitude 3KN/m is also applied on top starting from 6 meters away from starting point till end. Using the sign convention of upward forces and clockwise moment being positive.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> E, I = symbols('E, I')
>>> b = Beam(10, E, I)
>>> b.apply_load(-4, 0, -1)
>>> b.apply_load(-46, 6, -1)
>>> b.apply_load(10, 2, -1)
```
>>> b.apply_load(20, 4, -1)
>>> b.apply_load(3, 6, 0)
>>> b.point_cflexure()
[10/3]

property reaction_loads
Returns the reaction forces in a dictionary.

remove_load(value, start, order, end=None)
This method removes a particular load present on the beam object. Returns a ValueError if the load passed as an argument is not present on the beam.

Parameters
value : Sympifyable
The magnitude of an applied load.
start : Sympifyable
The starting point of the applied load. For point moments and point forces this is the location of application.
order : Integer
The order of the applied load. - For moments, order= -2 - For point loads, order= -1 - For constant distributed load, order=0 - For ramp loads, order=1 - For parabolic ramp loads, order=2 - ... so on.
end : Sympifyable, optional
An optional argument that can be used if the load has an end point within the length of the beam.

Examples
There is a beam of length 4 meters. A moment of magnitude 3 Nm is applied in the clockwise direction at the starting point of the beam. A pointload of magnitude 4 N is applied from the top of the beam at 2 meters from the starting point and a parabolic ramp load of magnitude 2 N/m is applied below the beam starting from 2 meters to 3 meters away from the starting point of the beam.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> E, I = symbols('E, I')
>>> b = Beam(4, E, I)
>>> b.apply_load(-3, 0, -2)
>>> b.apply_load(4, 2, -1)
>>> b.apply_load(-2, 2, 2, end=3)
>>> b.load
-3*SingularityFunction(x, 0, -2) + 4*SingularityFunction(x, 2, -1) - 2*SingularityFunction(x, 2, 2) + 2*SingularityFunction(x, 3, 0) + 4*SingularityFunction(x, 3, 1) + 2*SingularityFunction(x, 3, 2)
```
property second_moment
    Second moment of area of the Beam.

shear_force()
    Returns a Singularity Function expression which represents the shear force curve
    of the Beam object.

Examples

There is a beam of length 30 meters. A moment of magnitude 120 Nm is applied
in the clockwise direction at the end of the beam. A point load of magnitude 8 N
is applied from the top of the beam at the starting point. There are two simple supports
below the beam. One at the end and another one at a distance of 10 meters from
the start. The deflection is restricted at both the supports.

Using the sign convention of upward forces and clockwise moment being positive.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> E, I = symbols('E, I')
>>> R1, R2 = symbols('R1, R2')
>>> b = Beam(30, E, I)
>>> b.apply_load(-8, 0, -1)
>>> b.apply_load(R1, 10, -1)
>>> b.apply_load(R2, 30, -1)
>>> b.apply_load(120, 30, -2)
>>> b.bc_deflection = [(10, 0), (30, 0)]
>>> b.solve_for_reaction_loads(R1, R2)
>>> b.shear_force()
8*SingularityFunction(x, 0, 0) - 6*SingularityFunction(x, 10, 0) - 120*SingularityFunction(x, 30, -1) - 2*SingularityFunction(x, 30, 0)
```

shear_stress()
    Returns an expression representing the Shear Stress curve of the Beam object.

slope()
    Returns a Singularity Function expression which represents the slope the elastic
curve of the Beam object.

Examples

There is a beam of length 30 meters. A moment of magnitude 120 Nm is applied
in the clockwise direction at the end of the beam. A point load of magnitude 8 N
is applied from the top of the beam at the starting point. There are two simple supports
below the beam. One at the end and another one at a distance of 10 meters from
the start. The deflection is restricted at both the supports.

Using the sign convention of upward forces and clockwise moment being positive.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> E, I = symbols('E, I')
```
SymPy Documentation, Release 1.12.1

(continued from previous page)

```python
>>> R1, R2 = symbols('R1, R2')
>>> b = Beam(30, E, I)
>>> b.apply_load(-8, 0, -1)
>>> b.apply_load(R1, 10, -1)
>>> b.apply_load(R2, 30, -1)
>>> b.apply_load(120, 30, -2)
>>> b.bc_deflection = [(10, 0), (30, 0)]
>>> b.solve_for_reactionLoads(R1, R2)
>>> b.slope()
(-4*SingularityFunction(x, 0, 2) + 3*SingularityFunction(x, 10, 2) + 120*SingularityFunction(x, 30, 1) + SingularityFunction(x, 30, 2) + 4000/3)/(E*I)
```

`solve_for_ild_moment(distance, value, *reactions)`

Determines the Influence Line Diagram equations for moment at a specified point under the effect of a moving load.

**Parameters**

- **distance** : Integer
  Distance of the point from the start of the beam for which equations are to be determined

- **value** : Integer
  Magnitude of moving load

- **reactions** :
  The reaction forces applied on the beam.

**Examples**

There is a beam of length 12 meters. There are two simple supports below the beam, one at the starting point and another at a distance of 8 meters. Calculate the I.L.D. equations for Moment at a distance of 4 meters under the effect of a moving load of magnitude 1kN.

Using the sign convention of downwards forces being positive.

```python
>>> from sympy import symbols
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> E, I = symbols('E, I')
>>> R_0, R_8 = symbols('R_0, R_8')
>>> b = Beam(12, E, I)
>>> b.apply_support(0, 'roller')
>>> b.apply_support(8, 'roller')
>>> b.solve_for_ild_reactions(1, R_0, R_8)
>>> b.solve_for_ild_moment(4, 1, R_0, R_8)
>>> b.ild_moment
Piecewise((-x/2, x < 4), (x/2 - 4, x > 4))
```

`solve_for_ild_reactions(value, *reactions)`

Determines the Influence Line Diagram equations for reaction forces under the effect of a moving load.

---

2048 Chapter 5. API Reference
Parameters

- **value**: Integer
  
  Magnitude of moving load

- **reactions**: The reaction forces applied on the beam.

Examples

There is a beam of length 10 meters. There are two simple supports below the beam, one at the starting point and another at the ending point of the beam. Calculate the I.L.D. equations for reaction forces under the effect of a moving load of magnitude 1kN.

Using the sign convention of downwards forces being positive.

```python
>>> from sympy import symbols
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> E, I = symbols('E, I')
>>> R_0, R_10 = symbols('R_0, R_10')
>>> b = Beam(10, E, I)
>>> b.apply_support(0, 'roller')
>>> b.apply_support(10, 'roller')
>>> b.solve_for_ild_reactions(1, R_0, R_10)
{R_0: x/10 - 1, R_10: -x/10}
```

**solve_for_ild_shear** *(distance, value, *reactions)*

Determines the Influence Line Diagram equations for shear at a specified point under the effect of a moving load.

Parameters

- **distance**: Integer
  
  Distance of the point from the start of the beam for which equations are to be determined

- **value**: Integer
  
  Magnitude of moving load

- **reactions**: The reaction forces applied on the beam.

Examples

There is a beam of length 12 meters. There are two simple supports below the beam, one at the starting point and another at a distance of 8 meters. Calculate the I.L.D. equations for Shear at a distance of 4 meters under the effect of a moving load of magnitude 1kN.

Using the sign convention of downwards forces being positive.
```python
>>> from sympy import symbols
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> E, I = symbols('E, I')
>>> R_0, R_8 = symbols('R_0, R_8')
>>> b = Beam(12, E, I)
>>> b.apply_support(0, 'roller')
>>> b.apply_support(8, 'roller')
>>> b.solve_for_ild_reactions(1, R_0, R_8)
>>> b.solve_for_ild_shear(4, 1, R_0, R_8)
>>> b.ild_shear
Piecewise((x/8, x < 4), (x/8 - 1, x > 4))
```

**solve_for_reaction_loads(***reactions***)

Solves for the reaction forces.

**Examples**

There is a beam of length 30 meters. A moment of magnitude 120 Nm is applied in the clockwise direction at the end of the beam. A pointload of magnitude 8 N is applied from the top of the beam at the starting point. There are two simple supports below the beam. One at the end and another one at a distance of 10 meters from the start. The deflection is restricted at both the supports.

Using the sign convention of upward forces and clockwise moment being positive.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> E, I = symbols('E, I')
>>> R1, R2 = symbols('R1, R2')
>>> b = Beam(30, E, I)
>>> b.apply_load(-8, 0, -1)  # Reaction force at x = 10
>>> b.apply_load(R1, 10, -1)  # Reaction force at x = 10
>>> b.apply_load(R2, 30, -1)  # Reaction force at x = 30
>>> b.apply_load(120, 30, -2)
>>> b.bc_deflection = [(10, 0), (30, 0)]
>>> b.load
R1*SingularityFunction(x, 10, -1) + R2*SingularityFunction(x, 30, -1) - 8*SingularityFunction(x, 0, -1) + 120*SingularityFunction(x, 30, -2)
>>> b.solve_for_reaction_loads(R1, R2)
>>> b.reaction_loads
{R1: 6, R2: 2}
>>> b.load
-8*SingularityFunction(x, 0, -1) + 6*SingularityFunction(x, 10, -1) + 120*SingularityFunction(x, 30, -2) + 2*SingularityFunction(x, 30, -1)
```

**property variable**

A symbol that can be used as a variable along the length of the beam while representing load distribution, shear force curve, bending moment, slope curve and the deflection curve. By default, it is set to `Symbol('x')`, but this property is mutable.
Examples

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols
>>> E, I, A = symbols('E, I, A')
>>> x, y, z = symbols('x, y, z')
>>> b = Beam(4, E, I)
>>> b.variable = x
>>> b.variable = y
>>> b.variable = y
>>> b = Beam(4, E, I, A, z)
>>> b.variable = z
```

```python
class sympy.physics.continuum_mechanics.beam.Beam3D(length, elastic_modulus, shear_modulus, second_moment, area, variable=x)
```

This class handles loads applied in any direction of a 3D space along with unequal values of Second moment along different axes.

**Note:** A consistent sign convention must be used while solving a beam bending problem; the results will automatically follow the chosen sign convention. This class assumes that any kind of distributed load/moment is applied through out the span of a beam.

Examples

There is a beam of l meters long. A constant distributed load of magnitude q is applied along y-axis from start till the end of beam. A constant distributed moment of magnitude m is also applied along z-axis from start till the end of beam. Beam is fixed at both of its end. So, deflection of the beam at the both ends is restricted.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam3D
>>> from sympy import symbols, simplify, collect, factor
>>> l, E, G, I, A = symbols('l, E, G, I, A')
>>> b = Beam3D(l, E, G, I, A)
>>> x, q, m = symbols('x, q, m')
>>> b.apply_load(q, 0, 0, dir="y")
>>> b.apply_moment_load(m, 0, -1, dir="z")
>>> b.shear_force()
[0, -q*x, 0]
>>> b.bending_moment()
[0, 0, -m*x + q*x**2/2]
>>> b.bc_slope = [(0, [0, 0, 0]), (l, [0, 0, 0])]
>>> b.bc_deflection = [(0, [0, 0, 0]), (l, [0, 0, 0])]
>>> b.solve_slope_deflection()
>>> factor(b.slope())
[0, 0, x*(-l + x)*(-A*G*l**3*q + 2*A*G*l**2*q*x - 12*E*I*l*q
(continues on next page)
- 72*E*I*m + 24*E*I*q*x)/(12*E*I*(A*G*l**2 + 12*E*I))

```
>>> dx, dy, dz = b.deflection()
>>> dy = collect(simplify(dy), x)
>>> dx == dz == 0
True
>>> dy == (x*(12*E*I*l*(A*G*l**2*q - 2*A*G*l*m + 12*E*I*q))
    + x*(A*G*l*(3*l*(A*G*l**2*q - 2*A*G*l*m + 12*E*I*q) + x*(-
    2*A*G*l**2*q + 4*A*G*l*m - 24*E*I*q))
    + A*G*(A*G*l**2 + 12*E*I)*(-2*l**2*q + 6*l*m - 4*m*x + q*x**2)
```

References

[R670]

angular_deflection()

Returns a function in x depicting how the angular deflection, due to moments in the x-axis on the beam, varies with x.

apply_load(value, start, order, dir='y')

This method adds up the force load to a particular beam object.

Parameters

value : Sympifyable

The magnitude of an applied load.

dir : String

Axis along which load is applied.

order : Integer

The order of the applied load. - For point loads, order=-1 - For constant distributed load, order=0 - For ramp loads, order=1 - For parabolic ramp loads, order=2 - ... so on.

apply_moment_load(value, start, order, dir='y')

This method adds up the moment loads to a particular beam object.

Parameters

value : Sympifyable

The magnitude of an applied moment.

dir : String

Axis along which moment is applied.

order : Integer

The order of the applied load. - For point moments, order=-2 - For constant distributed moment, order=-1 - For ramp moments, order=0 - For parabolic ramp moments, order=1 - ... so on.

property area

Cross-sectional area of the Beam.
axial_force()
    Returns expression of Axial shear force present inside the Beam object.

axial_stress()
    Returns expression of Axial stress present inside the Beam object.

bending_moment()
    Returns a list of three expressions which represents the bending moment curve of
    the Beam object along all three axes.

property boundary_conditions
    Returns a dictionary of boundary conditions applied on the beam. The dictionary
    has two keywords namely slope and deflection. The value of each keyword is a list
    of tuple, where each tuple contains location and value of a boundary condition in
    the format (location, value). Further each value is a list corresponding to slope or
    deflection(s) values along three axes at that location.

Examples

There is a beam of length 4 meters. The slope at 0 should be 4 along the x-axis and
0 along others. At the other end of beam, deflection along all the three axes should
be zero.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam3D
>>> from sympy import symbols
>>> l, E, G, I, A, x = symbols('l, E, G, I, A, x')
>>> b = Beam3D(30, E, G, I, A, x)
>>> b.bc_slope = [(0, (4, 0, 0))]
>>> b.bc_deflection = [(4, [0, 0, 0])]
>>> b.boundary_conditions
{'deflection': [(4, [0, 0, 0])], 'slope': [(0, (4, 0, 0))]}
```

Here the deflection of the beam should be 0 along all the three axes at 4. Similarly,
the slope of the beam should be 4 along x-axis and 0 along y and z axis at 0.

deflection()
    Returns a three element list representing deflection curve along all the three axes.

property load vector
    Returns a three element list representing the load vector.

max_bending_moment()
    Returns point of max bending moment and its corresponding bending moment value
    along all directions in a Beam object as a list. solve_for_reaction_loads() must be
    called before using this function.
Examples

There is a beam of length 20 meters. It is supported by rollers at its end. A linear load having slope equal to 12 is applied along y-axis. A constant distributed load of magnitude 15 N is applied from start till its end along z-axis.

```python
from sympy.physics.continuum_mechanics.beam import Beam3D
from sympy import symbols

l, E, G, I, A, x = symbols('l, E, G, I, A, x')
b = Beam3D(20, 40, 21, 100, 25, x)
b.apply_load(15, start=0, order=0, dir="z")
b.apply_load(12*x, start=0, order=0, dir="y")
b.bc_deflection = [(0, [0, 0, 0]), (20, [0, 0, 0])]
R1, R2, R3, R4 = symbols('R1, R2, R3, R4')
b.apply_load(R1, start=0, order=-1, dir="z")
b.apply_load(R2, start=20, order=-1, dir="z")
b.apply_load(R3, start=0, order=-1, dir="y")
b.apply_load(R4, start=20, order=-1, dir="y")
b.solve_for_reaction_loads(R1, R2, R3, R4)
b.max_bending_moment()
```

`max_bmoment()`

Returns point of max bending moment and its corresponding bending moment value along all directions in a Beam object as a list. `solve_for_reaction_loads()` must be called before using this function.

Examples

There is a beam of length 20 meters. It is supported by rollers at its end. A linear load having slope equal to 12 is applied along y-axis. A constant distributed load of magnitude 15 N is applied from start till its end along z-axis.

```python
from sympy.physics.continuum_mechanics.beam import Beam3D
from sympy import symbols

l, E, G, I, A, x = symbols('l, E, G, I, A, x')
b = Beam3D(20, 40, 21, 100, 25, x)
b.apply_load(15, start=0, order=0, dir="z")
b.apply_load(12*x, start=0, order=0, dir="y")
b.bc_deflection = [(0, [0, 0, 0]), (20, [0, 0, 0])]
R1, R2, R3, R4 = symbols('R1, R2, R3, R4')
b.apply_load(R1, start=0, order=-1, dir="z")
b.apply_load(R2, start=20, order=-1, dir="z")
b.apply_load(R3, start=0, order=-1, dir="y")
b.apply_load(R4, start=20, order=-1, dir="y")
b.solve_for_reaction_loads(R1, R2, R3, R4)
b.max_bending_moment()
```

`max_deflection()`

Returns point of max deflection and its corresponding deflection value along all directions in a Beam object as a list. `solve_for_reaction_loads()` and `solve_slope_deflection()` must be called before using this function.
Examples

There is a beam of length 20 meters. It is supported by rollers at its end. A linear load having slope equal to 12 is applied along y-axis. A constant distributed load of magnitude 15 N is applied from start till its end along z-axis.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam3D
>>> from sympy import symbols

>>> l, E, G, I, A, x = symbols('l, E, G, I, A, x')
>>> b = Beam3D(20, 40, 21, 100, 25, x)
>>> b.apply_load(15, start=0, order=0, dir="z")
>>> b.apply_load(12*x, start=0, order=0, dir="y")
>>> b.bc_deflection = [(0, [0, 0, 0]), (20, [0, 0, 0])]
>>> R1, R2, R3, R4 = symbols('R1, R2, R3, R4')
>>> b.apply_load(R1, start=0, order=-1, dir="z")
>>> b.apply_load(R2, start=20, order=-1, dir="z")
>>> b.apply_load(R3, start=0, order=-1, dir="y")
>>> b.apply_load(R4, start=20, order=-1, dir="y")
>>> b.solve_for_reaction_loads(R1, R2, R3, R4)
>>> b.solve_slope_deflection()
>>> b.max_deflection()

max_deflection()

[(0, 0), (10, 495/14), (-10 + 10*sqrt(10793)/43, (10 - 10*sqrt(10793)/43)**3/160 - 20/7 + (10 - 10*sqrt(10793)/43)**4/6400 + 20*sqrt(10793)/301 + 27*(10 - 10*sqrt(10793)/43)**2/560)]

max_shear_force()

Returns point of max shear force and its corresponding shear value along all directions in a Beam object as a list. solve_for_reaction_loads() must be called before using this function.

Examples

There is a beam of length 20 meters. It is supported by rollers at its end. A linear load having slope equal to 12 is applied along y-axis. A constant distributed load of magnitude 15 N is applied from start till its end along z-axis.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam3D
>>> from sympy import symbols

>>> l, E, G, I, A, x = symbols('l, E, G, I, A, x')
>>> b = Beam3D(20, 40, 21, 100, 25, x)
>>> b.apply_load(15, start=0, order=0, dir="z")
>>> b.apply_load(12*x, start=0, order=0, dir="y")
>>> b.bc_deflection = [(0, [0, 0, 0]), (20, [0, 0, 0])]
>>> R1, R2, R3, R4 = symbols('R1, R2, R3, R4')
>>> b.apply_load(R1, start=0, order=-1, dir="z")
>>> b.apply_load(R2, start=20, order=-1, dir="z")
>>> b.apply_load(R3, start=0, order=-1, dir="y")
>>> b.apply_load(R4, start=20, order=-1, dir="y")
>>> b.solve_for_reaction_loads(R1, R2, R3, R4)
>>> b.max_shear_force()

max_shear_force()

[0, 20, 2400, (20, 300)]
```
property moment_load_vector
Returns a three element list representing moment loads on Beam.

plot_bending_moment(dir='all', subs=None)
Returns a plot for bending moment along all three directions present in the Beam object.

Parameters
dir : string (default)
    Direction along which bending moment plot is required. If no direction is specified, all plots are displayed.
subs : dictionary
    Python dictionary containing Symbols as key and their corresponding values.

Examples
There is a beam of length 20 meters. It is supported by rollers at its end. A linear load having slope equal to 12 is applied along y-axis. A constant distributed load of magnitude 15 N is applied from start till its end along z-axis.

```
>>> from sympy.physics.continuum_mechanics.beam import Beam3D
>>> from sympy import symbols

>>> l, E, G, I, A, x = symbols('l, E, G, I, A, x')
>>> b = Beam3D(20, E, G, I, A, x)
>>> b.apply_load(15, start=0, order=0, dir="z")
>>> b.apply_load(12*x, start=0, order=0, dir="y")
>>> b.bc_deflection = [(0, [0, 0, 0]), (20, [0, 0, 0])]
>>> R1, R2, R3, R4 = symbols('R1, R2, R3, R4')
>>> b.apply_load(R1, start=0, order=-1, dir="z")
>>> b.apply_load(R2, start=20, order=-1, dir="z")
>>> b.apply_load(R3, start=0, order=-1, dir="y")
>>> b.apply_load(R4, start=20, order=-1, dir="y")
>>> b.solve_for_reaction_loads(R1, R2, R3, R4)
>>> b.plot_bending_moment()
PlotGrid object containing:
Plot[0]: Plot object containing:
    [0]: cartesian line: 0 for x over (0.0, 20.0)
Plot[1]: Plot object containing:
    [0]: cartesian line: -15*x**2/2 for x over (0.0, 20.0)
Plot[2]: Plot object containing:
    [0]: cartesian line: 2*x**3 for x over (0.0, 20.0)
```

plot_deflection(dir='all', subs=None)
Returns a plot for Deflection along all three directions present in the Beam object.

Parameters
dir : string (default)
    Direction along which deflection plot is required. If no direction is specified, all plots are displayed.
subs : dictionary
Bending Moment along x direction

Bending Moment along y direction

Bending Moment along z direction
Examples

There is a beam of length 20 meters. It it supported by rollers at of its end. A linear load having slope equal to 12 is applied along y-axis. A constant distributed load of magnitude 15 N is applied from start till its end along z-axis.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam3D
>>> from sympy import symbols

>>> l, E, G, I, A, x = symbols('l, E, G, I, A, x')

>>> b = Beam3D(l=20, E=40, I=21, A=100, G=25, x=x)

>>> b.apply_load(15, start=0, order=0, dir="z")

>>> b.apply_load(12*x, start=0, order=0, dir="y")

>>> b.bc_deflection = [(0, [0, 0, 0]), (20, [0, 0, 0])]

>>> R1, R2, R3, R4 = symbols('R1, R2, R3, R4')

>>> b.apply_load(R1, start=0, order=-1, dir="z")

>>> b.apply_load(R2, start=20, order=-1, dir="z")

>>> b.solve_forReactionLoads(R1, R2, R3, R4)

>>> b.solve_slope_deflection()

>>> b.plot_deflection()

plot_loading_results(dir='x', subs=None)

Returns a subplot of Shear Force, Bending Moment, Slope and Deflection of the Beam object along the direction specified.

Parameters

dir: string (default)

Direction along which plots are required. If no direction is specified, plots along x-axis are displayed.

subs: dictionary

Python dictionary containing Symbols as key and their corresponding values.
Deflection along x direction

Deflection along y direction

Deflection along z direction
Examples

There is a beam of length 20 meters. It is supported by rollers at its end. A linear load having slope equal to 12 is applied along y-axis. A constant distributed load of magnitude 15 N is applied from start till its end along z-axis.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam3D
>>> from sympy import symbols

l, E, G, I, A, x = symbols('l, E, G, I, A, x')
>>> b = Beam3D(l, E, G, I, A, x)
>>> subs = {E: 40, G: 21, I: 100, A: 25}
>>> b.apply_load(15, start=0, order=0, dir="z")
>>> b.apply_load(12*x, start=0, order=0, dir="y")
>>> b.bc_deflection = [(0, [0, 0, 0]), (20, [0, 0, 0])]
>>> R1, R2, R3, R4 = symbols('R1, R2, R3, R4')
>>> b.apply_load(R1, start=0, order=-1, dir="z")
>>> b.apply_load(R2, start=20, order=-1, dir="z")
>>> b.apply_load(R3, start=0, order=-1, dir="y")
>>> b.apply_load(R4, start=20, order=-1, dir="y")
>>> b.solve_for_reaction_loads(R1, R2, R3, R4)
>>> b.solve_slope_deflection()
>>> b.plot_loading_results('y', subs)
PlotGrid object containing:
Plot[0]:Plot object containing:
  [0]: cartesian line: -6*x**2 for x over (0.0, 20.0)
Plot[1]:Plot object containing:
  [0]: cartesian line: -15*x**2/2 for x over (0.0, 20.0)
Plot[2]:Plot object containing:
  [0]: cartesian line: -x**3/1600 + 3*x**2/160 - x/8 for x over (0.0, 20.0)
  [1]: cartesian line: x**5/40000 - 4013*x**3/90300 + 26*x**2/43 +
       -1520*x/903 for x over (0.0, 20.0)
```

plot_shear_force(dir='all', subs=None)

Returns a plot for Shear force along all three directions present in the Beam object.

Parameters

dir : string (default)
    Direction along which shear force plot is required. If no direction is specified, all plots are displayed.

subs : dictionary
    Python dictionary containing Symbols as key and their corresponding values.
Shear Force along y direction

Bending Moment along y direction

Slope along y direction

Deflection along y direction
Examples

There is a beam of length 20 meters. It is supported by rollers at of its end. A linear load having slope equal to 12 is applied along y-axis. A constant distributed load of magnitude 15 N is applied from start till its end along z-axis.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam3D
global symbols
>>> l, E, G, I, A, x = symbols('l, E, G, I, A, x')
>>> b = Beam3D(20, E, G, I, A, x)
>>> b.apply_load(15, start=0, order=0, dir="z")
>>> b.apply_load(12*x, start=0, order=0, dir="y")
>>> b.bc_deflection = [(0, [0, 0, 0]), (20, [0, 0, 0])]
>>> R1, R2, R3, R4 = symbols('R1, R2, R3, R4')
>>> b.apply_load(R1, start=0, order=-1, dir="z")
>>> b.apply_load(R2, start=20, order=-1, dir="z")
>>> b.apply_load(R3, start=0, order=-1, dir="y")
>>> b.apply_load(R4, start=20, order=-1, dir="y")
>>> b.solve_for_reaction_loads(R1, R2, R3, R4)
>>> b.plot_shear_force()
```

plot\_shear\_stress\(dir='all', \text{subs=None}\)

Returns a plot for Shear Stress along all three directions present in the Beam object.

Parameters

- **dir** : string (default)
  Direction along which shear stress plot is required. If no direction is specified, all plots are displayed.

- **subs** : dictionary
  Python dictionary containing Symbols as key and their corresponding values.

Examples

There is a beam of length 20 meters and area of cross section 2 square meters. It is supported by rollers at of its end. A linear load having slope equal to 12 is applied along y-axis. A constant distributed load of magnitude 15 N is applied from start till its end along z-axis.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam3D
global symbols
>>> l, E, G, I, A, x = symbols('l, E, G, I, A, x')
>>> b = Beam3D(20, E, G, I, 2, x)
>>> b.apply_load(15, start=0, order=0, dir="z")
```
Shear Force along x direction

Shear Force along y direction

Shear Force along z direction
```python
>>> b.apply_load(12*x, start=0, order=0, dir="y")
>>> b.bc_deflection = [(0, [0, 0, 0]), (20, [0, 0, 0])]
>>> R1, R2, R3, R4 = symbols('R1, R2, R3, R4')
>>> b.apply_load(R1, start=0, order=-1, dir="z")
>>> b.apply_load(R2, start=20, order=-1, dir="z")
>>> b.apply_load(R3, start=0, order=-1, dir="y")
>>> b.apply_load(R4, start=20, order=-1, dir="y")
>>> b.solve_for_reaction_loads(R1, R2, R3, R4)
>>> b.plot_shear_stress()
```

Returns a plot for Slope along all three directions present in the Beam object.

**Parameters**
- **dir**: string (default 'all')
Direction along which Slope plot is required. If no direction is specified, all plots are displayed.

**subs**: dictionary

Python dictionary containing Symbols as keys and their corresponding values.

### Examples

There is a beam of length 20 meters. It is supported by rollers at its end. A linear load having slope equal to 12 is applied along y-axis. A constant distributed load of magnitude 15 N is applied from start till its end along z-axis.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam3D
>>> l, E, G, I, A = symbols('l, E, G, I, A')
>>> b = Beam3D(l, E, G, I, A)
```

```python
>>> b.apply_load(15, start=0, order=0, dir="z")
>>> b.apply_load(12*x, start=0, order=0, dir="y")
>>> b.bc_deflection = [(0, [0, 0, 0]), (20, [0, 0, 0])]
```

```python
>>> b.solve_for_reaction_loads(R1, R2, R3, R4)
```

```python
>>> b.solve_slope_deflection()
```

```python
>>> b.plot_slope()
```

`polar_moment()`

Returns the polar moment of area of the beam about the X axis with respect to the centroid.

### Examples

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam3D
>>> l, E, G, I, A = symbols('l, E, G, I, A')
>>> b = Beam3D(l, E, G, I, A)
```

```python
>>> b.polar_moment()
```

```python
>>> I1 = [9, 15]
```
property second_moment
Second moment of area of the Beam.

shear_force()
Returns a list of three expressions which represents the shear force curve of the
Beam object along all three axes.

property shear_modulus
Young’s Modulus of the Beam.

shear_stress()
Returns a list of three expressions which represents the shear stress curve of the
Beam object along all three axes.

tslope()
Returns a three element list representing slope of deflection curve along all the three
axes.

solve_for_reaction_loads(*reaction)
Solves for the reaction forces.

Examples
There is a beam of length 30 meters. It is supported by rollers at its end. A
constant distributed load of magnitude 8 N is applied from start till its end along
y-axis. Another linear load having slope equal to 9 is applied along z-axis.

>>> from sympy.physics.continuum_mechanics.beam import Beam3D
>>> l, E, G, I, A, x = symbols('l, E, G, I, A, x')
>>> b = Beam3D(l, E, G, I, A, x)
>>> b.apply_load(8, start=0, order=0, dir="y")
>>> b.apply_load(9*x, start=0, order=0, dir="z")
>>> b.bc_deflection = [(0, [0, 0, 0]), (30, [0, 0, 0])]
>>> R1, R2, R3, R4 = symbols('R1, R2, R3, R4')
>>> b.apply_load(R1, start=0, order=-1, dir="y")
>>> b.apply_load(R2, start=30, order=-1, dir="y")
>>> b.apply_load(R3, start=0, order=-1, dir="z")
>>> b.apply_load(R4, start=30, order=-1, dir="z")
>>> b.solve_for_reaction_loads(R1, R2, R3, R4)
>>> b.reaction_loads
{R1: -120, R2: -120, R3: -1350, R4: -2700}

solve_for_torsion()
Solves for the angular deflection due to the torsional effects of moments being
applied in the x-direction i.e. out of or into the beam.

Here, a positive torque means the direction of the torque is positive i.e. out of the
beam along the beam-axis. Likewise, a negative torque signifies a torque into the
beam cross-section.
Examples

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam3D
>>> from sympy import symbols
>>> l, E, G, I, A, x = symbols('l, E, G, I, A, x')
>>> b = Beam3D(20, E, G, I, A, x)
>>> b.apply_moment_load(4, 4, -2, dir='x')
>>> b.apply_moment_load(4, 8, -2, dir='x')
>>> b.apply_moment_load(4, 8, -2, dir='x')
>>> b.solve_for_torsion()
>>> b.angular_deflection().subs(x, 3)
18/(G*I)
```

torsional_moment()

Returns expression of Torsional moment present inside the Beam object.

Solving Beam Bending Problems using Singularity Functions

To make this document easier to read, enable pretty printing:

```python
>>> from sympy import *
>>> x, y, z = symbols('x y z')
>>> init_printing(use_unicode=True, wrap_line=False)
```

Beam

A planar beam is a structural element that is capable of withstanding load through resistance to internal shear and bending. Beams are characterized by their length, constraints, cross-sectional second moment of area, and elastic modulus. In SymPy, 2D beam objects are constructed by specifying the following properties:

- **Length**
- **Elastic Modulus**
- **Second Moment of Area**
- **Variable**: A symbol representing the location along the beam’s length. By default, this is set to Symbol(x).
- **Boundary Conditions**
  - bc_slope: Boundary conditions for slope.
  - bc_deflection: Boundary conditions for deflection.
- **Load Distribution**

Once the above are specified, the following methods are used to compute useful information about the loaded beam:

- `solve_for_reaction_loads()`
- `shear_force()`
- `bending_moment()`
• `slope()`

**Examples**

Below are examples of a variety two dimensional beam bending problems.

**Example 1**

A cantilever beam 9 meters in length has a distributed constant load of 8 kN/m applied downward from the fixed end over a 5 meter distance. A counterclockwise moment of 50 kN-m is applied 5 meters from the fixed end. Lastly, a downward point load of 12 kN is applied at the free end of the beam.

![Diagram of beam bending problem](image)

**Note:** The user is free to choose their own sign convention. In this case the downward forces and counterclockwise bending moment being positive.

The beam must be initialized with the length, modulus of elasticity, and the second moment of area. These quantities can be symbols or numbers.

```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> E, I = symbols('E, I')
>>> b = Beam(9, E, I)
```

The three loads are applied to the beam using the `apply_load()` method. This method supports point forces, point moments, and polynomial distributed loads of any order, i.e. \( c, cx, cx^2, cx^3, \ldots \).

The 12 kN point load is in the negative direction, at the location of 9 meters, and the polynomial order is specified as -1:

```python
>>> b.apply_load(12, 9, -1)
```

The `load` attribute can then be used to access the loading function in singularity function form:
Similarly, the positive moment can be applied with a polynomial order -2:

```python
>>> b.apply_load(50, 5, -2)
```

The distributed load is of order 0 and spans x=0 to x=5:

```python
>>> b.apply_load(8, 0, 0, end=5)
```

The fixed end imposes two boundary conditions: 1) no vertical deflection and 2) no rotation. These are specified by appending tuples of x values and the corresponding deflection or slope values:

```python
>>> b.bc_deflection.append((0, 0))
>>> b.bc_slope.append((0, 0))
```

These boundary conditions introduce an unknown reaction force and moment which need to be applied to the beam to maintain static equilibrium:

```python
>>> R, M = symbols('R, M')
>>> b.apply_load(R, 0, -1)
>>> b.apply_load(M, 0, -2)
>>> b.load
-2  -1  0   -2  0   -1
M·<x> + R·<x> + 8·<x> + 50·<x - 5> - 8·<x - 5> + 12·<x - 9>
```

These two variables can be solved for in terms of the applied loads and the final loading can be displayed:

```python
>>> b.solve_for_reaction_loads(R, M)
>>> b.reaction_loads
{M: 158, R: -52}
>>> b.load
-2  -1  0   -2  0   -1
158·<x> - 52·<x> + 8·<x> + 50·<x - 5> - 8·<x - 5> + 12·<x - 9>
```

At this point, the beam is fully defined and the internal shear and bending moments are calculated:

```python
>>> b.shear_force()
-1  0  1  1  0
- 158·<x> + 52·<x> - 8·<x> - 50·<x - 5> + 8·<x - 5> - 12·<x - 9>
```

```python
>>> b.bending_moment()
0  1  2  0  2  1
- 158·<x> + 52·<x> - 4·<x> - 50·<x - 5> + 4·<x - 5> - 12·<x - 9>
```

These can be visualized by calling the respective plot methods:

```python
>>> b.plot_shear_force()
>>> b.plot_bending_moment()
```
Shear Force

5.8. Topics
The beam will deform under load and the slope and deflection can be determined with:

```python
>>> b.slope()
\begin{pmatrix}
\frac{1}{3} & 2 & \frac{4 \cdot x}{3} \\
- \frac{158 \cdot x}{3} & \frac{26 \cdot x}{3} & - \frac{50 \cdot x - 5}{3} & + & \frac{4 \cdot x - 5}{3} & - \frac{6 \cdot x - 9}{3} \\
\end{pmatrix}

\frac{E \cdot I}{
\begin{pmatrix}
\frac{2}{3} & \frac{26 \cdot x}{3} & \frac{x}{3} & - \frac{25 \cdot x - 5}{3} & + & \frac{x - 5}{3} & - \frac{2 \cdot x - 9}{3} \\
\end{pmatrix}

\frac{E \cdot I}{\}

>>> b.deflection()
```

The slope and deflection of the beam can be plotted so long as numbers are provided for the modulus and second moment:

```python
>>> b.plot_slope(subs={E: 20E9, I: 3.25E-6})
>>> b.plot_deflection(subs={E: 20E9, I: 3.25E-6})
```

All of the plots can be shown in one figure with:
Example 2

There is a beam of length 30 meters. A moment of magnitude 120 Nm is applied in the counter-clockwise direction at the end of the beam. A point load of magnitude 8 N is applied from the top of the beam at the starting point. There are two simple supports below the beam. One at the end and another one at a distance of 10 meters from the start. The deflection is restricted at both the supports.

Note: Using the sign convention of downward forces and counterclockwise moment being positive.
```python
>>> from sympy.physics.continuum_mechanics.beam import Beam
>>> from sympy import symbols

>>> E, I = symbols('E, I')
>>> R1, R2 = symbols('R1, R2')

>>> b = Beam(30, E, I)
>>> b.apply_load(8, 0, -1)
>>> b.apply_load(R1, 10, -1)
>>> b.apply_load(R2, 30, -1)
>>> b.apply_load(120, 30, -2)

>>> b.bc_deflection.append((10, 0))
>>> b.bc_deflection.append((30, 0))

>>> b.solve_for_reaction_loads(R1, R2)

>>> b.reaction_loads

Example 11

Any type of load defined by a polynomial can be applied to the beam. This allows approximation of arbitrary load distributions. The following example shows six truncated polynomial loads across the surface of a beam.

```python
>>> n = 6
>>> b = Beam(10**n, E, I)
>>> for i in range(n):
...     b.apply_load(1 / (5**i), 10*i + 5, i, end=10*i + 10)
>>> plot(b.load, (x, 0, 10**n))
```

![Graph showing six truncated polynomial loads across the surface of a beam.](image)
Truss

Truss (Docstrings)

This module can be used to solve problems related to 2D Trusses.

```python
from sympy.physics.continuum_mechanics.truss import Truss
```

A Truss is an assembly of members such as beams, connected by nodes, that create a rigid structure. In engineering, a truss is a structure that consists of two-force members only.

Trusses are extremely important in engineering applications and can be seen in numerous real-world applications like bridges.

Examples

There is a Truss consisting of four nodes and five members connecting the nodes. A force $P$ acts downward on the node D and there also exist pinned and roller joints on the nodes A and B respectively.

```python
>>> t = Truss()
>>> t.add_node("node_1", 0, 0)
>>> t.add_node("node_2", 6, 0)
>>> t.add_node("node_3", 2, 2)
>>> t.add_node("node_4", 2, 0)
>>> t.add_member("member_1", "node_1", "node_4")
>>> t.add_member("member_2", "node_2", "node_4")
>>> t.add_member("member_3", "node_1", "node_3")
>>> t.add_member("member_4", "node_2", "node_3")
>>> t.add_member("member_5", "node_3", "node_4")
>>> t.apply_load("node_4", magnitude=10, direction=270)
>>> t.apply_support("node_1", type="fixed")
>>> t.apply_support("node_2", type="roller")
```

add_member($label$, $start$, $end$)

This method adds a member between any two nodes in the given truss.
Parameters

**label**: String or Symbol

The label for a member. It is the only way to identify a particular member.

**start**: String or Symbol

The label of the starting point/node of the member.

**end**: String or Symbol

The label of the ending point/node of the member.

Examples

```python
>>> from sympy.physics.continuum_mechanics.truss import Truss
>>> t = Truss()
>>> t.add_node('A', 0, 0)
>>> t.add_node('B', 3, 0)
>>> t.add_node('C', 2, 2)
>>> t.add_member('AB', 'A', 'B')
>>> t.members
{'AB': ['A', 'B']}
```

**add_node**(label, x, y)

This method adds a node to the truss along with its name/label and its location.

Parameters

**label**: String or a Symbol

The label for a node. It is the only way to identify a particular node.

**x**: Sympifyable

The x-coordinate of the position of the node.

**y**: Sympifyable

The y-coordinate of the position of the node.

Examples

```python
>>> from sympy.physics.continuum_mechanics.truss import Truss
>>> t = Truss()
>>> t.add_node('A', 0, 0)
>>> t.nodes
[('A', 0, 0)]
>>> t.add_node('B', 3, 0)
>>> t.nodes
[('A', 0, 0), ('B', 3, 0)]
```

**apply_load**(location, magnitude, direction)

This method applies an external load at a particular node

Parameters

**location**: String or Symbol
Label of the Node at which load is applied.

**magnitude: Sympifyable**

Magnitude of the load applied. It must always be positive and any changes in the direction of the load are not reflected here.

**direction: Sympifyable**

The angle, in degrees, that the load vector makes with the horizontal in the counter-clockwise direction. It takes the values 0 to 360, inclusive.

### Examples

```python
>>> from sympy.physics.continuum_mechanics.truss import Truss
>>> from sympy import symbols
>>> t = Truss()
>>> t.add_node('A', 0, 0)
>>> t.add_node('B', 3, 0)
>>> P = symbols('P')
>>> t.apply_load('A', P, 90)
>>> t.apply_load('A', P/2, 45)
>>> t.apply_load('A', P/4, 90)
>>> t.loads
{'A': [[P, 90], [P/2, 45], [P/4, 90]]}
```

**apply_support(location, type)**

This method adds a pinned or roller support at a particular node.

---

#### Parameters

- **location: String or Symbol**
  
  Label of the Node at which support is added.

- **type: String**
  
  Type of the support being provided at the node.

### Examples

```python
>>> from sympy.physics.continuum_mechanics.truss import Truss
>>> t = Truss()
>>> t.add_node('A', 0, 0)
>>> t.add_node('B', 3, 0)
>>> t.apply_support('A', 'pinned')
>>> t.supports
{'A': 'pinned'}
```

**change_member_label(label, new_label)**

This method changes the label of a member.

---

#### Parameters

- **label: String or Symbol**
  
  The label of the member for which the label has to be changed.
new_label: String or Symbol

The new label of the member.

Examples

```python
>>> from sympy.physics.continuum_mechanics.truss import Truss
>>> t = Truss()
>>> t.add_node('A', 0, 0)
>>> t.add_node('B', 3, 0)
>>> t.nodes
[('A', 0, 0), ('B', 3, 0)]
>>> t.change_node_label('A', 'C')
>>> t.nodes
[('C', 0, 0), ('B', 3, 0)]
>>> t.add_member('BC', 'B', 'C')
>>> t.members
{'BC': ['B', 'C']}
>>> t.change_member_label('BC', 'BC_new')
>>> t.members
{'BC_new': ['B', 'C']}
```

change_node_label(label, new_label)

This method changes the label of a node.

Parameters

- **label**: String or Symbol
  - The label of the node for which the label has to be changed.

- **new_label**: String or Symbol
  - The new label of the node.

Examples

```python
>>> from sympy.physics.continuum_mechanics.truss import Truss
>>> t = Truss()
>>> t.add_node('A', 0, 0)
>>> t.add_node('B', 3, 0)
>>> t.nodes
[('A', 0, 0), ('B', 3, 0)]
>>> t.change_node_label('A', 'C')
>>> t.nodes
[('C', 0, 0), ('B', 3, 0)]
```

property internal_forces

Returns the internal forces for all members which are all initialized to 0.

property loads

Returns the loads acting on the truss.
**property member_labels**
Returns the members of the truss along with the start and end points.

**property members**
Returns the members of the truss along with the start and end points.

**property node_labels**
Returns the node labels of the truss.

**property node_positions**
Returns the positions of the nodes of the truss.

**property nodes**
Returns the nodes of the truss along with their positions.

**property reaction_loads**
Returns the reaction forces for all supports which are all initialized to 0.

**remove_load**(location, magnitude, direction)
This method removes an already present external load at a particular node

Parameters

**location**: String or Symbol
Label of the Node at which load is applied and is to be removed.

**magnitude**: Sympifyable
Magnitude of the load applied.

**direction**: Sympifyable
The angle, in degrees, that the load vector makes with the horizontal in the counter-clockwise direction. It takes the values 0 to 360, inclusive.

**Examples**

```python
>>> from sympy.physics.continuum_mechanics.truss import Truss
>>> from sympy import symbols
>>> t = Truss()
>>> t.add_node('A', 0, 0)
>>> t.add_node('B', 3, 0)
>>> P = symbols('P')
>>> t.apply_load('A', P, 90)
>>> t.apply_load('A', P/2, 45)
>>> t.apply_load('A', P/4, 90)
>>> t.loads
{'A': [[P, 90], [P/2, 45], [P/4, 90]]}
>>> t.remove_load('A', P/4, 90)
>>> t.loads
{'A': [[P, 90], [P/2, 45]]}
```

**remove_member**(label)
This method removes a member from the given truss.
Parameters

label: String or Symbol

The label for the member to be removed.

Examples

```python
>>> from sympy.physics.continuum_mechanics.truss import Truss
>>> t = Truss()
>>> t.add_node('A', 0, 0)
>>> t.add_node('B', 3, 0)
>>> t.add_node('C', 2, 2)
>>> t.add_member('AB', 'A', 'B')
>>> t.add_member('AC', 'A', 'C')
>>> t.add_member('BC', 'B', 'C')
>>> t.members
{'AB': ['A', 'B'], 'AC': ['A', 'C'], 'BC': ['B', 'C']}
>>> t.remove_member('AC')
>>> t.members
{'AB': ['A', 'B'], 'BC': ['B', 'C']}
```

remove_node(label)

This method removes a node from the truss.

Parameters

label: String or Symbol

The label of the node to be removed.

Examples

```python
>>> from sympy.physics.continuum_mechanics.truss import Truss
>>> t = Truss()
>>> t.add_node('A', 0, 0)
>>> t.add_node('B', 3, 0)
>>> t.nodes
[('A', 0, 0)]
>>> t.add_node('B', 3, 0)
>>> t.nodes
[('A', 0, 0), ('B', 3, 0)]
>>> t.remove_node('A')
>>> t.nodes
[('B', 3, 0)]
```

remove_support(location)

This method removes support from a particular node.

Parameters

location: String or Symbol

Label of the Node at which support is to be removed.
Examples

```python
>>> from sympy.physics.continuum_mechanics.truss import Truss
>>> t = Truss()
>>> t.add_node('A', 0, 0)
>>> t.add_node('B', 3, 0)
>>> t.apply_support('A', 'pinned')
>>> t.supports
{'A': 'pinned'}
>>> t.remove_support('A')
>>> t.supports
{}```

`solve()`

This method solves for all reaction forces of all supports and all internal forces of all the members in the truss, provided the Truss is solvable.

A Truss is solvable if the following condition is met,

\[\text{2n} \geq \text{r + m}\]

Where \(n\) is the number of nodes, \(r\) is the number of reaction forces, where each pinned support has 2 reaction forces and each roller has 1, and \(m\) is the number of members.

The given condition is derived from the fact that a system of equations is solvable only when the number of variables is lesser than or equal to the number of equations. Equilibrium Equations in x and y directions give two equations per node giving \(2n\) number equations. However, the truss needs to be stable as well and may be unstable if \(2n > r + m\). The number of variables is simply the sum of the number of reaction forces and member forces.

**Note:** The sign convention for the internal forces present in a member revolves around whether each force is compressive or tensile. While forming equations for each node, internal force due to a member on the node is assumed to be away from the node i.e. each force is assumed to be compressive by default. Hence, a positive value for an internal force implies the presence of compressive force in the member and a negative value implies a tensile force.

Examples

```python
>>> from sympy.physics.continuum_mechanics.truss import Truss
>>> t = Truss()
>>> t.add_node("node_1", 0, 0)
>>> t.add_node("node_2", 6, 0)
>>> t.add_node("node_3", 2, 2)
>>> t.add_node("node_4", 2, 0)
>>> t.add_member("member_1", "node_1", "node_2")
>>> t.add_member("member_2", "node_2", "node_4")
>>> t.add_member("member_3", "node_1", "node_3")
>>> t.add_member("member_4", "node_2", "node_3")
>>> t.add_member("member_5", "node_3", "node_4")
```

(continues on next page)
>>> t.apply_load("node_4", magnitude=10, direction=270)
>>> t.apply_support("node_1", type="pinned")
>>> t.apply_support("node_2", type="roller")
>>> t.solve()
>>> t.reaction_loads
{'R_node_1_x': 0, 'R_node_1_y': 20/3, 'R_node_2_y': 10/3}
>>> t.internal_forces
{'member_1': 20/3, 'member_2': 20/3, 'member_3': -20*sqrt(2)/3,
 'member_4': -10*sqrt(5)/3, 'member_5': 10}

**property supports**

Returns the nodes with provided supports along with the kind of support provided i.e. pinned or roller.

### 5.8.7 Utilities

#### Contents

**Testing**

This module contains code for running the tests in SymPy.

Contents:

- **pytest**

  pytest hacks to support XFAIL/XPASS

  sympy.testing.pytest.SKIP(reason)

    Similar to skip(), but this is a decorator.

  sympy.testing.pytest.nocache_fail(func)

    Dummy decorator for marking tests that fail when cache is disabled

  sympy.testing.pytest.raises(expectedException, code=None)

    Tests that code raises the exception expectedException.

    code may be a callable, such as a lambda expression or function name.

    If code is not given or None, raises will return a context manager for use in with statements; the code to execute then comes from the scope of the with.

    raises() does nothing if the callable raises the expected exception, otherwise it raises an AssertionError.
Examples

```python
>>> from sympy.testing.pytest import raises

>>> raises(ZeroDivisionError, lambda: 1/0)
<ExceptionInfo ZeroDivisionError(...)>

>>> raises(ZeroDivisionError, lambda: 1/0)
Failed: DID NOT RAISE

>>> raises(ZeroDivisionError, lambda: 1/2)
Traceback (most recent call last):
... Failed: DID NOT RAISE

Note that you cannot test multiple statements via with raises:

```python
>>> with raises(ZeroDivisionError):
...     n = 1/0  # will execute and raise, aborting the `with`
...     n = 9999/0  # never executed
```

This is just what with is supposed to do: abort the contained statement sequence at the first exception and let the context manager deal with the exception.

To test multiple statements, you’ll need a separate with for each:

```python
>>> with raises(ZeroDivisionError):
...     n = 1/0  # will execute and raise
>>> with raises(ZeroDivisionError):
...     n = 9999/0  # will also execute and raise
```

sympy.testing.pytest.skip_under_pyodide(message)
Decorator to skip a test if running under pyodide.

sympy.testing.pytest.warns(warningcls, *, match='', test_stacklevel=True)
Like raises but tests that warnings are emitted.

```python
>>> from sympy.testing.pytest import warns
>>> import warnings

>>> with warns(UserWarning):
...     warnings.warn('deprecated', UserWarning, stacklevel=2)

>>> with warns(UserWarning):
...     pass
Traceback (most recent call last):
...     Failed: DID NOT WARN. No warnings of type UserWarning was emitted.
```

The list of emitted warnings is: [].

5.8. Topics
test_stacklevel makes it check that the stacklevel parameter to warn() is set so that
the warning shows the user line of code (the code under the warns() context manager).
Set this to False if this is ambiguous or if the context manager does not test the direct
user code that emits the warning.

If the warning is a SymPyDeprecationWarning, this additionally tests that the
active_deprecations_target is a real target in the active-deprecations.md file.

```python
sympy.testing.pytest.warns_deprecated_sympy()
```

Shorthand for warns(SymPyDeprecationWarning)

This is the recommended way to test that SymPyDeprecationWarning is emitted for depre-
cated features in SymPy. To test for other warnings use warns. To suppress warnings
without asserting that they are emitted use ignore_warnings.

**Note:** warns_deprecated_sympy() is only intended for internal use in the SymPy test
suite to test that a deprecation warning triggers properly. All other code in the SymPy
codebase, including documentation examples, should not use deprecated behavior.

If you are a user of SymPy and you want to disable SymPyDeprecationWarnings, use
warnings filters (see *Silencing SymPy Deprecation Warnings* (page 214)).

```python
>>> from sympy.testing.pytest import warns_deprecated_sympy
>>> from sympy.utilities.exceptions import sympy_deprecation_warning
```

```python
>>> with warns_deprecated_sympy():
    ...
    sympy_deprecation_warning("Don't use",
    ...
    deprecated_since_version="1.0",
    ...
    active_deprecations_target="active-deprecations")
```

```python
>>> with warns_deprecated_sympy():
    ...
    pass
```

`Traceback (most recent call last):`

```python
Failed: DID NOT WARN. No warnings of type SymPyDeprecationWarning were emitted. The list of emitted warnings is: [].
```

**Note:** Sometimes the stacklevel test will fail because the same warning is emitted mul-
tiple times. In this case, you can use sympy.utilities.exceptions.ignore_warnings() (page 2138) in the code to prevent the SymPyDeprecationWarning from being emitted
gain recursively. In rare cases it is impossible to have a consistent stacklevel for dep-
recation warnings because different ways of calling a function will produce different call
stacks.. In those cases, use warns(SymPyDeprecationWarning) instead.

**See also:**

sympy.utilities.exceptions.SymPyDeprecationWarning (page 2137), sympy.
utilities.exceptions.sympy_deprecation_warning (page 2138), sympy.utilities.
decorator.deprecated (page 2128)
Randomised Testing

Deprecated since version 1.10: sympy.testing.randtest functions have been moved to sympy.core.random (page 1122).

Run Tests

This is our testing framework.

Goals:

• it should be compatible with py.test and operate very similarly (or identically)
• does not require any external dependencies
• preferably all the functionality should be in this file only
• no magic, just import the test file and execute the test functions, that’s it
• portable

class sympy.testing.runtests.PyTestReporter(verbosel=False, tb='short', colorsel=True,
force_colorsel=False, splitel=None)

Py.test like reporter. Should produce output identical to py.test.

write(text, color='', align='left', width=None, force_colorsel=False)

Prints a text on the screen.

It uses sys.stdout.write(), so no readline library is necessary.

Parameters

color : choose from the colors below, ”” means default color

align : “left”/"right", “left” is a normal print, “right” is aligned on
the right-hand side of the screen, filled with spaces if necessary

width : the screen width

class sympy.testing.runtests.Reporter

Parent class for all reporters.

class sympy.testing.runtests.SymPyDocTestFinder(verbosel=False,
parser=<doctest.DocTestParser object>, recurseel=True,
exclude_emptyel=True)

A class used to extract the DocTests that are relevant to a given object, from its doc-
string and the docstrings of its contained objects. Doctests can currently be extracted
from the following object types: modules, functions, classes, methods, staticmethods,
classmethods, and properties.

Modified from doctest’s version to look harder for code that appears comes from a dif-
ferent module. For example, the @vectorize decorator makes it look like functions come
from multidimensional.py even though their code exists elsewhere.

class sympy.testing.runtests.SymPyDocTestRunner(checker=None, verbosel=None,
optionflags=0)

A class used to run DocTest test cases, and accumulate statistics. The run method is
used to process a single DocTest case. It returns a tuple (f, t), where t is the number of
test cases tried, and f is the number of test cases that failed.

5.8. Topics
Modified from the doctest version to not reset the sys.displayhook (see issue 5140).
See the docstring of the original DocTestRunner for more information.

```python
run(test, compileflags=None, out=None, clear_globs=True)
```
Run the examples in `test`, and display the results using the writer function `out`.

The examples are run in the namespace `test.globs`. If `clear_globs` is true (the default), then this namespace will be cleared after the test runs, to help with garbage collection. If you would like to examine the namespace after the test completes, then use `clear_globs=False`.

`compileflags` gives the set of flags that should be used by the Python compiler when running the examples. If not specified, then it will default to the set of future-import flags that apply to `globs`.

The output of each example is checked using SymPyDocTestRunner.check_output, and the results are formatted by the SymPyDocTestRunner.report_* methods.

class sympy.testing.runtests.SymPyOutputChecker
Compared to the OutputChecker from the stdlib our OutputChecker class supports numerical comparison of floats occurring in the output of the doctest examples

```python
check_output(want, got, optionflags)
```
Return True iff the actual output from an example (`got`) matches the expected output (`want`). These strings are always considered to match if they are identical; but depending on what option flags the test runner is using, several non-exact match types are also possible. See the documentation for TestRunner for more information about option flags.

class sympy.testing.runtests.SymPyTestResults(failed, attempted)

`attempted`  
Alias for field number 1

`failed`  
Alias for field number 0

```python
convert_to_native_paths(lst)
```
Converts a list of ‘/’ separated paths into a list of native (os.sep separated) paths and converts to lowercase if the system is case insensitive.

```python
doctest(*paths, subprocess=True, rerun=0, **kwargs)
```
Runs doctests in all *.py files in the SymPy directory which match any of the given strings in `paths` or all tests if `paths=[]`.

Notes:
- Paths can be entered in native system format or in unix, forward-slash format.
- Files that are on the blacklist can be tested by providing their path; they are only excluded if no paths are given.
Examples

```python
>>> import sympy
```

Run all tests:
```python
>>> sympy.doctest()
```

Run one file:
```python
>>> sympy.doctest("sympy/core/basic.py")
>>> sympy.doctest("polynomial.rst")
```

Run all tests in sympy/functions/ and some particular file:
```python
>>> sympy.doctest("/functions", "basic.py")
```

Run any file having polynomial in its name, doc/src/modules/polynomial.rst, sympy/functions/special/polynomials.py, and sympy/polys/polynomial.py:
```python
>>> sympy.doctest("polynomial")
```

The split option can be passed to split the test run into parts. The split currently only splits the test files, though this may change in the future. `split` should be a string of the form ‘a/b’, which will run part a of b. Note that the regular doctests and the Sphinx doctests are split independently. For instance, to run the first half of the test suite:
```python
>>> sympy.doctest(split='1/2')
```

The subprocess and verbose options are the same as with the function `test()` (see the docstring of that function for more information) except that verbose may also be set equal to 2 in order to print individual doctest lines, as they are being tested.

`sympy.testing.runtests.get_sympy_dir()`
Returns the root SymPy directory and set the global value indicating whether the system is case sensitive or not.

`sympy.testing.runtests.raise_on_deprecated()`
Context manager to make DeprecationWarning raise an error

This is to catch SymPyDeprecationWarning from library code while running tests and doctests. It is important to use this context manager around each individual test/doctest in case some tests modify the warning filters.

`sympy.testing.runtests.run_all_tests(test_args=(), test_kwargs=None, doctest_args=(), doctest_kwargs=None, examples_args=(), examples_kwargs=None)`

Run all tests.

Right now, this runs the regular tests (bin/test), the doctests (bin/doctest), and the examples (examples/all.py).

This is what `setup.py test` uses.

You can pass arguments and keyword arguments to the test functions that support them (for now, test, doctest, and the examples). See the docstrings of those functions for a description of the available options.
For example, to run the solvers tests with colors turned off:

```python
>>> from sympy.testing.runtests import run_all_tests
>>> run_all_tests(test_args=("solvers"),
... test_kwargs={"colors:False"})
```

sympy.testing.runtests.run_in_subprocess_with_hash_randomization(function, function_args=(), function_kwargs=None, command='/opt/hostedtoolcache/Python/3.10.14/x64/bin/python', module='sympy.testing.runtests', force=False)

Run a function in a Python subprocess with hash randomization enabled.

If hash randomization is not supported by the version of Python given, it returns False. Otherwise, it returns the exit value of the command. The function is passed to sys.exit(), so the return value of the function will be the return value.

The environment variable PYTHONHASHSEED is used to seed Python's hash randomization. If it is set, this function will return False, because starting a new subprocess is unnecessary in that case. If it is not set, one is set at random, and the tests are run. Note that if this environment variable is set when Python starts, hash randomization is automatically enabled. To force a subprocess to be created even if PYTHONHASHSEED is set, pass force=True. This flag will not force a subprocess in Python versions that do not support hash randomization (see below), because those versions of Python do not support the -R flag.

function should be a string name of a function that is importable from the module module, like "_test". The default for module is "sympy.testing.runtests". function_args and function_kwargs should be a repr-able tuple and dict, respectively. The default Python command is sys.executable, which is the currently running Python command.

This function is necessary because the seed for hash randomization must be set by the environment variable before Python starts. Hence, in order to use a predetermined seed for tests, we must start Python in a separate subprocess.

Hash randomization was added in the minor Python versions 2.6.8, 2.7.3, 3.1.5, and 3.2.3, and is enabled by default in all Python versions after and including 3.3.0.

Examples

```python
>>> from sympy.testing.runtests import (  
... run_in_subprocess_with_hash_randomization)
>>> # run the core tests in verbose mode
>>> run_in_subprocess_with_hash_randomization("_test",
... function_args=("core"),
... function_kwargs={'verbose': True})
# Will return 0 if sys.executable supports hash randomization and tests
# pass, 1 if they fail, and False if it does not support hash
# randomization.
```
sympy.testing.runtests.split_list(l, split, density=None)

Splits a list into part a of b

split should be a string of the form ‘a/b’. For instance, ‘1/3’ would give the split one of three.

If the length of the list is not divisible by the number of splits, the last split will have more items.

density may be specified as a list. If specified, tests will be balanced so that each split has as equal-as-possible amount of mass according to density.

```python
>>> from sympy.testing.runtests import split_list
>>> a = list(range(10))
>>> split_list(a, '1/3')
[0, 1, 2]
>>> split_list(a, '2/3')
[3, 4, 5]
>>> split_list(a, '3/3')
[6, 7, 8, 9]
```

sympy.testing.runtests.sympytestfile(filename, module_relative=True, name=None, package=None, globs=None, verbose=None, report=True, optionflags=0, extraglobs=None, raise_on_error=False, parser=<doctest.DocTestParser object>, encoding=None)

Test examples in the given file. Return (#failures, #tests).

Optional keyword arg module_relative specifies how filenames should be interpreted:

- If module_relative is True (the default), then filename specifies a module-relative path. By default, this path is relative to the calling module’s directory; but if the package argument is specified, then it is relative to that package. To ensure os-independence, filename should use “/” characters to separate path segments, and should not be an absolute path (i.e., it may not begin with “/”).

- If module_relative is False, then filename specifies an os-specific path. The path may be absolute or relative (to the current working directory).

Optional keyword arg name gives the name of the test; by default use the file’s basename.

Optional keyword argument package is a Python package or the name of a Python package whose directory should be used as the base directory for a module relative filename. If no package is specified, then the calling module’s directory is used as the base directory for module relative filenames. It is an error to specify package if module_relative is False.

Optional keyword arg globs gives a dict to be used as the globals when executing examples; by default, use {}. A copy of this dict is actually used for each docstring, so that each docstring’s examples start with a clean slate.

Optional keyword arg extraglobs gives a dictionary that should be merged into the globals that are used to execute examples. By default, no extra globals are used.

Optional keyword arg verbose prints lots of stuff if true, prints only failures if false; by default, it’s true iff “-v” is in sys.argv.

5.8. Topics
Optional keyword arg `report` prints a summary at the end when true, else prints nothing at the end. In verbose mode, the summary is detailed, else very brief (in fact, empty if all tests passed).

Optional keyword arg `optionflags` or `s` together module constants, and defaults to 0. Possible values (see the docs for details):

- `DONT_ACCEPT_TRUE_FOR_1`
- `DONT_ACCEPT_BLANKLINE`
- `NORMALIZE_WHITESPACE`
- `ELLIPSIS`
- `SKIP`
- `IGNORE_EXCEPTION_DETAIL`
- `REPORT_UDIFF`
- `REPORT_CDIFF`
- `REPORT_NDIFF`
- `REPORT_ONLY_FIRST_FAILURE`

Optional keyword arg `raise_on_error` raises an exception on the first unexpected exception or failure. This allows failures to be post-mortem debugged.

Optional keyword arg `parser` specifies a `DocTestParser` (or subclass) that should be used to extract tests from the files.

Optional keyword arg `encoding` specifies an encoding that should be used to convert the file to unicode.

Advanced tomfoolery: `testmod` runs methods of a local instance of class `doctest.Tester`, then merges the results into (or creates) global `Tester` instance `doctest.master`. Methods of `doctest.master` can be called directly too, if you want to do something unusual. Passing `report=0` to `testmod` is especially useful then, to delay displaying a summary. Invoke `doctest.master.summarize(verbos)` when you’re done fiddling.

```python
sympy.testing.runtests.test(*paths, subprocess=True, rerun=0, **kwargs)
```

Run tests in the specified test_*.py files.

Tests in a particular test_*.py file are run if any of the given strings in `paths` matches a part of the test file’s path. If `paths=[]`, tests in all test_*.py files are run.

Notes:

- If `sort=False`, tests are run in random order (not default).
- Paths can be entered in native system format or in unix, forward-slash format.
- Files that are on the blacklist can be tested by providing their path; they are only excluded if no paths are given.

**Explanation of test results**
<table>
<thead>
<tr>
<th>Output</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>.</td>
<td>passed</td>
</tr>
<tr>
<td>F</td>
<td>failed</td>
</tr>
<tr>
<td>X</td>
<td>XPassed (expected to fail but passed)</td>
</tr>
<tr>
<td>f</td>
<td>XFAILed (expected to fail and indeed failed)</td>
</tr>
<tr>
<td>s</td>
<td>skipped</td>
</tr>
<tr>
<td>w</td>
<td>slow</td>
</tr>
<tr>
<td>T</td>
<td>timeout (e.g., when --timeout is used)</td>
</tr>
<tr>
<td>K</td>
<td>KeyboardInterrupt (when running the slow tests with --slow, you can interrupt one of them without killing the test runner)</td>
</tr>
</tbody>
</table>

Colors have no additional meaning and are used just to facilitate interpreting the output.

**Examples**

```python
>>> import sympy
```

Run all tests:

```python
>>> sympy.test()
```

Run one file:

```python
>>> sympy.test("sympy/core/tests/test_basic.py")
>>> sympy.test("_basic")
```

Run all tests in sympy/functions/ and some particular file:

```python
>>> sympy.test("sympy/core/tests/test_basic.py",...
          "sympy/functions")
```

Run all tests in sympy/core and sympy/utilities:

```python
>>> sympy.test("/core", "/util")
```

Run specific test from a file:

```python
>>> sympy.test("sympy/core/tests/test_basic.py",...
            kw="test_equality")
```

Run specific test from any file:

```python
>>> sympy.test(kw="subs")
```

Run the tests with verbose mode on:

```python
>>> sympy.test(verbosetrue)
```

Do not sort the test output:
>>> sympy.test(sort=False)

Turn on post-mortem pdb:

>>> sympy.test(pdb=True)

Turn off colors:

>>> sympy.test(colors=False)

Force colors, even when the output is not to a terminal (this is useful, e.g., if you are piping to less -r and you still want colors)

>>> sympy.test(force_colors=False)

The traceback verboseness can be set to "short" or "no" (default is "short")

>>> sympy.test(tb='no')

The split option can be passed to split the test run into parts. The split currently only splits the test files, though this may change in the future. split should be a string of the form ‘a/b’, which will run part a of b. For instance, to run the first half of the test suite:

>>> sympy.test(split='1/2')

The time_balance option can be passed in conjunction with split. If time_balance=True (the default for sympy.test), SymPy will attempt to split the tests such that each split takes equal time. This heuristic for balancing is based on pre-recorded test data.

>>> sympy.test(split='1/2', time_balance=True)

You can disable running the tests in a separate subprocess using subprocess=False. This is done to support seeding hash randomization, which is enabled by default in the Python versions where it is supported. If subprocess=False, hash randomization is enabled/disabled according to whether it has been enabled or not in the calling Python process. However, even if it is enabled, the seed cannot be printed unless it is called from a new Python process.

Hash randomization was added in the minor Python versions 2.6.8, 2.7.3, 3.1.5, and 3.2.3, and is enabled by default in all Python versions after and including 3.3.0.

If hash randomization is not supported subprocess=False is used automatically.

>>> sympy.test(subprocess=False)

To set the hash randomization seed, set the environment variable PYTHONHASHSEED before running the tests. This can be done from within Python using

>>> import os
>>> os.environ['PYTHONHASHSEED'] = '42'

Or from the command line using

$ PYTHONHASHSEED=42 ./bin/test

If the seed is not set, a random seed will be chosen.
Note that to reproduce the same hash values, you must use both the same seed as well as the same architecture (32-bit vs. 64-bit).

Utilities

This module contains some general purpose utilities that are used across SymPy.

Contents:

Autowrap Module

The autowrap module works very well in tandem with the Indexed classes of the Tensor (page 1432). Here is a simple example that shows how to setup a binary routine that calculates a matrix-vector product.

```python
>>> from sympy.utilities.autowrap import autowrap
>>> from sympy import symbols, IndexedBase, Idx, Eq

>>> A, x, y = map(IndexedBase, ['A', 'x', 'y'])

>>> m, n = symbols('m n', integer=True)

>>> i = Idx('i', m)

>>> j = Idx('j', n)

>>> instruction = Eq(y[i], A[i,j]*x[j])

>>> matvec = autowrap(instruction)
```

Because the code printers treat Indexed objects with repeated indices as a summation, the above equality instance will be translated to low-level code for a matrix-vector product. This is how you tell SymPy to generate the code, compile it and wrap it as a python function:

```python
>>> matvec(M, [2, 3])
[ 3.  2.]
```

Implementation details

The autowrap module is implemented with a backend consisting of CodeWrapper objects. The base class CodeWrapper takes care of details about module name, filenames and options. It also contains the driver routine, which runs through all steps in the correct order, and also takes care of setting up and removing the temporary working directory.

The actual compilation and wrapping is done by external resources, such as the system installed f2py command. The Cython backend runs a distutils setup script in a subprocess. Subclasses of CodeWrapper takes care of these backend-dependent details.
API Reference

Module for compiling codegen output, and wrap the binary for use in python.

**Note:** To use the autowrap module it must first be imported

```python
>>> from sympy.utilities.autowrap import autowrap
```

This module provides a common interface for different external backends, such as f2py, fwrap, Cython, SWIG(?) etc. (Currently only f2py and Cython are implemented) The goal is to provide access to compiled binaries of acceptable performance with a one-button user interface, e.g.,

```python
>>> from sympy.abc import x,y
>>> expr = (x - y)**25
>>> flat = expr.expand()
>>> binary_callable = autowrap(flat)
>>> binary_callable(2, 3)
-1.0
```

Although a SymPy user might primarily be interested in working with mathematical expressions and not in the details of wrapping tools needed to evaluate such expressions efficiently in numerical form, the user cannot do so without some understanding of the limits in the target language. For example, the expanded expression contains large coefficients which result in loss of precision when computing the expression:

```python
>>> binary_callable(3, 2)
0.0
>>> binary_callable(4, 5), binary_callable(5, 4)
(-22925376.0, 25165824.0)
```

Wrapping the unexpanded expression gives the expected behavior:

```python
>>> e = autowrap(expr)
>>> e(4, 5), e(5, 4)
(-1.0, 1.0)
```

The callable returned from autowrap() is a binary Python function, not a SymPy object. If it is desired to use the compiled function in symbolic expressions, it is better to use binary_function() which returns a SymPy Function object. The binary callable is attached as the _imp_attribute and invoked when a numerical evaluation is requested with evalf(), or with lambdify().

```python
>>> from sympy.utilities.autowrap import binary_function
>>> f = binary_function('f', expr)
>>> 2*f(x, y) + y
y + 2*f(x, y)
>>> (2*f(x, y) + y).evalf(2, subs={x: 1, y:2})
0.e-110
```

When is this useful?

1) For computations on large arrays, Python iterations may be too slow, and depending on the mathematical expression, it may be difficult to exploit the advanced index operations provided by NumPy.
2) For really long expressions that will be called repeatedly, the compiled binary should be significantly faster than SymPy’s .evalf()

3) If you are generating code with the codegen utility in order to use it in another project, the automatic Python wrappers let you test the binaries immediately from within SymPy.

4) To create customized ufuncs for use with numpy arrays. See ufuncify.

When is this module NOT the best approach?

1) If you are really concerned about speed or memory optimizations, you will probably get better results by working directly with the wrapper tools and the low level code. However, the files generated by this utility may provide a useful starting point and reference code. Temporary files will be left intact if you supply the keyword tempdir="path/to/files/".

2) If the array computation can be handled easily by numpy, and you do not need the binaries for another project.

class sympy.utilities.autowrap.CodeWrapper(generator, filepath=None, flags=[], verbose=False)

Base Class for code wrappers

class sympy.utilities.autowrap.CythonCodeWrapper(*args, **kwargs)

Wrapper that uses Cython
dump_pyx(routines, f, prefix)
Write a Cython file with Python wrappers
This file contains all the definitions of the routines in c code and refers to the header file.

Arguments

routines
List of Routine instances

f
File-like object to write the file to

prefix
The filename prefix, used to refer to the proper header file. Only the basename of the prefix is used.

class sympy.utilities.autowrap.DummyWrapper(generator, filepath=None, flags=[], verbose=False)

Class used for testing independent of backends

class sympy.utilities.autowrap.F2PyCodeWrapper(*args, **kwargs)
Wrapper that uses f2py

class sympy.utilities.autowrap.UfuncifyCodeWrapper(*args, **kwargs)
Wrapper for Ufuncify
dump_c(routines, f, prefix, funcname=None)
Write a C file with Python wrappers
This file contains all the definitions of the routines in c code.
Arguments

routines
   List of Routine instances

f
   File-like object to write the file to

prefix
   The filename prefix, used to name the imported module.

funcname
   Name of the main function to be returned.

sympy.utilities.autowrap.autowrap(expr, language=None, backend='f2py',
   tempdir=None, args=None, flags=None,
   verbose=False, helpers=None, code_gen=None, **kwargs)

Generates Python callable binaries based on the math expression.

Parameters

expr
   The SymPy expression that should be wrapped as a binary routine.

language : string, optional
   If supplied, (options: 'C' or 'F95'), specifies the language of the generated code. If None [default], the language is inferred based upon the specified backend.

backend : string, optional
   Backend used to wrap the generated code. Either 'f2py' [default], or 'cython'.

tempdir : string, optional
   Path to directory for temporary files. If this argument is supplied, the generated code and the wrapper input files are left intact in the specified path.

args : iterable, optional
   An ordered iterable of symbols. Specifies the argument sequence for the function.

flags : iterable, optional
   Additional option flags that will be passed to the backend.

verbose : bool, optional
   If True, autowrap will not mute the command line backends. This can be helpful for debugging.

helpers : 3-tuple or iterable of 3-tuples, optional
   Used to define auxiliary expressions needed for the main expr. If the main expression needs to call a specialized function it should be passed in via helpers. Autowrap will then make sure that the compiled main expression can link to the helper routine. Items should
be 3-tuples with (function_name, sympy_expression, argument_tuple). It is mandatory to supply an argument sequence to helper routines.

code_gen : CodeGen instance

include_dirs : [string]
A list of directories to search for C/C++ header files (in Unix form for portability).

library_dirs : [string]
A list of directories to search for C/C++ libraries at link time.

libraries : [string]
A list of library names (not filenames or paths) to link against.

extra_compile_args : [string]
Any extra platform- and compiler-specific information to use when compiling the source files in ‘sources’. For platforms and compilers where “command line” makes sense, this is typically a list of command-line arguments, but for other platforms it could be anything.

extra_link_args : [string]
Any extra platform- and compiler-specific information to use when linking object files together to create the extension (or to create a new static Python interpreter). Similar interpretation as for ‘extra_compile_args’.

Examples

```python
>>> from sympy.abc import x, y, z
>>> from sympy.utilities.autowrap import autowrap
>>> expr = ((x - y + z) ** (13)).expand()
>>> binary_func = autowrap(expr)
>>> binary_func(1, 4, 2)
-1.0
```

sympy.utilities.autowrap.binary_function(symfunc, expr, **kwargs)
Returns a SymPy function with expr as binary implementation

This is a convenience function that automates the steps needed to autowrap the SymPy expression and attaching it to a Function object with implemented_function().

Parameters

symfunc : SymPy Function
The function to bind the callable to.

expr : SymPy Expression
The expression used to generate the function.

kwargs : dict
Any kwargs accepted by autowrap.

Examples

```python
>>> from sympy.abc import x, y
>>> from sympy.utilities.autowrap import binary_function
>>> expr = ((x - y)**(25)).expand()
>>> f = binary_function('f', expr)
>>> type(f)
<class 'sympy.core.function.UndefinedFunction'>
>>> 2*f(x, y)
2*f(x, y)
>>> f(x, y).evalf(2, subs={x: 1, y: 2})
-1.0
```

`sympy.utilities.autowrap.ufuncify(args, expr, language=None, backend='numpy', tempdir=None, flags=None, verbose=False, helpers=None, **kwargs)`

Generates a binary function that supports broadcasting on numpy arrays.

**Parameters**

- **args** : iterable
  Either a Symbol or an iterable of symbols. Specifies the argument sequence for the function.

- **expr**
  A SymPy expression that defines the element wise operation.

- **language** : string, optional
  If supplied, (options: ‘C’ or ‘F95’), specifies the language of the generated code. If None [default], the language is inferred based upon the specified backend.

- **backend** : string, optional
  Backend used to wrap the generated code. Either ‘numpy’ [default], ‘cython’, or ‘f2py’.

- **tempdir** : string, optional
  Path to directory for temporary files. If this argument is supplied, the generated code and the wrapper input files are left intact in the specified path.

- **flags** : iterable, optional
  Additional option flags that will be passed to the backend.

- **verbose** : bool, optional
  If True, autowrap will not mute the command line backends. This can be helpful for debugging.

- **helpers** : iterable, optional
  Used to define auxiliary expressions needed for the main `expr`. If the main expression needs to call a specialized function it should be put in
the helpers iterable. Autowrap will then make sure that the compiled main expression can link to the helper routine. Items should be tuples with (<function_name>, <sympy_expression>, <arguments>). It is mandatory to supply an argument sequence to helper routines.

**kwargs : dict

These kwargs will be passed to autowrap if the f2py or cython backend is used and ignored if the numpy backend is used.

**Notes**

The default backend (‘numpy’) will create actual instances of numpy.ufunc. These support ndimensional broadcasting, and implicit type conversion. Use of the other backends will result in a “ufunc-like” function, which requires equal length 1-dimensional arrays for all arguments, and will not perform any type conversions.

**Examples**

```python
>>> from sympy.utilities.autowrap import ufuncify
>>> from sympy.abc import x, y
>>> import numpy as np
>>> f = ufuncify((x, y), y + x**2)
>>> type(f)
<class 'numpy.ufunc'>
>>> f([1, 2, 3], 2)
array([ 3.,  6., 11.])
>>> f(np.arange(5), 3)
array([ 3.,  4.,  7., 12., 19.])
```

For the ‘f2py’ and ‘cython’ backends, inputs are required to be equal length 1-dimensional arrays. The ‘f2py’ backend will perform type conversion, but the Cython backend will error if the inputs are not of the expected type.

```python
>>> f_fortran = ufuncify((x, y), y + x**2, backend='f2py')
>>> f_fortran(1, 2)
array([ 3.])
>>> f_fortran(np.array([1, 2, 3]), np.array([1.0, 2.0, 3.0]))
array([ 2.,  6., 12.])
>>> f_cython = ufuncify((x, y), y + x**2, backend='Cython')
>>> f_cython(1, 2)
Traceback (most recent call last):
  ...
TypeError: Argument '_x' has incorrect type (expected numpy.ndarray, got <class 'int'>)
>>> f_cython(np.array([1.0]), np.array([2.0]))
array([ 3.0])
```

Codegen

This module provides functionality to generate directly compilable code from SymPy expressions. The codegen function is the user interface to the code generation functionality in SymPy. Some details of the implementation is given below for advanced users that may want to use the framework directly.

**Note:** The codegen callable is not in the sympy namespace automatically, to use it you must first execute

```python
>>> from sympy.utilities.codegen import codegen
```

Implementation Details

Here we present the most important pieces of the internal structure, as advanced users may want to use it directly, for instance by subclassing a code generator for a specialized application. **It is very likely that you would prefer to use the codegen() function documented above.**

Basic assumptions:

- A generic Routine data structure describes the routine that must be translated into C/Fortran/... code. This data structure covers all features present in one or more of the supported languages.
- Descendants from the CodeGen class transform multiple Routine instances into compilable code. Each derived class translates into a specific language.
- In many cases, one wants a simple workflow. The friendly functions in the last part are a simple api on top of the Routine/CodeGen stuff. They are easier to use, but are less powerful.

Routine

The Routine class is a very important piece of the codegen module. Viewing the codegen utility as a translator of mathematical expressions into a set of statements in a programming language, the Routine instances are responsible for extracting and storing information about how the math can be encapsulated in a function call. Thus, it is the Routine constructor that decides what arguments the routine will need and if there should be a return value.
API Reference

module for generating C, C++, Fortran77, Fortran90, Julia, Rust and Octave/Matlab routines that evaluate SymPy expressions. This module is work in progress. Only the milestones with a ‘+’ character in the list below have been completed.

— How is sympy.utilities.codegen different from sympy.printing.ccode? —

We considered the idea to extend the printing routines for SymPy functions in such a way that it prints complete compilable code, but this leads to a few unsurmountable issues that can only be tackled with dedicated code generator:

• For C, one needs both a code and a header file, while the printing routines generate just one string. This code generator can be extended to support .pyf files for f2py.

• SymPy functions are not concerned with programming-technical issues, such as input, output and input-output arguments. Other examples are contiguous or non-contiguous arrays, including headers of other libraries such as GSL or others.

• It is highly interesting to evaluate several SymPy functions in one C routine, eventually sharing common intermediate results with the help of the cse routine. This is more than just printing.

• From the programming perspective, expressions with constants should be evaluated in the code generator as much as possible. This is different for printing.

— Basic assumptions —

• A generic Routine data structure describes the routine that must be translated into C/Fortran/... code. This data structure covers all features present in one or more of the supported languages.

• Descendants from the CodeGen class transform multiple Routine instances into compilable code. Each derived class translates into a specific language.

• In many cases, one wants a simple workflow. The friendly functions in the last part are a simple api on top of the Routine/CodeGen stuff. They are easier to use, but are less powerful.

— Milestones —

• First working version with scalar input arguments, generating C code, tests

• Friendly functions that are easier to use than the rigorous Routine/CodeGen workflow.

• Integer and Real numbers as input and output

• Output arguments

• InputOutput arguments

• Sort input/output arguments properly

• Contiguous array arguments (numpy matrices)

• Also generate .pyf code for f2py (in autowrap module)

• Isolate constants and evaluate them beforehand in double precision

• Fortran 90

• Octave/Matlab

• Common Subexpression Elimination

• User defined comments in the generated code
- Optional extra include lines for libraries/objects that can eval special functions
- Test other C compilers and libraries: gcc, tcc, libtcc, gcc+gsl, ...
- Contiguous array arguments (SymPy matrices)
- Non-contiguous array arguments (SymPy matrices)
- ccode must raise an error when it encounters something that cannot be translated into c. 
code(integrate(sin(x)/x,x)) does not make sense.
- Complex numbers as input and output
- A default complex datatype
- Include extra information in the header: date, user, hostname, sha1 hash, ...
- Fortran 77
- C++
- Python
- Julia
- Rust
- ...

```python
class sympy.utilities.codegen.Argument(name, datatype=None, dimensions=None, precision=None)
```

An abstract Argument data structure: a name and a data type.
This structure is refined in the descendants below.

```python
class sympy.utilities.codegen.CCodeGen(project='project', printer=None, preprocessor_statements=None, cse=False)
```

Generator for C code.
The .write() method inherited from CodeGen will output a code file and an interface file, 
<prefix>.c and <prefix>.h respectively.

```python
dump_c(routines, f, prefix, header=True, empty=True)
```

Write the code by calling language specific methods.
The generated file contains all the definitions of the routines in low-level code and refers to the header file if appropriate.

**Parameters**

- **routines**: list
  A list of Routine instances.
- **f**: file-like
  Where to write the file.
- **prefix**: string
  The filename prefix, used to refer to the proper header file. Only the basename of the prefix is used.
- **header**: bool, optional
  When True, a header comment is included on top of each source file.
  [default : True]
empty : bool, optional
    When True, empty lines are included to structure the source files.
    [default : True]

dump_h(routines, f, prefix, header=True, empty=True)
    Writes the C header file.
    This file contains all the function declarations.

    Parameters
    routines : list
        A list of Routine instances.
    f : file-like
        Where to write the file.
    prefix : string
        The filename prefix, used to construct the include guards. Only the
basename of the prefix is used.
    header : bool, optional
        When True, a header comment is included on top of each source file.
        [default : True]
    empty : bool, optional
        When True, empty lines are included to structure the source files.
        [default : True]

get_prototype(routine)
    Returns a string for the function prototype of the routine.
    If the routine has multiple result objects, an CodeGenError is raised.
    See: https://en.wikipedia.org/wiki/Function_prototype

class sympy.utilities.codegen.CodeGen(project='project', cse=False)
    Abstract class for the code generators.

dump_code(routines, f, prefix, header=True, empty=True)
    Write the code by calling language specific methods.
    The generated file contains all the definitions of the routines in
    low-level code and refers to the header file if appropriate.

    Parameters
    routines : list
        A list of Routine instances.
    f : file-like
        Where to write the file.
    prefix : string
        The filename prefix, used to refer to the proper header file. Only the
        basename of the prefix is used.
    header : bool, optional
When True, a header comment is included on top of each source file. [default: True]

empty : bool, optional
      When True, empty lines are included to structure the source files. [default: True]

routine(name, expr, argument_sequence=None, global_vars=None)
      Creates a Routine object that is appropriate for this language.
      This implementation is appropriate for at least C/Fortran. Subclasses can override
      this if necessary.
      Here, we assume at most one return value (the l-value) which must be scalar. Additional
      outputs are OutputArguments (e.g., pointers on right-hand-side or pass-by-reference). Matrices
      are always returned via OutputArguments. If argument_sequence is None, arguments will be ordered
      alphabetically, but with all InputArguments first, and then OutputArgument and InOutArguments.

write(routines, prefix, to_files=False, header=True, empty=True)
      Writes all the source code files for the given routines.
      The generated source is returned as a list of (filename, contents) tuples, or is written
      to files (see below). Each filename consists of the given prefix, appended with an
      appropriate extension.

Parameters
routine : list
      A list of Routine instances to be written
prefix : string
      The prefix for the output files
to_files : bool, optional
      When True, the output is written to files. Otherwise, a list of (filename, contents) tuples is returned. [default: False]
header : bool, optional
      When True, a header comment is included on top of each source file. [default: True]
empty : bool, optional
      When True, empty lines are included to structure the source files. [default: True]

class sympy.utilities.codegen.DataType(cname, fname, pyname, jlname, octname, rsname)
      Holds strings for a certain datatype in different languages.

class sympy.utilities.codegen.FCodeGen(project='project', printer=None)
      Generator for Fortran 95 code
      The .write() method inherited from CodeGen will output a code file and an interface file,
      <prefix>.f90 and <prefix>.h respectively.
dump_f95\((routines, f, prefix, header=True, empty=True)\)
Write the code by calling language specific methods.
The generated file contains all the definitions of the routines in low-level code and refers to the header file if appropriate.

**Parameters**
- **routines**: list
  A list of Routine instances.
- **f**: file-like
  Where to write the file.
- **prefix**: string
  The filename prefix, used to refer to the proper header file. Only the basename of the prefix is used.
- **header**: bool, optional
  When True, a header comment is included on top of each source file. [default: True]
- **empty**: bool, optional
  When True, empty lines are included to structure the source files. [default: True]

dump_h\((routines, f, prefix, header=True, empty=True)\)
Writes the interface to a header file.
This file contains all the function declarations.

**Parameters**
- **routines**: list
  A list of Routine instances.
- **f**: file-like
  Where to write the file.
- **prefix**: string
  The filename prefix.
- **header**: bool, optional
  When True, a header comment is included on top of each source file. [default: True]
- **empty**: bool, optional
  When True, empty lines are included to structure the source files. [default: True]

get_interface\(\text{routine}\)
Returns a string for the function interface.
The routine should have a single result object, which can be None. If the routine has multiple result objects, a CodeGenError is raised.

See: https://en.wikipedia.org/wiki/Function_prototype
class sympy.utilities.codegen.JuliaCodeGen(project='project', printer=None)
Generator for Julia code.

The .write() method inherited from CodeGen will output a code file <prefix>.jl.

dump_jl(routines, f, prefix, header=True, empty=True)
Write the code by calling language specific methods.

The generated file contains all the definitions of the routines in low-level code and refers to the header file if appropriate.

Parameters
routines : list
A list of Routine instances.
f : file-like
Where to write the file.

prefix : string
The filename prefix, used to refer to the proper header file. Only the basename of the prefix is used.

header : bool, optional
When True, a header comment is included on top of each source file.
[default: True]

empty : bool, optional
When True, empty lines are included to structure the source files.
[default: True]

routine(name, expr, argument_sequence, global_vars)
Specialized Routine creation for Julia.

class sympy.utilities.codegen.OctaveCodeGen(project='project', printer=None)
Generator for Octave code.

The .write() method inherited from CodeGen will output a code file <prefix>.m.

Octave .m files usually contain one function. That function name should match the filename (prefix). If you pass multiple name_expr pairs, the latter ones are presumed to be private functions accessed by the primary function.

You should only pass inputs to argument_sequence: outputs are ordered according to their order in name_expr.

dump_m(routines, f, prefix, header=True, empty=True, inline=True)
Write the code by calling language specific methods.

The generated file contains all the definitions of the routines in low-level code and refers to the header file if appropriate.

Parameters
routines : list
A list of Routine instances.
f : file-like
Where to write the file.
prefix : string
    The filename prefix, used to refer to the proper header file. Only the
    basename of the prefix is used.

header : bool, optional
    When True, a header comment is included on top of each source file.
    [default : True]

empty : bool, optional
    When True, empty lines are included to structure the source files.
    [default : True]

routine(name, expr, argument_sequence, global_vars)
    Specialized Routine creation for Octave.

class sympy.utilities.codegen.OutputArgument(name, result_var, expr,
    datatype=None, dimensions=None, precision=None)

    OutputArgument are always initialized in the routine.

class sympy.utilities.codegen.Result(expr, name=None, result_var=None,
    datatype=None, dimensions=None, precision=None)

    An expression for a return value.
    The name result is used to avoid conflicts with the reserved word “return” in the Python
    language. It is also shorter than ReturnValue.
    These may or may not need a name in the destination (e.g., “return(x*y)” might return
    a value without ever naming it).

class sympy.utilities.codegen.Routine(name, arguments, results, local_vars,
    global_vars)

    Generic description of evaluation routine for set of expressions.
    A CodeGen class can translate instances of this class into code in a particular language.
    The routine specification covers all the features present in these languages. The Code-
    Gen part must raise an exception when certain features are not present in the target
    language. For example, multiple return values are possible in Python, but not in C or
    Fortran. Another example: Fortran and Python support complex numbers, while C does
    not.

    property result_variables
        Returns a list of OutputArgument, InOutArgument and Result.
        If return values are present, they are at the end of the list.

    property variables
        Returns a set of all variables possibly used in the routine.
        For routines with unnamed return values, the dummies that may or may not be used
        will be included in the set.

class sympy.utilities.codegen.RustCodeGen(project='project', printer=None)

    Generator for Rust code.
    The .write() method inherited from CodeGen will output a code file <prefix>.rs
dump_rs(routines, f, prefix, header=True, empty=True)

Write the code by calling language specific methods.

The generated file contains all the definitions of the routines in low-level code and refers to the header file if appropriate.

Parameters

- **routines**: list
  A list of Routine instances.

- **f**: file-like
  Where to write the file.

- **prefix**: string
  The filename prefix, used to refer to the proper header file. Only the basename of the prefix is used.

- **header**: bool, optional
  When True, a header comment is included on top of each source file. [default: True]

- **empty**: bool, optional
  When True, empty lines are included to structure the source files. [default: True]

get_prototype(routine)

Returns a string for the function prototype of the routine.

If the routine has multiple result objects, an CodeGenError is raised.

See: https://en.wikipedia.org/wiki/Function_prototype

routine(name, expr, argument_sequence, global_vars)

Specialized Routine creation for Rust.

sympy.utilities.codegen.codegen(name_expr, language=None, prefix=None, project='project', to_files=False, header=True, empty=True, argument_sequence=None, global_vars=None, standard=None, code_gen=None, printer=None)

Generate source code for expressions in a given language.

Parameters

- **name_expr**: tuple, or list of tuples
  A single (name, expression) tuple or a list of (name, expression) tuples. Each tuple corresponds to a routine. If the expression is an equality (an instance of class Equality) the left hand side is considered an output argument. If expression is an iterable, then the routine will have multiple outputs.

- **language**: string
  A string that indicates the source code language. This is case insensitive. Currently, ‘C’, ‘F95’ and ‘Octave’ are supported. ‘Octave’ generates code compatible with both Octave and Matlab.

- **prefix**: string, optional
A prefix for the names of the files that contain the source code. Language-dependent suffixes will be appended. If omitted, the name of the first name_expr tuple is used.

**project**: string, optional
A project name, used for making unique preprocessor instructions. [default: “project”]

**to_files**: bool, optional
When True, the code will be written to one or more files with the given prefix, otherwise strings with the names and contents of these files are returned. [default: False]

**header**: bool, optional
When True, a header is written on top of each source file. [default: True]

**empty**: bool, optional
When True, empty lines are used to structure the code. [default: True]

**argument_sequence**: iterable, optional
Sequence of arguments for the routine in a preferred order. A CodeGenError is raised if required arguments are missing. Redundant arguments are used without warning. If omitted, arguments will be ordered alphabetically, but with all input arguments first, and then output or in-out arguments.

**global_vars**: iterable, optional
Sequence of global variables used by the routine. Variables listed here will not show up as function arguments.

**standard**: string

**code_gen**: CodeGen instance

**Examples**

```python
>>> from sympy.utilities.codegen import codegen
>>> from sympy.abc import x, y, z
>>> [(c_name, c_code), (h_name, c_header)] = codegen(
...   ("f", x+y*z), "C89", "test", header=False, empty=False)
>>> print(c_name)
test.c
>>> print(c_code)
#include "test.h"
#include "math.h"
double f(double x, double y, double z) {
    double f_result;
    f_result = x + y*z;
    return f_result;
}(continues on next page)```
Another example using Equality objects to give named outputs. Here the filename (prefix) is taken from the first (name, expr) pair.

```python
>>> from sympy import f, g
>>> from sympy import Eq
>>> [(c_name, c_code), (h_name, c_header)] = codegen(...
    ["myfcn", x + y], ["fcn2", [Eq(f, 2*x), Eq(g, y)]],
    "C99", header=False, empty=False)
>>> print(c_name)
myfcn.c
>>> print(c_code)
#include "myfcn.h"
#include <math.h>
double myfcn(double x, double y) {
    double myfcn_result;
    myfcn_result = x + y;
    return myfcn_result;
}
void fcn2(double x, double y, double *f, double *g) {
    (*f) = 2*x;
    (*g) = y;
}
```

If the generated function(s) will be part of a larger project where various global variables have been defined, the ‘global_vars’ option can be used to remove the specified variables from the function signature.

```python
>>> from sympy.utilities.codegen import codegen
>>> from sympy import x, y, z
>>> [(f_name, f_code), header] = codegen(...
    ["f", x+y*z], ["F95", header=False, empty=False,
    argument_sequence=(x, y), global_vars=(z,))
>>> print(f_code)
REAL*8 function f(x, y)
implicit none
REAL*8, intent(in) :: x
REAL*8, intent(in) :: y
f = x + y*z
end function
```

`sympy.utilities.codegen.get_default_datatype(expr, complex_allowed=None)`

Derives an appropriate datatype based on the expression.
sympy.utilities.codegen.make_routine(name, expr, argument_sequence=None, global_vars=None, language='F95')

A factory that makes an appropriate Routine from an expression.

**Parameters**

- **name**: string
  
  The name of this routine in the generated code.

- **expr**: expression or list/tuple of expressions
  
  A SymPy expression that the Routine instance will represent. If given a list or tuple of expressions, the routine will be considered to have multiple return values and/or output arguments.

- **argument_sequence**: list or tuple, optional
  
  List arguments for the routine in a preferred order. If omitted, the results are language dependent, for example, alphabetical order or in the same order as the given expressions.

- **global_vars**: iterable, optional
  
  Sequence of global variables used by the routine. Variables listed here will not show up as function arguments.

- **language**: string, optional
  
  Specify a target language. The Routine itself should be language-agnostic but the precise way one is created, error checking, etc depend on the language. [default: “F95”].

**Notes**

A decision about whether to use output arguments or return values is made depending on both the language and the particular mathematical expressions. For an expression of type Equality, the left hand side is typically made into an OutputArgument (or perhaps an InOutArgument if appropriate). Otherwise, typically, the calculated expression is made a return values of the routine.

**Examples**

```python
>>> from sympy.utilities.codegen import make_routine
>>> from sympy.abc import x, y, f, g
>>> from sympy import Eq
>>> r = make_routine('test', [Eq(f, 2*x), Eq(g, x + y)])
>>> [arg.result_var for arg in r.results]
[]
>>> [arg.name for arg in r.arguments]
[x, y, f, g]
>>> [arg.name for arg in r.result_variables]
[f, g]
>>> r.local_vars
set()
```
Another more complicated example with a mixture of specified and automatically-assigned names. Also has Matrix output.

```
>>> from sympy import Matrix
>>> r = make_routine('fcn', [x*y, Eq(f, 1), Eq(g, x + g), Matrix([[x, y], [-2]])])
>>> [arg.result_var for arg in r.results]
[result_53974605702048505]
>>> [arg.expr for arg in r.results]
[x*y]
>>> [arg.name for arg in r.arguments]
[x, y, f, g, out_8598435338387848786]
```

We can examine the various arguments more closely:

```
>>> from sympy.utilities.codegen import (InputArgument, OutputArgument, ...
     InOutArgument)
>>> [a.name for a in r.arguments if isinstance(a, InputArgument)]
[x, y]
>>> [a.name for a in r.arguments if isinstance(a, OutputArgument)]
[f, out_8598435338387848786]
>>> [a.expr for a in r.arguments if isinstance(a, OutputArgument)]
[1, Matrix([[x, 2]])]
>>> [a.name for a in r.arguments if isinstance(a, InOutArgument)]
[g]
>>> [a.expr for a in r.arguments if isinstance(a, InOutArgument)]
[g + x]
```

**Decorator**

Useful utility decorators.

@sympy.utilities.decorator.deprecated(*message, *, deprecated_since_version, active_deprecations_target, stacklevel=3)

Mark a function as deprecated.

This decorator should be used if an entire function or class is deprecated. If only a certain functionality is deprecated, you should use warns_deprecated_sympy() (page 2100) directly. This decorator is just a convenience. There is no functional difference between using this decorator and calling warns_deprecated_sympy() at the top of the function.

The decorator takes the same arguments as warns_deprecated_sympy() (page 2100). See its documentation for details on what the keywords to this decorator do.

See the *Deprecation Policy* (page 3101) document for details on when and how things should be deprecated in SymPy.
Examples

```python
>>> from sympy.utilities.decorator import deprecated
>>> from sympy import simplify
>>> @deprecated("... The simplify_this(expr) function is deprecated. Use simplify(expr) instead.", deprecated_since_version="1.1",
... active_deprecations_target='simplify-this-deprecation')
... def simplify_this(expr):
...     ""
...     Simplify `expr`.
...     .. deprecated:: 1.1
...     The `simplify_this` function is deprecated. Use :func:`simplify` instead. See its documentation for more information. See :ref:`simplify-this-deprecation` for details.
...     ""
...     return simplify(expr)
>>> from sympy.abc import x
>>> simplify_this(x*(x + 1) - x**2)
<stdin>:1: SymPyDeprecationWarning: The simplify_this(expr) function is deprecated. Use simplify(expr) instead.
See https://docs.sympy.org/latest/explanation/active-deprecations.html for details.
This has been deprecated since SymPy version 1.1. It will be removed in a future version of SymPy.

simplify_this(x)
```

See also:

- `sympy.utilities.exceptions.SymPyDeprecationWarning` (page 2137)
- `sympy.utilities.exceptions.sympy_deprecation_warning` (page 2138)
- `sympy.utilities.exceptions.ignore_warnings` (page 2138)
- `sympy.testing.pytest.warns_deprecated_sympy` (page 2100)

`sympy.utilities.decorator.conserve_mpmath_dps(func)`

After the function finishes, resets the value of mpmath.mp.dps to the value it had before the function was run.

`sympy.utilities.decorator.doctest_depends_on(exe=None, modules=None, disable_viewers=None, python_version=None)`

Adds metadata about the dependencies which need to be met for doctesting the docstrings of the decorated objects.

5.8. Topics 2129
exe should be a list of executables
modules should be a list of modules
disable_viewers should be a list of viewers for preview() to disable
python_version should be the minimum Python version required, as a tuple (like (3, 0))

```python
sympy.utilities.decorator.memoize_property(propfunc)
```  
Property decorator that caches the value of potentially expensive `propfunc` after the first evaluation. The cached value is stored in the corresponding property name with an attached underscore.

```python
class sympy.utilities.decorator.no_attrs_in_subclass(cls, f)
```  
Don’t ‘inherit’ certain attributes from a base class

```python
>>> from sympy.utilities.decorator import no_attrs_in_subclass
```

```python
>>> class A(object):
...    x = 'test'
```

```python
>>> A.x = no_attrs_in_subclass(A, A.x)
```

```python
>>> class B(A):
...    pass
```

```python
>>> hasattr(A, 'x')
True
>>> hasattr(B, 'x')
False
```

```python
sympy.utilities.decorator.public(obj)
```  
Append obj's name to global `__all__` variable (call site).

By using this decorator on functions or classes you achieve the same goal as by filling `__all__` variables manually, you just do not have to repeat yourself (object’s name). You also know if object is public at definition site, not at some random location (where `__all__` was set).

Note that in multiple decorator setup (in almost all cases) @public decorator must be applied before any other decorators, because it relies on the pointer to object's global namespace. If you apply other decorators first, @public may end up modifying the wrong namespace.

**Examples**

```python
>>> from sympy.utilities.decorator import public
```

```python
>>> __all__ # noqa: F821
Traceback (most recent call last):
...
NameError: name '__all__' is not defined
```
sympy.utilities.decorator.threaded(func)

Apply func to sub-elements of an object, including Add (page 1062).

This decorator is intended to make it uniformly possible to apply a function to all elements of composite objects, e.g. matrices, lists, tuples and other iterable containers, or just expressions.

This version of threaded() (page 2131) decorator allows threading over elements of Add (page 1062) class. If this behavior is not desirable use xthreaded() (page 2131) decorator.

Functions using this decorator must have the following signature:

```python
@threaded
def function(expr, *args, **kwargs):
```

sympy.utilities.decorator.threaded_factory(func, use_add)

A factory for threaded decorators.

sympy.utilities.decorator.xthreaded(func)

Apply func to sub-elements of an object, excluding Add (page 1062).

This decorator is intended to make it uniformly possible to apply a function to all elements of composite objects, e.g. matrices, lists, tuples and other iterable containers, or just expressions.

This version of threaded() (page 2131) decorator disallows threading over elements of Add (page 1062) class. If this behavior is not desirable use threaded() (page 2131) decorator.

Functions using this decorator must have the following signature:

```python
@xthreaded
def function(expr, *args, **kwargs):
```

Enumerative

This module includes functions and classes for enumerating and counting multiset partitions.

sympy.utilities.enumerative.multiset_partitions_taocp(multiplicities)

Enumerates partitions of a multiset.

Parameters

multiplicities

list of integer multiplicities of the components of the multiset.

Yields

state
Internal data structure which encodes a particular partition. This output is then usually processed by a visitor function which combines the information from this data structure with the components themselves to produce an actual partition.

Unless they wish to create their own visitor function, users will have little need to look inside this data structure. But, for reference, it is a 3-element list with components:

- **f** is a frame array, which is used to divide pstack into parts.
- **lpart** points to the base of the topmost part.
- **pstack** is an array of PartComponent objects.

The state output offers a peek into the internal data structures of the enumeration function. The client should treat this as read-only; any modification of the data structure will cause unpredictable (and almost certainly incorrect) results. Also, the components of state are modified in place at each iteration. Hence, the visitor must be called at each loop iteration. Accumulating the state instances and processing them later will not work.

### Examples

```python
>>> from sympy.utilities.enumerative import list_visitor
>>> from sympy.utilities.enumerative import multiset_partitions_taocp
>>> # variables components and multiplicities represent the multiset 'abb'
>>> components = 'ab'
>>> multiplicities = [1, 2]
>>> states = multiset_partitions_taocp(multiplicities)
>>> list(list_visitor(state, components) for state in states)
[[['a', 'b', 'b']], [['a', 'b'], ['b']], [['a'], ['b', 'b']], [['a'], ['b'], ['b']]]
```

**See also:**

- `sympy.utilities.iterables.multiset_partitions` *(page 2154)*
  
  Takes a multiset as input and directly yields multiset partitions. It dispatches to a number of functions, including this one, for implementation. Most users will find it more convenient to use than multiset_partitions_taocp.

- `sympy.utilities.enumerative.factoring_visitor(state, primes)`
  
  Use with multiset_partitions_taocp to enumerate the ways a number can be expressed as a product of factors. For this usage, the exponents of the prime factors of a number are arguments to the partition enumerator, while the corresponding prime factors are input here.
Examples

To enumerate the factorings of a number we can think of the elements of the partition as being the prime factors and the multiplicities as being their exponents.

```python
>>> from sympy.utilities.enumerative import factoring_visitor
>>> from sympy.utilities.enumerative import multiset_partitions_taocp
>>> primes, multiplicities = zip(*factorint(24).items())
>>> primes
(2, 3)
>>> multiplicities
(3, 1)
>>> states = multiset_partitions_taocp(multiplicities)
>>> list(factoring_visitor(state, primes) for state in states)
[[24], [8, 3], [12, 2], [4, 6], [4, 2, 3], [6, 2, 2], [2, 2, 2, 3]]
```

```
sympy.utilities.enumerative.list_visitor(state, components)
Return a list of lists to represent the partition.
```

Examples

```python
>>> from sympy.utilities.enumerative import list_visitor
>>> from sympy.utilities.enumerative import multiset_partitions_taocp
>>> states = multiset_partitions_taocp([1, 2, 1])
>>> s = next(states)
>>> list_visitor(s, 'abc')  # for multiset 'a b b c'
[['a', 'b', 'b', 'c']]
>>> s = next(states)
>>> list_visitor(s, [1, 2, 3])  # for multiset '1 2 2 3'
[[1, 2, 2], [3]]
```

The approach of the function multiset_partitions_taocp is extended and generalized by the class MultisetPartitionTraverser.

class sympy.utilities.enumerative.MultisetPartitionTraverser

Has methods to enumerate and count the partitions of a multiset.

This implements a refactored and extended version of Knuth’s algorithm 7.1.2.5M [AOCP].”

The enumeration methods of this class are generators and return data structures which can be interpreted by the same visitor functions used for the output of multiset_partitions_taocp.

5.8. Topics 2133
Examples

>>> from sympy.utilities.enumerative import MultisetPartitionTraverser
>>> m = MultisetPartitionTraverser()
>>> m.count_partitions([4,4,4,2])
127750
>>> m.count_partitions([3,3,3])
686

See also:

multiset_partitions_taocp (page 2131), sympy.utilities.iterables.

multiset_partitions (page 2154)

References

[AOCP], [Factorisatio], [Yorgey]

count_partitions(multiplicities)

Returns the number of partitions of a multiset whose components have the multiplicities given in multiplicities.

For larger counts, this method is much faster than calling one of the enumerators and counting the result. Uses dynamic programming to cut down on the number of nodes actually explored. The dictionary used in order to accelerate the counting process is stored in the MultisetPartitionTraverser object and persists across calls. If the user does not expect to call count_partitions for any additional multisets, the object should be cleared to save memory. On the other hand, the cache built up from one count run can significantly speed up subsequent calls to count_partitions, so it may be advantageous not to clear the object.

Examples

>>> from sympy.utilities.enumerative import MultisetPartitionTraverser
>>> m = MultisetPartitionTraverser()
>>> m.count_partitions([9,8,2])
288716
>>> m.count_partitions([2,2])
9
>>> del m

Notes

If one looks at the workings of Knuth’s algorithm M [AOCP], it can be viewed as a traversal of a binary tree of parts. A part has (up to) two children, the left child resulting from the spread operation, and the right child from the decrement operation. The ordinary enumeration of multiset partitions is an in-order traversal of this tree, and with the partitions corresponding to paths from the root to the leaves. The mapping from paths to partitions is a little complicated, since the partition would contain only those parts which are leaves or the parents of a spread link, not those which are parents of a decrement link.
For counting purposes, it is sufficient to count leaves, and this can be done with a recursive in-order traversal. The number of leaves of a subtree rooted at a particular part is a function only of that part itself, so memoizing has the potential to speed up the counting dramatically.

This method follows a computational approach which is similar to the hypothetical memoized recursive function, but with two differences:

1) This method is iterative, borrowing its structure from the other enumerations and maintaining an explicit stack of parts which are in the process of being counted. (There may be multisets which can be counted reasonably quickly by this implementation, but which would overflow the default Python recursion limit with a recursive implementation.)

2) Instead of using the part data structure directly, a more compact key is constructed. This saves space, but more importantly coalesces some parts which would remain separate with physical keys.

Unlike the enumeration functions, there is currently no _range version of count_partitions. If someone wants to stretch their brain, it should be possible to construct one by memoizing with a histogram of counts rather than a single count, and combining the histograms.

**enum_all(multiplicities)**

Enumerate the partitions of a multiset.

**Examples**

```python
>>> from sympy.utilities.enumerative import list_visitor
>>> from sympy.utilities.enumerative import MultisetPartitionTraverser
>>> m = MultisetPartitionTraverser()
>>> states = m.enum_all([2, 2])
>>> list(list_visitor(state, 'ab') for state in states)
[['a', 'a', 'b', 'b'], ['a', 'a', 'b'], ['b'], ['a', 'a'], ['b', 'b'], ['a'], ['a'], ['b', 'b'], ['a', 'b'], ['b'], ['a', 'b'], ['b', 'b'], ['a'], ['a'], ['a'], ['b', 'b'], ['a', 'b'], ['b'], ['a', 'b'], ['b', 'b'], ['a'], ['a'], ['b', 'b'], ['a'], ['a'], ['b', 'b']]
```

**See also:**

*multiset_partitions_taoecp* (page 2131)

which provides the same result as this method, but is about twice as fast. Hence, *enum_all* is primarily useful for testing. Also see the function for a discussion of states and visitors.

**enum_large(multiplicities, lb)**

Enumerate the partitions of a multiset with lb < num(parts)

Equivalent to *enum_range(multiplicities, lb, sum(multiplicities))*
Parameters

multiplicities

list of multiplicities of the components of the multiset.

lb

Number of parts in the partition must be greater than this lower bound.

Examples

```python
>>> from sympy.utilities.enumerative import list_visitor
>>> from sympy.utilities.enumerative import MultisetPartitionTraverser
>>> m = MultisetPartitionTraverser()
>>> states = m.enum_large([2, 2], 2)
>>> list(list_visitor(state, 'ab') for state in states)
[['a', 'a'], ['b'], ['b']],
[['a', 'b'], ['a'], ['b']],
[['a'], ['a'], ['b', 'b']],
[['a'], ['a'], ['b'], ['b']]]
```

See also:

`enum_all` (page 2135), `enum_small` (page 2136), `enum_range` (page 2136)

**enum_range** *(multiplicities, lb, ub)*

Enumerate the partitions of a multiset with lb < num(parts) <= ub.

In particular, if partitions with exactly k parts are desired, call with (multiplicities, k - 1, k). This method generalizes enum_all, enum_small, and enum_large.

Examples

```python
>>> from sympy.utilities.enumerative import list_visitor
>>> from sympy.utilities.enumerative import MultisetPartitionTraverser
>>> m = MultisetPartitionTraverser()
>>> states = m.enum_range([2, 2], 1, 2)
>>> list(list_visitor(state, 'ab') for state in states)
[['a', 'a', 'b'], ['b']],
[['a', 'a'], ['b', 'b']],
[['a', 'b', 'b'], ['a']],
[['a', 'b'], ['a', 'b']]]
```

**enum_small** *(multiplicities, ub)*

Enumerate multiset partitions with no more than ub parts.

Equivalent to enum_range(multiplicities, 0, ub)

Parameters

multiplicities

list of multiplicities of the components of the multiset.

ub
Maximum number of parts

Examples

```python
>>> from sympy.utilities.enumerative import list_visitor
>>> from sympy.utilities.enumerative import MultisetPartitionTraverser
>>> m = MultisetPartitionTraverser()
>>> states = m.enum_small([[2, 2]], 2)
>>> list(list_visitor(state, 'ab') for state in states)

[[['a', 'a', 'b', 'b']],
[['a', 'a', 'b'], ['b']],
[['a', 'a'], ['b', 'b']],
[['a', 'b'], ['a']],
[['a', 'b'], ['a', 'b']]]
```

The implementation is based, in part, on the answer given to exercise 69, in Knuth [AOCP].

`enum_all` (page 2135), `enum_large` (page 2135), `enum_range` (page 2136)

Exceptions and Warnings

General SymPy exceptions and warnings.

```python
exception sympy.utilities.exceptions.SymPyDeprecationWarning(message, *, deprecated_since_version, active_deprecations_target)
```

A warning for deprecated features of SymPy.

See the *Deprecation Policy* (page 3101) document for details on when and how things should be deprecated in SymPy.

Note that simply constructing this class will not cause a warning to be issued. To do that, you must call the :func:`sympy_deprecation_warning` function. For this reason, it is not recommended to ever construct this class directly.

Explanation

The SymPyDeprecationWarning class is a subclass of DeprecationWarning that is used for all deprecations in SymPy. A special subclass is used so that we can automatically augment the warning message with additional metadata about the version the deprecation was introduced in and a link to the documentation. This also allows users to explicitly filter deprecation warnings from SymPy using warnings filters (see *Silencing SymPy DeprecationWarnings* (page 214)).

Additionally, SymPyDeprecationWarning is enabled to be shown by default, unlike normal DeprecationWarnings, which are only shown by default in interactive sessions. This ensures that deprecation warnings in SymPy will actually be seen by users.

See the documentation of `sympy_deprecation_warning()` (page 2138) for a description of the parameters to this function.
To mark a function as deprecated, you can use the `@deprecated` (page 2128) decorator.

**See also:**

`sympy.utilities.exceptions.sympy_deprecation_warning` (page 2138), `sympy.utilities.exceptions.ignore_warnings` (page 2138), `sympy.utilities.decorator.deprecated` (page 2128), `sympy.testing.pytest.warns_deprecated_sympy` (page 2100)

`sympy.utilities.exceptions.ignore_warnings(warningcls)`

Context manager to suppress warnings during tests.

**Note:** Do not use this with SymPyDeprecationWarning in the tests. `warns_deprecated_sympy()` should be used instead.

This function is useful for suppressing warnings during tests. The `warns` function should be used to assert that a warning is raised. The `ignore_warnings` function is useful in situation when the warning is not guaranteed to be raised (e.g. on importing a module) or if the warning comes from third-party code.

This function is also useful to prevent the same or similar warnings from being issue twice due to recursive calls.

When the warning is coming (reliably) from SymPy the `warns` function should be preferred to `ignore_warnings`.

```python
>>> from sympy.utilities.exceptions import ignore_warnings
>>> import warnings

Here’s a warning:

```python
>>> with warnings.catch_warnings():  # reset warnings in doctest
...    warnings.simplefilter('error')
...    warnings.warn('deprecated', UserWarning)
Traceback (most recent call last):
...  UserWarning: deprecated
```

Let’s suppress it with `ignore_warnings`:

```python
>>> with warnings.catch_warnings():  # reset warnings in doctest
...    warnings.simplefilter('error')
...    with ignore_warnings(UserWarning):
...        warnings.warn('deprecated', UserWarning)
```

(No warning emitted)

**See also:**

`sympy.utilities.exceptions.SymPyDeprecationWarning` (page 2137), `sympy.utilities.exceptions.sympy_deprecation_warning` (page 2138), `sympy.utilities.decorator.deprecated` (page 2128), `sympy.testing.pytest.warns_deprecated_sympy` (page 2100)

`sympy.utilities.exceptions.sympy_deprecation_warning(message, *,
    deprecated_since_version,
    active_deprecations_target,
    stacklevel=3)`
Warn that a feature is deprecated in SymPy.

See the Deprecation Policy (page 3101) document for details on when and how things should be deprecated in SymPy.

To mark an entire function or class as deprecated, you can use the @deprecated (page 2128) decorator.

**Parameters**

message: str

The deprecation message. This may span multiple lines and contain code examples. Messages should be wrapped to 80 characters. The message is automatically dedented and leading and trailing whitespace stripped. Messages may include dynamic content based on the user input, but avoid using str(expression) if an expression can be arbitrary, as it might be huge and make the warning message unreadable.

deprecated_since_version: str

The version of SymPy the feature has been deprecated since. For new deprecations, this should be the version in sympy/release.py without the .dev. If the next SymPy version ends up being different from this, the release manager will need to update any SymPyDeprecationWarnings using the incorrect version. This argument is required and must be passed as a keyword argument. (example: deprecated_since_version="1.10").

active_deprecations_target: str

The Sphinx target corresponding to the section for the deprecation in the List of active deprecations (page 214) document (see doc/src/explanation/active-deprecations.md). This is used to automatically generate a URL to the page in the warning message. This argument is required and must be passed as a keyword argument. (example: active_deprecations_target="deprecated-feature-abc")

stacklevel: int (default: 3)

The stacklevel parameter that is passed to warnings.warn. If you create a wrapper that calls this function, this should be increased so that the warning message shows the user line of code that produced the warning. Note that in some cases there will be multiple possible different user code paths that could result in the warning. In that case, just choose the smallest common stacklevel.

**Examples**

```python
>>> from sympy.utilities.exceptions import sympy_deprecation_warning
>>> def is_this_zero(x, y=0):
...     """
...     Determine if x = 0.
...     ...
...     Parameters
...     ========
```
x : Expr
The expression to check.

y : Expr, optional
If provided, check if x = y.

.. deprecated:: 1.1

The ``y`` argument to ``is_this_zero`` is deprecated. Use
``is_this_zero(x - y)`` instead.

""
from sympy import simplify

if y != 0:
sympy_deprecation_warning(""
    The y argument to is_zero() is deprecated. Use is_zero(x - y)\n    instead."",
    deprecated_since_version="1.1",
    active_deprecations_target='is-this-zero-y-deprecation')

return simplify(x - y) == 0

(page 2100)
Iterables

```python
from sympy.utilities.iterables import binary_partitions

for i in binary_partitions(5):
    print(i)
```

doesn't print anything because binary_partitions returns a generator of lists of partitions, not the partitions themselves.

```
>>> from sympy.utilities.iterables import capture
>>> from sympy import pprint
>>> from sympy.abc import x

>>> def foo():
    print('hello world!')
    ...

>>> 'hello' in capture(foo)  # foo, not foo()
True
>>> capture(lambda: pprint(2/x))
'2\n-\nx
'
```

References

[R983]
```python
>>> from sympy.utilities.iterables import common_prefix
>>> common_prefix(list(range(3)))
[0, 1, 2]
>>> common_prefix(list(range(3)), list(range(4)))
[0, 1, 2]
>>> common_prefix([1, 2, 3], [1, 2, 5])
[1, 2]
>>> common_prefix([1, 2, 3], [1, 3, 5])
[1]
```

The `common_suffix` function returns the subsequence that is a common ending of sequences in `seqs`.

```python
>>> from sympy.utilities.iterables import common_suffix
>>> common_suffix(list(range(3)))
[0, 1, 2]
>>> common_suffix(list(range(3)), list(range(4)))
[]
>>> common_suffix([1, 2, 3], [9, 2, 3])
[2, 3]
>>> common_suffix([1, 2, 3], [9, 7, 3])
[3]
```

The `connected_components` function finds the connected components of a graph.

```python
sympy.utilities.iterables.connected_components(G)
```

### Parameters
- **graph**: `tuple[list, list[tuple[T, T]]]`
  - A tuple consisting of a list of vertices and a list of edges of a graph whose connected components are to be found.

### Examples

Given an undirected graph:

```python
graph {
    A -- B
    C -- D
}
```
We can find the connected components using this function if we include each edge in both directions:

```python
from sympy.utilities.iterables import connected_components

V = ['A', 'B', 'C', 'D']
E = [('A', 'B'), ('B', 'A'), ('C', 'D'), ('D', 'C')]
connected_components((V, E))
```

The weakly connected components of a directed graph can be found the same way.

**Notes**

The vertices of the graph must be hashable for the data structures used. If the vertices are unhashable replace them with integer indices.

This function uses Tarjan’s algorithm to compute the connected components in $O(|V|+|E|)$ (linear) time.

**See also:**

`sympy.utilities.iterables.strongly_connected_components` (page 2166)

**References**

[R984], [R985]

`sympy.utilities.iterables.dict_merge(*dicts)`  
Merge dictionaries into a single dictionary.

`sympy.utilities.iterables.filter_symbols(iterator, exclude)`  
Only yield elements from `iterator` that do not occur in `exclude`.

**Parameters**

- `iterator`: iterable
  - iterator to take elements from
**include** : iterable

elements to exclude

**Returns**

**iterator** : iterator

filtered iterator

```python
sympy.utilities.iterables.flatten(iterable, levels=None, cls=None)
```

Recursively denest iterable containers.

```python
from sympy import flatten

>>> flatten([1, 2, 3])
[1, 2, 3]
>>> flatten([1, 2, [3]])
[1, 2, 3]
>>> flatten([1, [2, 3], [4, 5]])
[1, 2, 3, 4, 5]
>>> flatten([1.0, 2, (1, None)])
[1.0, 2, 1, None]
```

If you want to denest only a specified number of levels of nested containers, then set `levels` flag to the desired number of levels:

```python
ls = [[(-2, -1), (1, 2)], [(0, 0)]]

>>> flatten(ls, levels=1)
[(-2, -1), (1, 2), (0, 0)]
```

If `cls` argument is specified, it will only flatten instances of that class, for example:

```python
from sympy import Basic, S
class MyOp(Basic):
    ...
    pass
    ...

>>> flatten([MyOp(S(1), MyOp(S(2), S(3)))]), cls=MyOp)
[1, 2, 3]
```

adapted from https://kogs-www.informatik.uni-hamburg.de/~meine/python_tricks

```python
sympy.utilities.iterables.generate_bell(n)
```

Return permutations of \([0, 1, \ldots, n - 1]\) such that each permutation differs from the last by the exchange of a single pair of neighbors. The \(n!\) permutations are returned as an iterator. In order to obtain the next permutation from a random starting permutation, use the `next_trotterjohnson` method of the `Permutation` class (which generates the same sequence in a different manner).
Examples

```python
>>> from itertools import permutations
>>> from sympy.utilities.iterables import generate_bell
>>> from sympy import zeros, Matrix
```

This is the sort of permutation used in the ringing of physical bells, and does not produce permutations in lexicographical order. Rather, the permutations differ from each other by exactly one inversion, and the position at which the swapping occurs varies periodically in a simple fashion. Consider the first few permutations of 4 elements generated by permutations and generate_bell:

```python
>>> list(permutations(range(4)))[5:
[(0, 1, 2, 3), (0, 1, 3, 2), (0, 2, 1, 3), (0, 2, 3, 1), (0, 3, 1, 2)]
``` 

```python
>>> list(generate_bell(4))[5:
[(0, 1, 2, 3), (0, 1, 3, 2), (0, 3, 1, 2), (3, 0, 1, 2), (3, 0, 2, 1)]
``` 

Notice how the 2nd and 3rd lexicographical permutations have 3 elements out of place whereas each “bell” permutation always has only two elements out of place relative to the previous permutation (and so the signature (+/-1) of a permutation is opposite of the signature of the previous permutation).

How the position of inversion varies across the elements can be seen by tracing out where the largest number appears in the permutations:

```python
>>> m = zeros(4, 24)
>>> for i, p in enumerate(generate_bell(4)):
...    m[:, i] = Matrix([j - 3 for j in list(p)])  # make largest zero
>>> m.print_nonzero('X')
[XXX XXXXXX XXXXXX XXX]
[XX XX XXXX XX XXXX XX XX]
[X XXXX XX XXXX XX XXXX X]
[ XXXXXX XXXXXX XXXXXX ]
```

sympy.utilities.iterables.generate_derangements(s)

Return unique derangements of the elements of iterable s.

**Examples**

```python
>>> from sympy.utilities.iterables import generate_derangements
>>> list(generate_derangements([0, 1, 2]))
[[1, 2, 0], [2, 0, 1]]
>>> list(generate_derangements([0, 1, 2, 2]))
[[2, 2, 0, 1], [2, 2, 1, 0]]
>>> list(generate_derangements([0, 1, 1]))
[]
```

See also:
sympy.functions.combinatorial.factorials.subfactorial (page 491)

sympy.utilities.iterables.generate_involutions(n)

Generates involutions.

An involution is a permutation that when multiplied by itself equals the identity permutation. In this implementation the involutions are generated using Fixed Points.

Alternatively, an involution can be considered as a permutation that does not contain any cycles with a length that is greater than two.

**Examples**

```python
>>> from sympy.utilities.iterables import generate_involutions
>>> list(generate_involutions(3))
[(0, 1, 2), (0, 2, 1), (1, 0, 2), (2, 1, 0)]
>>> len(list(generate_involutions(4)))
10
```

**References**

[R991]

sympy.utilities.iterables.generate_oriented_forest(n)

This algorithm generates oriented forests.

An oriented graph is a directed graph having no symmetric pair of directed edges. A forest is an acyclic graph, i.e., it has no cycles. A forest can also be described as a disjoint union of trees, which are graphs in which any two vertices are connected by exactly one simple path.
Examples

```python
>>> from sympy.utilities.iterables import generate_oriented_forest
>>> list(generate_oriented_forest(4))
[[0, 1, 2, 3], [0, 1, 2, 2], [0, 1, 2, 1], [0, 1, 2, 0], [0, 1, 1, 1], [0, 1, 1, 0], [0, 1, 0, 1], [0, 1, 0, 0], [0, 0, 0, 0]]
```

References

[R992], [R993]
sympy.utilities.iterables.group(seq, multiple=True)
Splits a sequence into a list of lists of equal, adjacent elements.

Examples

```python
>>> from sympy import group

>>> group([1, 1, 1, 2, 2, 3])
[[1, 1, 1], [2, 2], [3]]

>>> group([1, 1, 1, 2, 2, 3], multiple=False)
[(1, 3), (2, 2), (3, 1)]

>>> group([1, 1, 3, 2, 2, 1], multiple=False)
[(1, 2), (3, 1), (2, 2), (1, 1)]
```

See also:

`multiset` (page 2153)
sympy.utilities.iterables.has_dups(seq)
Return True if there are any duplicate elements in seq.

Examples

```python
>>> from sympy import has_dups, Dict, Set

>>> has_dups((1, 2, 1))
True

>>> has_dups(range(3))
False

>>> all(has_dups(c) is False for c in (set(), Set(), dict(), Dict()))
True
```
sympy.utilities.iterables.has_variety(seq)
Return True if there are any different elements in seq.
SymPy Documentation, Release 1.12.1

Examples

```python
>>> from sympy import has_variety

>>> has_variety((1, 2, 1))
True
>>> has_variety((1, 1, 1))
False
```

**sympy.utilities.iterables.ibin** *(n, bits=None, str=False)*

Return a list of length bits corresponding to the binary value of n with small bits to the right (last). If bits is omitted, the length will be the number required to represent n. If the bits are desired in reversed order, use the `[::-1]` slice of the returned list.

If a sequence of all bits-length lists starting from `[0, 0,..., 0]` through `[1, 1,..., 1]` are desired, pass a non-integer for bits, e.g. `'all'`.

If the bit string is desired pass `str=True`.

Examples

```python
>>> from sympy.utilities.iterables import ibin

>>> ibin(2)
[1, 0]
>>> ibin(2, 4)
[0, 0, 1, 0]
```

If all lists corresponding to 0 to 2**n - 1, pass a non-integer for bits:

```python
>>> bits = 2
>>> for i in ibin(2, 'all'):
...    print(i)
(0, 0)
(0, 1)
(1, 0)
(1, 1)
```

If a bit string is desired of a given length, use `str=True`:

```python
>>> n = 123
>>> bits = 10
>>> ibin(n, bits, str=True)
'0001111011'
>>> ibin(n, bits, str=True)[::-1]  # small bits left
'1101111000'
>>> list(ibin(3, 'all', str=True))
['000', '001', '010', '011', '100', '101', '110', '111']
```

**sympy.utilities.iterables.iproduct(**iterables)**

Cartesian product of iterables.

Generator of the Cartesian product of iterables. This is analogous to `itertools.product` except that it works with infinite iterables and will yield any item from the infinite product eventually.
Examples

```python
from sympy.utilities.iterables import iproduct
sorted(iproduct([1,2], [3,4]))
[(1, 3), (1, 4), (2, 3), (2, 4)]
```

With an infinite iterator:

```python
from sympy import S
(3,) in iproduct(S.Integers)
True
(3, 4) in iproduct(S.Integers, S.Integers)
True
```

See also:

- `itertools.product`
- `sympy.utilities.iterables.is_palindromic(s, i=0, j=None)`

    Return True if the sequence is the same from left to right as it is from right to left in the whole sequence (default) or in the Python slice s[i: j]; else False.

Examples

```python
from sympy.utilities.iterables import is_palindromic
is_palindromic([1, 0, 1])
True
is_palindromic('abcbb')
False
is_palindromic('abcbb', 1)
False
```

Normal Python slicing is performed in place so there is no need to create a slice of the sequence for testing:

```python
is_palindromic('abcbb', 1, -1)
True
is_palindromic('abcbb', -4, -1)
True
```

See also:

- `sympy.ntheory.digits.is_palindromic` (page 1573) tests integers
- `sympy.utilities.iterables.is_sequence(i, include=None)`

    Return a boolean indicating whether i is a sequence in the SymPy sense. If anything that fails the test below should be included as being a sequence for your application, set ‘include’ to that object’s type; multiple types should be passed as a tuple of types.

    Note: although generators can generate a sequence, they often need special handling to make sure their elements are captured before the generator is exhausted, so these are not included by default in the definition of a sequence.
See also: iterable

Examples

```python
>>> from sympy.utilities.iterables import is_sequence
>>> from types import GeneratorType

>>> is_sequence([])
True
>>> is_sequence(set())
False
>>> is_sequence('abc')
False
>>> is_sequence('abc', include=str)
True
>>> generator = (c for c in 'abc')
>>> is_sequence(generator)
False
>>> is_sequence(generator, include=(str, GeneratorType))
True
```

```python
sympy.utilities.iterables.iterable(i, exclude=(<class 'str'>, <class 'dict'>, <class 'sympy.utilities.iterables.NotIterable'>))
```

Return a boolean indicating whether i is SymPy iterable. True also indicates that the
iterator is finite, e.g. you can call list(...) on the instance.

When SymPy is working with iterables, it is almost always assuming that the iterable is
not a string or a mapping, so those are excluded by default. If you want a pure Python
definition, make exclude=None. To exclude multiple items, pass them as a tuple.

You can also set the _iterable attribute to True or False on your class, which will override
the checks here, including the exclude test.

As a rule of thumb, some SymPy functions use this to check if they should recursively
map over an object. If an object is technically iterable in the Python sense but does not
desire this behavior (e.g., because its iteration is not finite, or because iteration might
induce an unwanted computation), it should disable it by setting the _iterable attribute
to False.

See also: is_sequence

Examples

```python
>>> from sympy.utilities.iterables import iterable
>>> from sympy import Tuple

>>> things = [[1], (1,), set([1]), Tuple(1), (j for j in [1, 2]), [1:2], 
... '1', 1]
>>> for i in things:
...     print('%s %s' % (iterable(i), type(i)))
True <... 'list'>
True <... 'tuple'>
True <... 'set'>
True <class 'sympy.core.containers.Tuple'>
```

(continues on next page)
True <... 'generator'>
False <... 'dict'>
False <... 'str'>
False <... 'int'>

```python
>>> iterable({}, exclude=None)
True
>>> iterable({}, exclude=str)
True
>>> iterable("no", exclude=str)
False
```

**Examples**

The default is to give the items in the same order, but grouped into k partitions without any reordering:

```python
from sympy.utilities.iterables import kbins
for p in kbins(list(range(5)), 2):
    print(p)
...
[[0], [1, 2, 3, 4]]
[[0, 1], [2, 3, 4]]
[[0, 1, 2], [3, 4]]
[[0, 1, 2, 3], [4]]
```

The ordered flag is either None (to give the simple partition of the elements) or is a 2 digit integer indicating whether the order of the bins and the order of the items in the bins matters. Given:

```python
A = [[0], [1, 2]]
B = [[1, 2], [0]]
C = [[2, 1], [0]]
D = [[0], [2, 1]]
```

the following values for ordered have the shown meanings:

- **00** means A == B == C == D
- **01** means A == B
- **10** means A == D
- **11** means A == A

```python
>>> for ordered_flag in [None, 0, 1, 10, 11]:
...    print('%s' % ordered_flag)
...    for p in kbins(list(range(3)), 2, ordered=ordered_flag):
...        print(' %s' % p)
...    ordered = None
```
See also:

partitions (page 2159), multiset_partitions (page 2154)

See also:

partitions (page 2159), multiset_partitions (page 2154)

sympy.utilities.iterables.least_rotation(x, key=None)

Returns the number of steps of left rotation required to obtain lexicographically minimal string/list/tuple, etc.

Examples

```python
>>> from sympy.utilities.iterables import least_rotation, rotate_left
>>> a = [3, 1, 5, 1, 2]
>>> least_rotation(a)
3
>>> rotate_left(a, _)
[1, 2, 3, 1, 5]
```
References

[R994]

sympy.utilities.iterables.minlex(seq, directed=True, key=None)

Return the rotation of the sequence in which the lexically smallest elements appear first, e.g. $cba \rightarrowacb$.

The sequence returned is a tuple, unless the input sequence is a string in which case a string is returned.

If directed is False then the smaller of the sequence and the reversed sequence is returned, e.g. $cba \rightarrow abc$.

If key is not None then it is used to extract a comparison key from each element in iterable.

Examples

```python
>>> from sympy.combinatorics.polyhedron import minlex
>>> minlex((1, 2, 0))
(0, 1, 2)
>>> minlex((1, 0, 2))
(0, 2, 1)
>>> minlex((1, 0, 2), directed=False)
(0, 1, 2)
>>> minlex('11010011000', directed=True)
'00011010011'
>>> minlex('11010011000', directed=False)
'00011001011'
>>> minlex(('bb', 'aaa', 'c', 'a'))
('a', 'bb', 'aaa', 'c')
>>> minlex(('bb', 'aaa', 'c', 'a'), key=len)
('c', 'a', 'bb', 'aaa')
```

sympy.utilities.iterables.multiset(seq)

Return the hashable sequence in multiset form with values being the multiplicity of the item in the sequence.

Examples

```python
>>> from sympy.utilities.iterables import multiset
>>> multiset('mississippi')
{'i': 4, 'm': 1, 'p': 2, 's': 4}
```

See also:

[group](page 2147)

sympy.utilities.iterables.multiset_combinations(m, n, g=None)

Return the unique combinations of size $n$ from multiset $m$.  

5.8. Topics
Examples

```python
>>> from sympy.utilities.iterables import multiset_combinations
>>> from itertools import combinations

>>> [''.join(i) for i in multiset_combinations('baby', 3)]
['abb', 'aby', 'bby']

>>> def count(f, s):
...     return len(list(f(s, 3)))
```

The number of combinations depends on the number of letters; the number of unique combinations depends on how the letters are repeated.

```python
>>> s1 = 'abracadabra'
>>> s2 = 'banana tree'

>>> count(combinations, s1), count(multiset_combinations, s1)
(165, 23)

>>> count(combinations, s2), count(multiset_combinations, s2)
(165, 54)
```

```
sympy.utilities.iterables.multiset_derangements(s)
Generate derangements of the elements of s in place.

Examples

```python
>>> from sympy.utilities.iterables import multiset_derangements, uniq
```

Because the derangements of multisets (not sets) are generated in place, copies of the return value must be made if a collection of derangements is desired or else all values will be the same:

```python
>>> list(uniq([i for i in multiset_derangements('1233')]))
[[None, None, None, None]]

>>> [i.copy() for i in multiset_derangements('1233')]
[[[3', '3', '1', '2'], ['3', '3', '2', '1']]
>>> [''.join(i) for i in multiset_derangements('1233')]
['3312', '3321']
```

```
sympy.utilities.iterables.multiset_partitions(multiset, m=None)
Return unique partitions of the given multiset (in list form). If m is None, all multisets will be returned, otherwise only partitions with m parts will be returned.

If multiset is an integer, a range [0, 1, ..., multiset - 1] will be supplied.
Examples

```python
>>> from sympy.utilities.iterables import multiset_partitions

>>> list(multiset_partitions([1, 2, 3, 4], 2))
[[[1, 2, 3], [4]], [[1, 2, 4], [3]], [[1, 2], [3, 4]],
 [[1, 3, 4], [2]], [[1, 3], [2, 4]], [[1, 4], [2, 3]],
 [[1], [2, 3, 4]]]

>>> list(multiset_partitions([1, 2, 3, 4], 1))
[[[1, 2, 3, 4]]]
```

Only unique partitions are returned and these will be returned in a canonical order regardless of the order of the input:

```python
>>> a = [1, 2, 2, 1]
>>> ans = list(multiset_partitions(a, 2))
>>> a.sort()
list(multiset_partitions(a, 2)) == ans
True
>>> a = range(3, 1, -1)
>>> (list(multiset_partitions(a)) == ...
... list(multiset_partitions(sorted(a))))
True
```

If \(m\) is omitted then all partitions will be returned:

```python
>>> list(multiset_partitions([1, 1, 2]))
[[[1, 1, 2]], [[1, 1], [2]], [[1, 2], [1]], [[1], [1], [2]]]
>>> list(multiset_partitions([1]*3))
[[[1, 1, 1]], [[1], [1, 1]], [[1], [1], [1]]]
```

Counting

The number of partitions of a set is given by the bell number:

```python
>>> from sympy import bell

>>> len(list(multiset_partitions(5))) == bell(5) == 52
True
```

The number of partitions of length \(k\) from a set of size \(n\) is given by the Stirling Number of the 2nd kind:

```python
>>> from sympy.functions.combinatorial.numbers import stirling

>>> stirling(5, 2) == len(list(multiset_partitions(5, 2))) == 15
True
```

These comments on counting apply to sets, not multisets.
Notes

When all the elements are the same in the multiset, the order of the returned partitions is determined by the partitions routine. If one is counting partitions then it is better to use the nT function.

See also:

partitions (page 2159), sympy.combinatorics.partitions.Partition (page 306),
sympy.combinatorics.partitions.IntegerPartition (page 308), sympy.functions.
combinatorial.numbers.nT (page 505)

sympy.utilities.iterables.multiset_permutations(m, size=None, g=None)

Return the unique permutations of multiset m.

Examples

```python
>>> from sympy.utilities.iterables import multiset_permutations
>>> from sympy import factorial

['aab', 'aba', 'baa']

720

60
```

sympy.utilities.iterables.necklaces(n, k, free=False)

A routine to generate necklaces that may (free=True) or may not (free=False) be turned over to be viewed. The “necklaces” returned are comprised of n integers (beads) with k different values (colors). Only unique necklaces are returned.

Examples

```python
>>> from sympy.utilities.iterables import necklaces, bracelets

>>> def show(s, i):
...     return ''.join(s[j] for j in i)
...     return ''

>>> B = [show('ABC', i) for i in bracelets(3, 3)]
>>> N = [show('ABC', i) for i in necklaces(3, 3)]
>>> set(N) - set(B)
{'ACB'}
```

(mnemonic: Bracelets can be viewed Backwards, but Not Necklaces.)
```python
>>> list(necklaces(4, 2))
[(0, 0, 0, 0), (0, 0, 0, 1), (0, 0, 1, 1),
 (0, 1, 0, 1), (0, 1, 1, 1), (1, 1, 1, 1)]

>>> [show('.o', i) for i in bracelets(4, 2)]
['....', '...o', '..oo', '.o.o', '.ooo', 'oooo']
```

References

[R995], [R996]

```python
sympy.utilities.iterables.numbered_symbols(prefix='x', cls=None, start=0,
 exclude=(), *args, **assumptions)
```

Generate an infinite stream of Symbols consisting of a prefix and increasing subscripts provided that they do not occur in exclude.

**Parameters**

- `prefix` : str, optional
  The prefix to use. By default, this function will generate symbols of the form “x0”, “x1”, etc.

- `cls` : class, optional
  The class to use. By default, it uses Symbol, but you can also use Wild or Dummy.

- `start` : int, optional
  The start number. By default, it is 0.

**Returns**

- `sym` : Symbol
  The subscripted symbols.

```python
sympy.utilities.iterables.ordered_partitions(n, m=None, sort=True)
```

Generates ordered partitions of integer n.

**Parameters**

- `m` : integer (default None)
  The default value gives partitions of all sizes else only those with size m. In addition, if m is not None then partitions are generated in place (see examples).

- `sort` : bool (default True)
  Controls whether partitions are returned in sorted order when m is not None; when False, the partitions are returned as fast as possible with elements sorted, but when m|n the partitions will not be in ascending lexicographical order.
Examples

```python
>>> from sympy.utilities.iterables import ordered_partitions
```

All partitions of 5 in ascending lexicographical:

```python
>>> for p in ordered_partitions(5):
...     print(p)
[1, 1, 1, 1, 1]
[1, 1, 1, 2]
[1, 1, 3]
[1, 2, 2]
[1, 4]
[2, 3]
[5]
```

Only partitions of 5 with two parts:

```python
>>> for p in ordered_partitions(5, 2):
...     print(p)
[1, 4]
[2, 3]
```

When \( m \) is given, a given list objects will be used more than once for speed reasons so you will not see the correct partitions unless you make a copy of each as it is generated:

```python
>>> [p for p in ordered_partitions(7, 3)]
[[1, 1, 1], [1, 1, 1], [1, 1, 1], [2, 2, 2]]
>>> [list(p) for p in ordered_partitions(7, 3)]
[[1, 1, 5], [1, 2, 4], [1, 3, 3], [2, 2, 3]]
```

When \( n \) is a multiple of \( m \), the elements are still sorted but the partitions themselves will be unordered if sort is False; the default is to return them in ascending lexicographical order.

```python
>>> for p in ordered_partitions(6, 2):
...     print(p)
[1, 5]
[2, 4]
[3, 3]
```

But if speed is more important than ordering, sort can be set to False:

```python
>>> for p in ordered_partitions(6, 2, sort=False):
...     print(p)
[1, 5]
[3, 3]
[2, 4]
```
References

[R997], [R998]

sympy.utilities.iterables.partitions(n, m=None, k=None, size=False)
Generate all partitions of positive integer, n.

Parameters

- **m**: integer (default gives partitions of all sizes)
  limits number of parts in partition (mnemonic: m, maximum parts)
- **k**: integer (default gives partitions number from 1 through n)
  limits the numbers that are kept in the partition (mnemonic: k, keys)
- **size**: bool (default False, only partition is returned)
  when True then (M, P) is returned where M is the sum of the multi-
  plicities and P is the generated partition.

Each partition is represented as a dictionary, mapping an integer
to the number of copies of that integer in the partition. For example,
the first partition of 4 returned is {4: 1}, “4: one of them”.

Examples

```python
>>> from sympy.utilities.iterables import partitions

The numbers appearing in the partition (the key of the returned dict) are limited with k:
```n
```python
>>> for p in partitions(6, k=2):
...     print(p)
{2: 3}
{1: 2, 2: 2}
{1: 4, 2: 1}
{1: 6}
```n
The maximum number of parts in the partition (the sum of the values in the returned
dict) are limited with m (default value, None, gives partitions from 1 through n):

```python
>>> for p in partitions(6, m=2):
...     print(p)

{6: 1}
{1: 1, 5: 1}
{2: 1, 4: 1}
{3: 2}
```n

sympy.combinatorics.partitions.Partition (page 306), sympy.combinatorics.
partitions.IntegerPartition (page 308)
References

[R999]
sympy.utilities.iterables.permute_signs(t)
Return iterator in which the signs of non-zero elements of t are permuted.

Examples

```python
>>> from sympy.utilities.iterables import permute_signs
>>> list(permute_signs((0, 1, 2)))
[(0, 1, 2), (0, -1, 2), (0, 1, -2), (0, -1, -2)]
```

sympy.utilities.iterables.postfixes(seq)
Generate all postfixes of a sequence.

Examples

```python
>>> from sympy.utilities.iterables import postfixes
>>> list(postfixes([1, 2, 3, 4]))
[[4], [3, 4], [2, 3, 4], [1, 2, 3, 4]]
```

sympy.utilities.iterables.prefixes(seq)
Generate all prefixes of a sequence.

Examples

```python
>>> from sympy.utilities.iterables import prefixes
>>> list(prefixes([1, 2, 3, 4]))
[[1], [1, 2], [1, 2, 3], [1, 2, 3, 4]]
```

sympy.utilities.iterables.random_derangement(t, choice=None, strict=True)
Return a list of elements in which none are in the same positions as they were originally. If an element fills more than half of the positions then an error will be raised since no derangement is possible. To obtain a derangement of as many items as possible–with some of the most numerous remaining in their original positions–pass strict = False. To produce a pseudorandom derangement, pass a pseudorandom selector like choice (see below).
Examples

```python
>>> from sympy.utilities.iterables import random_derangement
>>> t = 'SymPy: a CAS in pure Python'
>>> d = random_derangement(t)
>>> all(i != j for i, j in zip(d, t))
True

A predictable result can be obtained by using a pseudorandom generator for the choice:

```python
>>> from sympy.core.random import seed, choice as c
>>> seed(1)
>>> d = [''.join(random_derangement(t, c)) for i in range(5)]
>>> assert len(set(d)) != 1  # we got different values
```

By reseeding, the same sequence can be obtained:

```python
>>> seed(1)
>>> d2 = [''.join(random_derangement(t, c)) for i in range(5)]
>>> assert d == d2
```

```
sympy.utilities.iterables.reshape(seq, how)
Reshape the sequence according to the template in how.
```

Examples

```python
>>> from sympy.utilities import reshape
>>> seq = list(range(1, 9))

>>> reshape(seq, [4])  # lists of 4
[[1, 2, 3, 4], [5, 6, 7, 8]]

>>> reshape(seq, (4,))  # tuples of 4
[(1, 2, 3, 4), (5, 6, 7, 8)]

>>> reshape(seq, (2, 2))  # tuples of 4
[(1, 2, 3, 4), (5, 6, 7, 8)]

>>> reshape(seq, (2, [2]))  # (i, i, [i, i])
[(1, 2, [3, 4]), (5, 6, [7, 8])]

>>> reshape(seq, ((2,), [2]))  # etc....
[((1, 2), [3, 4]), ((5, 6), [7, 8])]

>>> reshape(seq, (1, [2], 1))
[(1, [2, 3], 4), (5, [6, 7], 8)]

>>> reshape(tuple(seq), (([[1], 1, (2,)]),)
(([[1], 2, (3, 4)]), (5, [6, (7, 8)]),))
```
reshape(
tuple(seq), ([1], 1, (2,)))

(([1], 2, (3, 4)), ([5], 6, (7, 8)))

reshape(
list(range(12)), [2, [3], {2}, (1, (3,), 1)])

[[0, 1, [2, 3, 4], {5, 6}, (7, (8, 9, 10), 11)]]

sympy.utilities.iterables.rotate_left(x, y)
Left rotates a list x by the number of steps specified in y.

Examples

```python
>>> from sympy.utilities.iterables import rotate_left
>>> a = [0, 1, 2]
>>> rotate_left(a, 1)
[1, 2, 0]
```

sympy.utilities.iterables.rotate_right(x, y)
Right rotates a list x by the number of steps specified in y.

Examples

```python
>>> from sympy.utilities.iterables import rotate_right
>>> a = [0, 1, 2]
>>> rotate_right(a, 1)
[2, 0, 1]
```

sympy.utilities.iterables.rotations(s, dir=1)
Return a generator giving the items in s as list where each subsequent list has the items rotated to the left (default) or right (dir=-1) relative to the previous list.

Examples

```python
>>> from sympy import rotations
>>> list(rotations([1,2,3]))
[[1, 2, 3], [2, 3, 1], [3, 1, 2]]
>>> list(rotations([1,2,3], -1))
[[1, 2, 3], [3, 1, 2], [2, 3, 1]]
```

sympy.utilities.iterables.roundrobin(*iterables)
roundrobin recipe taken from itertools documentation: https://docs.python.org/3/library/itertools.html#itertools-recipes

roundrobin('ABC', 'D', 'EF') -> A D E B F C
Recipe credited to George Sakkis

sympy.utilities.iterables.runs(seq, op=<built-in function gt>)
Group the sequence into lists in which successive elements all compare the same with the comparison operator, op: op(seq[i + 1], seq[i]) is True from all elements in a run.
Examples

```python
>>> import runs
>>> runs([0, 1, 2, 2, 1, 4, 3, 2, 2])
[[0, 1, 2, 2, 1], [4, 3, 2, 2]]
>>> runs([0, 1, 2, 2, 1, 4, 3, 2, 2], op=ge)
[[0, 1, 2, 2, 1], [4, 3, 2, 2]]
```

```python
sympy.utilities.iterables.sequence_partitions(l, n, /)

Returns the partition of sequence l into n bins

Parameters
l : Sequence[T]
    A nonempty sequence of any Python objects

n : int
    A positive integer

Yields
out : list[Sequence[T]]
    A list of sequences with concatenation equals l. This should conform
    with the type of l.

Explanation

Given the sequence \(l_1 \cdots l_m \in V^+\) where \(V^+\) is the Kleene plus of \(V\)
The set of n partitions of l is defined as:
\[
\{(s_1, \cdots, s_n) | s_1 \in V^+, \cdots, s_n \in V^+, s_1 \cdots s_n = l_1 \cdots l_m\}
\]

Examples

```python
>>> sequence_partitions([1, 2, 3, 4], 2):
...    print(out)
[[1, [2, 3, 4]]
[[1, 2], [3, 4]]
[[1, 2, 3], [4]]
```
Notes

This is modified version of EnricoGiampieri’s partition generator from https://stackoverflow.com/questions/13131491/partition-n-items-into-k-bins-in-python-lazily

See also:

sequence_partitions_empty (page 2164)
sympy.utilities.iterables.sequence_partitions_empty(l, n, /)

Returns the partition of sequence l into n bins with empty sequence

Parameters

l : Sequence[T]
    A sequence of any Python objects (can be possibly empty)

n : int
    A positive integer

Yields

out : list[Sequence[T]]
    A list of sequences with concatenation equals l. This should conform with the type of l.

Explanation

Given the sequence $l_1 \ldots l_m \in V^*$ where $V^*$ is the Kleene star of $V$
The set of $n$ partitions of $l$ is defined as:

$$\{(s_1, \ldots, s_n) | s_1 \in V^*, \ldots, s_n \in V^*, s_1 \ldots s_n = l_1 \ldots l_m\}$$

There are more combinations than sequence_partitions() (page 2163) because empty sequence can fill everywhere, so we try to provide different utility for this.

Examples

>>> from sympy.utilities.iterables import sequence_partitions_empty
>>> for out in sequence_partitions_empty([1, 2, 3, 4], 2):
...   print(out)
[[], [1, 2, 3, 4]]
[[1], [2, 3, 4]]
[[1, 2], [3, 4]]
[[1, 2, 3], [4]]
[[1, 2, 3, 4], []]

See also:

sequence_partitions (page 2163)
sympy.utilities.iterables.sift(seq, keyfunc, binary=False)

Sift the sequence, seq according to keyfunc.
Returns
When binary is False (default), the output is a dictionary where elements of seq are stored in a list keyed to the value of keyfunc for that element. If binary is True then a tuple with lists T and F are returned where T is a list containing elements of seq for which keyfunc was True and F containing those elements for which keyfunc was False; a ValueError is raised if the keyfunc is not binary.

Examples

```python
>>> from sympy.utilities import sift
>>> from sympy.abc import x, y
>>> from sympy import sqrt, exp, pi, Tuple

>>> sift(range(5), lambda x: x % 2)
{0: [0, 2, 4], 1: [1, 3]}

sift() returns a defaultdict() object, so any key that has no matches will give [].

>>> sift([x], lambda x: x.is_commutative)
{True: [x], False: []}

Sometimes you will not know how many keys you will get:

>>> sift([sqrt(x), exp(x), (y**x)**2], lambda x: x.as_base_exp()[0])
{E: [exp(x)], x: [sqrt(x)], y: [y**(2*x)]}

Sometimes you expect the results to be binary; the results can be unpacked by setting binary to True:

>>> sift(range(4), lambda x: x % 2, binary=True)
([1, 3], [0, 2])

>>> sift(Tuple(1, pi), lambda x: x.is_rational, binary=True)
([[1], [pi]])

A ValueError is raised if the predicate was not actually binary (which is a good test for the logic where sifting is used and binary results were expected):

```python
>>> unknown = exp(1) - pi # the rationality of this is unknown
>>> args = Tuple(1, pi, unknown)
>>> sift(args, lambda x: x.is_rational, binary=True)
Traceback (most recent call last):
...
ValueError: keyfunc gave non-binary output
```

The non-binary sifting shows that there were 3 keys generated:
>>> set(sift(args, lambda x: x.is_rational).keys())
{None, False, True}

If you need to sort the sifted items it might be better to use ordered which can economically apply multiple sort keys to a sequence while sorting.

See also:

ordered (page 1121)

sympy.utilities.iterables.signed_permutations(t)

Return iterator in which the signs of non-zero elements of t and the order of the elements are permuted.

Examples

>>> from sympy.utilities.iterables import signed_permutations
>>> list(signed_permutations((0, 1, 2)))
[(0, 1, 2), (0, -1, 2), (0, 1, -2), (0, -1, -2), (0, 2, 1),
 (0, -2, 1), (0, 2, -1), (0, -2, -1), (1, 0, 2), (-1, 0, 2),
 (1, 0, -2), (-1, 0, -2), (1, 2, 0), (-1, 2, 0), (1, -2, 0),
 (-1, -2, 0), (2, 0, 1), (-2, 0, 1), (2, 0, -1), (-2, 0, -1),
 (2, 1, 0), (-2, 1, 0), (2, -1, 0), (-2, -1, 0)]

sympy.utilities.iterables.strongly_connected_components(G)

Strongly connected components of a directed graph in reverse topological order.

Parameters

graph : tuple[list, list[tuple[T, T]]]

A tuple consisting of a list of vertices and a list of edges of a graph whose strongly connected components are to be found.

Examples

Consider a directed graph (in dot notation):

digraph {
  A -> B
  A -> C
  B -> C
  C -> B
  B -> D
}
where vertices are the letters A, B, C and D. This graph can be encoded using Python’s elementary data structures as follows:

```
>>> V = ['A', 'B', 'C', 'D']
>>> E = [('A', 'B'), ('A', 'C'), ('B', 'C'), ('C', 'B'), ('B', 'D')]
```

The strongly connected components of this graph can be computed as

```
>>> from sympy.utilities.iterables import strongly_connected_components

>>> strongly_connected_components((V, E))
[['D'], ['B', 'C'], ['A']]
```

This also gives the components in reverse topological order.

Since the subgraph containing B and C has a cycle they must be together in a strongly connected component. A and D are connected to the rest of the graph but not in a cyclic manner so they appear as their own strongly connected components.

**Notes**

The vertices of the graph must be hashable for the data structures used. If the vertices are unhashable replace them with integer indices.

This function uses Tarjan’s algorithm to compute the strongly connected components in \(O(|V| + |E|)\) (linear) time.

**See also:**

`sympy.utilities.iterables.connected_components` (page 2142)
References

[R1000], [R1001]

sympy.utilities.iterables.subsets(seq, k=None, repetition=False)
Generates all $k$-subsets (combinations) from an $n$-element set, seq.

A $k$-subset of an $n$-element set is any subset of length exactly $k$. The number of $k$-subsets of an $n$-element set is given by $\binom{n}{k}$, whereas there are $2^n$ subsets altogether. If $k$ is None then all $2^n$ subsets will be returned from shortest to longest.

Examples

```python
>>> from sympy import subsets

subsets(seq, k) will return the $\binom{n}{k}$ $k$-subsets (combinations) without repetition, i.e. once an item has been removed, it can no longer be “taken”:

```python
>>> list(subsets([1, 2], 2))
[(1, 2)]
>>> list(subsets([1, 2]))
[(), (1,), (2,), (1, 2)]
>>> list(subsets([1, 2, 3], 2))
[(1, 2), (1, 3), (2, 3)]
```  

subsets(seq, k, repetition=True) will return the $\binom{n^{1+k}}{k}$ combinations with repetition:

```python
>>> list(subsets([1, 2], 2, repetition=True))
[(1, 1), (1, 2), (2, 2)]
```  

If you ask for more items than are in the set you get the empty set unless you allow repetitions:

```python
>>> list(subsets([0, 1], 3, repetition=False))
[]
>>> list(subsets([0, 1], 3, repetition=True))
[(0, 0, 0), (0, 0, 1), (0, 1, 1), (1, 1, 1)]
```  

sympy.utilities.iterables.take(iter, n)
Return $n$ items from iter iterator.

sympy.utilities.iterables.topological_sort(graph, key=None)
Topological sort of graph’s vertices.

Parameters
  graph : tuple[list, list[tuple[T, T]]]
    A tuple consisting of a list of vertices and a list of edges of a graph to be sorted topologically.
  key : callable[T] (optional)
    Ordering key for vertices on the same level. By default the natural (e.g. lexicographic) ordering is used (in this case the base type must implement ordering relations).
Examples

Consider a graph:

```
+----+----+----+
| 7  | 5  | 3  |
+----+----+----+
|     |     |     |
V V V V V V V V
+----+----+----+
| 11 | 8  |     |
+----+----+----+
|     |     |     |
V V V V V V V V
+----+----+----+
| 2  | 9  | 10 |
+----+----+----+
```

where vertices are integers. This graph can be encoded using elementary Python’s data structures as follows:

```python
>>> V = [2, 3, 5, 7, 8, 9, 10, 11]
>>> E = [(7, 11), (7, 8), (5, 11), (3, 8), (3, 10), ...
     (11, 2), (11, 9), (11, 10), (8, 9)]
```

To compute a topological sort for graph \((V, E)\) issue:

```python
>>> from sympy.utilities.iterables import topological_sort
>>> topological_sort((V, E))
[3, 5, 7, 8, 11, 2, 9, 10]
```

If specific tie breaking approach is needed, use key parameter:

```python
>>> topological_sort((V, E), key=lambda v: -v)
[7, 5, 11, 3, 10, 8, 9, 2]
```

Only acyclic graphs can be sorted. If the input graph has a cycle, then ValueError will be raised:

```python
>>> topological_sort((V, E + [(10, 7)]))
Traceback (most recent call last):
  ...
ValueError: cycle detected
```
References

[R1002]
sympy.utilities.iterables.unflatten(iter, n=2)
Group iter into tuples of length n. Raise an error if the length of iter is not a multiple
of n.
sympy.utilities.iterables.uniq(seq, result=None)
Yield unique elements from seq as an iterator. The second parameter result is used
internally; it is not necessary to pass anything for this.
Note: changing the sequence during iteration will raise a RuntimeError if the size of the
sequence is known; if you pass an iterator and advance the iterator you will change the
output of this routine but there will be no warning.

Examples

```python
>>> from sympy.utilities.iterables import uniq
>>> dat = [1, 4, 1, 5, 4, 2, 1, 2]
>>> type(uniq(dat)) in (list, tuple)
False
```

```python
>>> list(uniq(dat))
[1, 4, 5, 2]
>>> list(uniq(x for x in dat))
[1, 4, 5, 2]
>>> list(uniq([[1], [2, 1], [1]]))
[[1], [2, 1]]
```
sympy.utilities.iterables.variations(seq, n, repetition=False)
Returns an iterator over the n-sized variations of seq (size N). repetition controls
whether items in seq can appear more than once;

Examples

variations(seq, n) will return \( \frac{N!}{(N-n)!} \) permutations without repetition of seq’s ele-
ments:

```python
>>> from sympy import variations
>>> list(variations([1, 2], 2))
[(1, 2), (2, 1)]
```

variations(seq, n, True) will return the \( N^n \) permutations obtained by allowing rep-
etition of elements:

```python
>>> list(variations([1, 2], 2, repetition=True))
[((1, 1), (1, 2), (2, 1), (2, 2))
```
If you ask for more items than are in the set you get the empty set unless you allow
repetitions:
>> list(variations([0, 1], 3, repetition=False))
[]
>> list(variations([0, 1], 3, repetition=True))[:4]
[(0, 0, 0), (0, 0, 1), (0, 1, 0), (0, 1, 1)]

See also:
- itertools.permutations
- itertools.product

**variations**

`variations(seq, n)` Returns all the variations of the list of size `n`.

Has an optional third argument. Must be a boolean value and makes the method return the variations with repetition if set to True, or the variations without repetition if set to False.

**Examples:**

```python
>>> from sympy.utilities.iterables import variations
>>> list(variations([1, 2, 3], 2))
[(1, 2), (1, 3), (2, 1), (2, 3), (3, 1), (3, 2)]
>>> list(variations([1, 2, 3], 2, True))
[(1, 1), (1, 2), (1, 3), (2, 1), (2, 2), (2, 3), (3, 1), (3, 2), (3, 3)]
```

**partitions**

Although the combinatorics module contains Partition and IntegerPartition classes for investigation and manipulation of partitions, there are a few functions to generate partitions that can be used as low-level tools for routines: `partitions` and `multiset_partitions`. The former gives integer partitions, and the latter gives enumerated partitions of elements. There is also a routine `kbins` that will give a variety of permutations of partitions. And to obtain partitions as a list instead of a dictionary, there is the `ordered_partition` function which is quite fast. Finally, to simply obtain a count of the number of partitions without enumerating them, there is the `nT` function.

**See Also**

- sympy.utilities.iterables.ordered_partitions
- sympy.functions.combinatorial.numbers.nT
- partitions:

```python
>>> from sympy.utilities.iterables import partitions
>>> [p.copy() for s, p in partitions(7, m=2, size=True) if s == 2]
[{{1: 1, 6: 1}, {2: 1, 5: 1}, {3: 1, 4: 1}}]
```

- multiset_partitions:

```python
>>> from sympy.utilities.iterables import multiset_partitions
>>> [p for p in multiset_partitions([1, 1, 1, 2], 2)]
[[[1, 1, 1], [2]], [[1, 1, 2], [1]], [[1, 1], [1, 2]], [[1, 2], [1, 1]]]
```
kbins:

```python
from sympy.utilities.iterables import kbins

def show(k):
    rv = []
    for p in k:
        rv.append(', '.join([''.join(j) for j in p]))
    return sorted(rv)

>>> show(kbins("ABCD", 2))
['A,BCD', 'AB,CD', 'ABC,D']
>>> show(kbins("ABC", 2))
['A,BC', 'AB,C']
>>> show(kbins("ABC", 2, ordered=0))  # same as multiset_partitions
['A,BC', 'AB,C', 'AC,B']
>>> show(kbins("ABC", 2, ordered=1))
>>> show(kbins("ABC", 2, ordered=10))
>>> show(kbins("ABC", 2, ordered=11))
```

### Lambdify

This module provides convenient functions to transform SymPy expressions to lambda functions which can be used to calculate numerical values very fast.

`sympy.utilities.lambdify.implemented_function(symfunc, implementation)`

Add numerical implementation to function `symfunc`.

`symfunc` can be an `UndefinedFunction` instance, or a name string. In the latter case we create an `UndefinedFunction` instance with that name.

Be aware that this is a quick workaround, not a general method to create special symbolic functions. If you want to create a symbolic function to be used by all the machinery of SymPy you should subclass the `Function` class.

**Parameters**

- `symfunc`: `str` or `UndefinedFunction` instance
  
  If `str`, then create new `UndefinedFunction` with this as name. If `symfunc` is an `UndefinedFunction`, create a new function with the same name and the implemented function attached.

- `implementation`: `callable`
  
  numerical implementation to be called by `evalf()` or `lambdify`

**Returns**

- `afunc`: `sympy.FunctionClass` instance
function with attached implementation

Examples

```python
>>> from sympy.abc import x
>>> from sympy.utilities.lambdify import implemented_function
>>> from sympy import lambdify

>>> f = implemented_function('f', lambda x: x+1)
>>> lam_f = lambdify(x, f(x))
>>> lam_f(4)
5
```

sympy.utilities.lambdify.lambdastr(args, expr, printer=None, dummify=None)

Returns a string that can be evaluated to a lambda function.

Examples

```python
>>> from sympy.abc import x, y, z
>>> from sympy.utilities.lambdify import lambdastr

>>> lambdastr(x, x**2)
'lambda x: (x**2)'
>>> lambdastr((x,y,z), [z,y,x])
'lambda x,y,z: ([z, y, x])'
```

Although tuples may not appear as arguments to lambda in Python 3, lambdastr will create a lambda function that will unpack the original arguments so that nested arguments can be handled:

```python
>>> lambdastr((x, (y, z)), x + y)
'lambda _0,_1: (lambda x,y,z: (x + y)(_0,_1[0],_1[1]))'
```

sympy.utilities.lambdify.lambdify(args, expr, modules=None, printer=None, use_imps=True, dummify=False, cse=False, docstring_limit=1000)

Convert a SymPy expression into a function that allows for fast numeric evaluation.

**Warning:** This function uses exec, and thus should not be used on unsanitized input.

Deprecated since version 1.7: Passing a set for the `args` parameter is deprecated as sets are unordered. Use an ordered iterable such as a list or tuple.

**Parameters**

- **args**: List[Symbol]
  
  A variable or a list of variables whose nesting represents the nesting of the arguments that will be passed to the function.

  Variables can be symbols, undefined functions, or matrix symbols.

```python
>>> from sympy import Eq
>>> from sympy import x, y, z
```
The list of variables should match the structure of how the arguments will be passed to the function. Simply enclose the parameters as they will be passed in a list.

To call a function like $f(x)$ then $[x]$ should be the first argument to lambdify; for this case a single $x$ can also be used:

```python
>>> f = lambdify(x, x + 1)
>>> f(1)
2
>>> f = lambdify([x], x + 1)
>>> f(1)
2
```

To call a function like $f(x, y)$ then $[x, y]$ will be the first argument of the lambdify:

```python
>>> f = lambdify([x, y], x + y)
>>> f(1, 1)
2
```

To call a function with a single 3-element tuple like $f((x, y, z))$ then $[(x, y, z)]$ will be the first argument of the lambdify:

```python
>>> f = lambdify([(x, y, z)], Eq(z**2, x**2 + y**2))
>>> f((3, 4, 5))
True
```

If two args will be passed and the first is a scalar but the second is a tuple with two arguments then the items in the list should match that structure:

```python
>>> f = lambdify([x, (y, z)], x + y + z)
>>> f(1, (2, 3))
6
```

**expr**: Expr

An expression, list of expressions, or matrix to be evaluated.

Lists may be nested. If the expression is a list, the output will also be a list.

```python
>>> f = lambdify(x, [x, [x + 1, x + 2]])
>>> f(1)
[1, [2, 3]]
```

If it is a matrix, an array will be returned (for the NumPy module).

```python
>>> from sympy import Matrix
>>> f = lambdify(x, Matrix([x, x + 1]))
>>> f(1)
[[1]
 [2]]
```

Note that the argument order here (variables then expression) is used to emulate the Python lambda keyword. `lambdify(x, expr)` works
(roughly) like lambda x: expr (see *How It Works* (page 2179) below).

**modules**: str, optional

Specifies the numeric library to use.

If not specified, *modules* defaults to:
- ["scipy", "numpy"] if SciPy is installed
- ["numpy"] if only NumPy is installed
- ["math", "mpmath", "sympy"] if neither is installed.

That is, SymPy functions are replaced as far as possible by either scipy or numpy functions if available, and Python’s standard library math, or mpmath functions otherwise.

*modules* can be one of the following types:

- The strings "math", "mpmath", "numpy", "numexpr", "scipy", "sympy", or "tensorflow" or "jax". This uses the corresponding printer and namespace mapping for that module.
- A module (e.g., math). This uses the global namespace of the module. If the module is one of the above known modules, it will also use the corresponding printer and namespace mapping (i.e., *modules=numpy* is equivalent to *modules="numpy"*).
- A dictionary that maps names of SymPy functions to arbitrary functions (e.g., \{'sin': custom_sin\}).
- A list that contains a mix of the arguments above, with higher priority given to entries appearing first (e.g., to use the NumPy module but override the \sin\ function with a custom version, you can use \[[\{'sin': custom_sin\}, 'numpy']\).

**dummify**: bool, optional

Whether or not the variables in the provided expression that are not valid Python identifiers are substituted with dummy symbols.

This allows for undefined functions like `Function('f')(t)` to be supplied as arguments. By default, the variables are only dummified if they are not valid Python identifiers.

Set `dummify=True` to replace all arguments with dummy symbols (if `args` is not a string) - for example, to ensure that the arguments do not redefine any built-in names.

**cse**: bool, or callable, optional

Large expressions can be computed more efficiently when common subexpressions are identified and precomputed before being used multiple time. Finding the subexpressions will make creation of the 'lambdify' function slower, however.

When `True`, `sympy.simplify.cse` is used, otherwise (the default) the user may pass a function matching the cse signature.

**docstring_limit**: int or None

When lambdifying large expressions, a significant proportion of the time spent inside lambdify is spent producing a string representation
of the expression for use in the automatically generated docstring of
the returned function. For expressions containing hundreds or more
nodes the resulting docstring often becomes so long and dense that it
is difficult to read. To reduce the runtime of lambdify, the rendering
of the full expression inside the docstring can be disabled.

When None, the full expression is rendered in the docstring. When \(0\)
or a negative int, an ellipsis is rendering in the docstring instead of
the expression. When a strictly positive int, if the number of nodes
in the expression exceeds docstring_limit an ellipsis is rendered in
the docstring, otherwise a string representation of the expression is
rendered as normal. The default is 1000.

**Explanation**

For example, to convert the SymPy expression \(\sin(x) + \cos(x)\) to an equivalent NumPy
function that numerically evaluates it:

```python
>>> from sympy import sin, cos, symbols, lambdify
>>> import numpy as np
>>> x = symbols('x')
>>> expr = sin(x) + cos(x)
>>> expr
sin(x) + cos(x)
>>> f = lambdify(x, expr, 'numpy')
>>> a = np.array([1, 2])
>>> f(a)
[1.38177329 0.49315059]
```

The primary purpose of this function is to provide a bridge from SymPy expressions
to numerical libraries such as NumPy, SciPy, NumExpr, mpmath, and tensorflow. In
general, SymPy functions do not work with objects from other libraries, such as NumPy
arrays, and functions from numeric libraries like NumPy or mpmath do not work on
SymPy expressions. lambdify bridges the two by converting a SymPy expression to an
equivalent numeric function.

The basic workflow with lambdify is to first create a SymPy expression representing
whatever mathematical function you wish to evaluate. This should be done using only
SymPy functions and expressions. Then, use lambdify to convert this to an equivalent
function for numerical evaluation. For instance, above we created expr using the SymPy
symbol \(x\) and SymPy functions \(\sin\) and \(\cos\), then converted it to an equivalent NumPy
function \(f\), and called it on a NumPy array \(a\).

**Examples**

```python
>>> from sympy.utilities.lambdify import implemented_function
>>> from sympy import sqrt, sin, Matrix
>>> from sympy import Function
>>> from sympy.abc import w, x, y, z

>>> f = lambdify(x, x**2)
>>> f(2)
```

(continues on next page)
lambdify can be used to translate SymPy expressions into mpmath functions. This may be preferable to using evalf (which uses mpmath on the backend) in some cases.

```
>>> f = lambdify(x, sin(x), 'mpmath')
>>> f(1)
0.8414709848078965
```

Tuple arguments are handled and the lambdified function should be called with the same type of arguments as were used to create the function:

```
>>> f = lambdify((x, (y, z)), x + y)
>>> f(1, (2, 4))
3
```

The flatten function can be used to always work with flattened arguments:

```
>>> from sympy.utilities.iterables import flatten
>>> Args = w, (x, (y, z))
>>> vals = 1, (2, (3, 4))
>>> f = lambdify(flatten(args), w + x + y + z)
>>> f(*flatten(vals))
10
```

Functions present in expr can also carry their own numerical implementations, in a callable attached to the _imp_ attribute. This can be used with undefined functions using the implemented_function factory:

```
>>> f = implemented_function(Function('f'), lambda x: x+1)
>>> func = lambdify(x, f(x))
>>> func(4)
5
```

lambdify always prefers _imp_ implementations to implementations in other namespaces, unless the use_imps input parameter is False.

Usage with Tensorflow:

```
>>> import tensorflow as tf
>>> from sympy import Max, sin, lambdify
>>> from sympy.abc import x
```
>>> f = Max(x, sin(x))
>>> func = lambdify(x, f, 'tensorflow')

After tensorflow v2, eager execution is enabled by default. If you want to get the compatible result across tensorflow v1 and v2 as same as this tutorial, run this line.

>>> tf.compat.v1.enable_eager_execution()

If you have eager execution enabled, you can get the result out immediately as you can use numpy.
If you pass tensorflow objects, you may get an EagerTensor object instead of value.

>>> result = func(tf.constant(1.0))
>>> print(result)
Tensor(1.0, shape=(), dtype=float32)
>>> print(result.__class__)
<class 'tensorflow.python.framework.ops.EagerTensor'>

You can use .numpy() to get the numpy value of the tensor.

>>> result.numpy()
1.0

>>> var = tf.Variable(2.0)
>>> result = func(var) # also works for tf.Variable and tf.Placeholder
>>> result.numpy()
2.0

And it works with any shape array.

>>> tensor = tf.constant([[1.0, 2.0], [3.0, 4.0]])
>>> result = func(tensor)
>>> result.numpy()
[[1. 2.]
 [3. 4.]]

Notes

- For functions involving large array calculations, numexpr can provide a significant speedup over numpy. Please note that the available functions for numexpr are more limited than numpy but can be expanded with implemented_function and user defined subclasses of Function. If specified, numexpr may be the only option in modules. The official list of numexpr functions can be found at: https://numexpr.readthedocs.io/projects/NumExpr3/en/latest/user_guide.html#supported-functions

- In the above examples, the generated functions can accept scalar values or numpy arrays as arguments. However, in some cases the generated function relies on the input being a numpy array:
>>> from sympy.test.pytest import ignore_warnings
>>> f = lambdify(x, Piecewise((x, x <= 1), (1/x, x > 1)), "numpy")

>>> with ignore_warnings(RuntimeWarning):
...   f(numpy.array([-1, 0, 1, 2]))
[-1. 0. 1. 0.5]

>>> f(0)
Traceback (most recent call last):
  ... ZeroDivisionError: division by zero

In such cases, the input should be wrapped in a numpy array:

>>> with ignore_warnings(RuntimeWarning):
...   float(f(numpy.array([0])))
0.0

Or if numpy functionality is not required another module can be used:

>>> f = lambdify(x, Piecewise((x, x <= 1), (1/x, x > 1)), "math")
>>> f(0)
0

**How It Works**

When using this function, it helps a great deal to have an idea of what it is doing. At its core, lambdify is nothing more than a namespace translation, on top of a special printer that makes some corner cases work properly.

To understand lambdify, first we must properly understand how Python namespaces work. Say we had two files. One called sin_cos_sympy.py, with

```python
# sin_cos_sympy.py
from sympy.functions.elementary.trigonometric import (cos, sin)
def sin_cos(x):
    return sin(x) + cos(x)
```

and one called sin_cos_numpy.py with

```python
# sin_cos_numpy.py
from numpy import sin, cos
def sin_cos(x):
    return sin(x) + cos(x)
```

The two files define an identical function sin_cos. However, in the first file, sin and cos are defined as the SymPy sin and cos. In the second, they are defined as the NumPy versions.
If we were to import the first file and use the `sin_cos` function, we would get something like

```python
>>> from sin_cos_sympy import sin_cos
>>> sin_cos(1)
cos(1) + sin(1)
```

On the other hand, if we imported `sin_cos` from the second file, we would get

```python
>>> from sin_cos_numpy import sin_cos
>>> sin_cos(1)
1.38177329068
```

In the first case we got a symbolic output, because it used the symbolic `sin` and `cos` functions from SymPy. In the second, we got a numeric result, because `sin_cos` used the numeric `sin` and `cos` functions from NumPy. But notice that the versions of `sin` and `cos` that were used was not inherent to the `sin_cos` function definition. Both `sin_cos` definitions are exactly the same. Rather, it was based on the names defined at the module where the `sin_cos` function was defined.

The key point here is that when function in Python references a name that is not defined in the function, that name is looked up in the “global” namespace of the module where that function is defined.

Now, in Python, we can emulate this behavior without actually writing a file to disk using the `exec` function. `exec` takes a string containing a block of Python code, and a dictionary that should contain the global variables of the module. It then executes the code “in” that dictionary, as if it were the module globals. The following is equivalent to the `sin_cos` defined in `sin_cos_sympy.py`:

```python
>>> import sympy
>>> module_dictionary = {'sin': sympy.sin, 'cos': sympy.cos}
>>> exec('...
... def sin_cos(x):
...     return sin(x) + cos(x)
... ''', module_dictionary)
>>> sin_cos = module_dictionary['sin_cos']
>>> sin_cos(1)
cos(1) + sin(1)
```

and similarly with `sin_cos_numpy`:

```python
>>> import numpy
>>> module_dictionary = {'sin': numpy.sin, 'cos': numpy.cos}
>>> exec('...
... def sin_cos(x):
...     return sin(x) + cos(x)
... ''', module_dictionary)
>>> sin_cos = module_dictionary['sin_cos']
>>> sin_cos(1)
1.38177329068
```

So now we can get an idea of how `lambdify` works. The name “lambdify” comes from the fact that we can think of something like `lambdify(x, sin(x) + cos(x), 'numpy')` as lambda `x`: `sin(x) + cos(x)`, where `sin` and `cos` come from the `numpy` namespace.
This is also why the symbols argument is first in lambdify, as opposed to most SymPy functions where it comes after the expression: to better mimic the lambda keyword.

lambdify takes the input expression (like \(\sin(x) + \cos(x)\)) and

1. Converts it to a string
2. Creates a module globals dictionary based on the modules that are passed in (by default, it uses the NumPy module)
3. Creates the string "def func({vars}): return {expr}", where {vars} is the list of variables separated by commas, and {expr} is the string created in step 1., then exec``s that string with the module globals namespace and returns ``func.

In fact, functions returned by lambdify support inspection. So you can see exactly how they are defined by using inspect.getsource, or ?? if you are using IPython or the Jupyter notebook.

```python
>>> f = lambdify(x, sin(x) + cos(x))
>>> import inspect
>>> print(inspect.getsource(f))
def _lambdifygenerated(x):
    return sin(x) + cos(x)
```

This shows us the source code of the function, but not the namespace it was defined in. We can inspect that by looking at the __globals__ attribute of f:

```python
>>> f.__globals__[\'sin\']
<ufunc 'sin'>
>>> f.__globals__[\'cos\']
<ufunc 'cos'>
>>> f.__globals__[\'sin\'] is numpy.sin
True
```

This shows us that \(\sin\) and \(\cos\) in the namespace of f will be numpy.sin and numpy.cos.

Note that there are some convenience layers in each of these steps, but at the core, this is how lambdify works. Step 1 is done using the LambdaPrinter printers defined in the printing module (see sympy.printing.lambdarepr (page 2245)). This allows different SymPy expressions to define how they should be converted to a string for different modules. You can change which printer lambdify uses by passing a custom printer in to the printer argument.

Step 2 is augmented by certain translations. There are default translations for each module, but you can provide your own by passing a list to the modules argument. For instance,

```python
>>> def mysin(x):
...     print('taking the sin of', x)
...     return numpy.sin(x)
... >>> f = lambdify(x, sin(x), [{\'sin\': mysin}, \'numpy\'])
>>> f(1)
taking the sin of 1
0.8414709848078965
```
The globals dictionary is generated from the list by merging the dictionary `{ 'sin': mysin }` and the module dictionary for NumPy. The merging is done so that earlier items take precedence, which is why `mysin` is used above instead of `numpy.sin`.

If you want to modify the way `lambdify` works for a given function, it is usually easiest to do so by modifying the globals dictionary as such. In more complicated cases, it may be necessary to create and pass in a custom printer.

Finally, step 3 is augmented with certain convenience operations, such as the addition of a docstring.

Understanding how `lambdify` works can make it easier to avoid certain gotchas when using it. For instance, a common mistake is to create a lambdified function for one module (say, NumPy), and pass it objects from another (say, a SymPy expression).

For instance, say we create

```python
>>> from sympy.abc import x
>>> f = lambdify(x, x + 1, 'numpy')
```

Now if we pass in a NumPy array, we get that array plus 1

```python
>>> import numpy
>>> a = numpy.array([1, 2])
>>> f(a)
[2 3]
```

But what happens if you make the mistake of passing in a SymPy expression instead of a NumPy array:

```python
>>> f(x + 1)
x + 2
```

This worked, but it was only by accident. Now take a different lambdified function:

```python
>>> from sympy import sin
>>> g = lambdify(x, x + sin(x), 'numpy')
```

This works as expected on NumPy arrays:

```python
>>> g(a)
[1.84147098 2.90929743]
```

But if we try to pass in a SymPy expression, it fails

```python
>>> try:
...     g(x + 1)
...     # NumPy release after 1.17 raises TypeError instead of
...     # AttributeError
...     except (AttributeError, TypeError):
...         raise AttributeError()
Traceback (most recent call last):
  raise AttributeError()
AttributeError:
```

Now, let’s look at what happened. The reason this fails is that `g` calls `numpy.sin` on the input expression, and `numpy.sin` does not know how to operate on a SymPy object. As
a general rule, NumPy functions do not know how to operate on SymPy expressions, and SymPy functions do not know how to operate on NumPy arrays. This is why lambdify exists: to provide a bridge between SymPy and NumPy.

However, why is it that f did work? That’s because f does not call any functions, it only adds 1. So the resulting function that is created, def _lambdifygenerated(x): return x + 1 does not depend on the globals namespace it is defined in. Thus it works, but only by accident. A future version of lambdify may remove this behavior.

Be aware that certain implementation details described here may change in future versions of SymPy. The API of passing in custom modules and printers will not change, but the details of how a lambda function is created may change. However, the basic idea will remain the same, and understanding it will be helpful to understanding the behavior of lambdify.

In general: you should create lambdified functions for one module (say, NumPy), and only pass it input types that are compatible with that module (say, NumPy arrays). Remember that by default, if the module argument is not provided, lambdify creates functions using the NumPy and SciPy namespaces.

**Memoization**

sympy.utilities.memoization.assoc_recurrence_memo(base_seq)

Memo decorator for associated sequences defined by recurrence starting from base

base_seq(n) - callable to get base sequence elements

XXX works only for Pn0 = base_seq(0) cases XXX works only for m <= n cases

sympy.utilities.memoization.recurrence_memo(initial)

Memo decorator for sequences defined by recurrence

See usage examples e.g. in the specfun/combinatorial module

**Miscellaneous**

Miscellaneous stuff that does not really fit anywhere else.

sympy.utilities.misc.as_int(n, strict=True)

Convert the argument to a builtin integer.

The return value is guaranteed to be equal to the input. ValueError is raised if the input has a non-integral value. When strict is True, this uses __index__ and when it is False it uses int.
Examples

```python
>>> from sympy.utilities.misc import as_int
>>> from sympy import sqrt, S
```

The function is primarily concerned with sanitizing input for functions that need to work with built-in integers, so anything that is unambiguously an integer should be returned as an int:

```python
>>> as_int(S(3))
3
```

Floats, being of limited precision, are not assumed to be exact and will raise an error unless the `strict` flag is False. This precision issue becomes apparent for large floating point numbers:

```python
>>> big = 1e23
>>> type(big) is float
True
>>> big == int(big)
True
>>> as_int(big)
Traceback (most recent call last):
  ... ValueError: ... is not an integer
>>> as_int(big, strict=False)
99999999999999991611392
```

Input that might be a complex representation of an integer value is also rejected by default:

```python
>>> one = sqrt(3 + 2*sqrt(2)) - sqrt(2)
>>> int(one) == 1
True
>>> as_int(one)
Traceback (most recent call last):
  ... ValueError: ... is not an integer
```

`sympy.utilities.misc.debug(*args)`
Print `*args` if SYMPY_DEBUG is True, else do nothing.

`sympy.utilities.misc.debug_decorator(func)`
If SYMPY_DEBUG is True, it will print a nice execution tree with arguments and results of all decorated functions, else do nothing.

`sympy.utilities.misc.debugf(string, args)`
Print `string%args` if SYMPY_DEBUG is True, else do nothing. This is intended for debug messages using formatted strings.

`sympy.utilities.misc.filldedent(s, w=70, **kwargs)`
Strips leading and trailing empty lines from a copy of `s`, then dedents, fills and returns it.

Empty line stripping serves to deal with docstrings like this one that start with a newline after the initial triple quote, inserting an empty line at the beginning of the string.
Additional keyword arguments will be passed to `textwrap.fill()`.

**See also:**

- `strlines` (page 2187), `rawlines` (page 2185)

**sympy.utilities.misc.find_executable(executable, path=None)**

Try to find `executable` in the directories listed in `path` (a string listing directories separated by `os.pathsep`; defaults to `os.environ['PATH']`). Returns the complete filename or None if not found.

**sympy.utilities.misc.func_name(x, short=False)**

Return function name of `x` (if defined) else the `type(x)`. If short is True and there is a shorter alias for the result, return the alias.

### Examples

```python
>>> from sympy.utilities.misc import func_name
>>> from sympy import Matrix
>>> from sympy.abc import x

>>> func_name(Matrix.eye(3))
'MutableDenseMatrix'

>>> func_name(x < 1)
'StrictLessThan'

>>> func_name(x < 1, short=True)
'Lt'
```

**sympy.utilities.misc.ordinal(num)**

Return ordinal number string of num, e.g. 1 becomes 1st.

**sympy.utilities.misc.rawlines(s)**

Return a cut-and-pasteable string that, when printed, is equivalent to the input. Use this when there is more than one line in the string. The string returned is formatted so it can be indented nicely within tests; in some cases it is wrapped in the dedent function which has to be imported from `textwrap`.

### Examples

Note: because there are characters in the examples below that need to be escaped because they are themselves within a triple quoted docstring, expressions below look more complicated than they would be if they were printed in an interpreter window.

```python
>>> from sympy.utilities.misc import rawlines
>>> from sympy import TableForm

>>> s = str(TableForm([[1, 10]], headings=(None, ['a', 'bee'])))

>>> print(rawlines(s))
(a bee
 -----
 1 10 )

>>> print(rawlines('''this
(continues on next page)'''))
```

5.8. Topics
... that''')
dedent('''
    this
    that''')

>>> print(rawlines('''this
... that
... '''))
dedent('''
    this
    that''')

>>> s = """"this
... is a triple ''
... ""

>>> print(rawlines(s))
dedent(""""
    this
    is a triple '''
    """)

>>> print(rawlines('''this
... that
... '''))
('this
' 'that
'
)

See also:
filldedent (page 2184), strlines (page 2187)
sympy.utilities.misc.replace(string, *reps)
Return string with all keys in reps replaced with their corresponding values, longer strings first, irrespective of the order they are given. reps may be passed as tuples or a single mapping.

Examples

>>> from sympy.utilities.misc import replace
>>> replace('foo', {'oo': 'ar', 'f': 'b'})
'bar'

>>> replace("spamham sha", ("spam", "eggs"), ("sha","md5"))
'eggsham md5'

There is no guarantee that a unique answer will be obtained if keys in a mapping overlap (i.e. are the same length and have some identical sequence at the beginning/end):
>>> reps = [
... ('ab', 'x'),
... ('bc', 'y'))
>>> replace('abc', *reps) in ('xc', 'ay')
True

References

[R1003]
sympy.utilities.misc.strlines(s, c=64, short=False)

Return a cut-and-pastable string that, when printed, is equivalent to the input. The lines will be surrounded by parentheses and no line will be longer than c (default 64) characters. If the line contains newlines characters, the rawlines result will be returned. If short is True (default is False) then if there is one line it will be returned without bounding parentheses.

Examples

```python
>>> from sympy.utilities.misc import strlines
>>> q = 'this is a long string that should be broken into shorter lines'
>>> print(strlines(q, 40))
('this is a long string that should be b'
'roken into shorter lines'
)
```

```python
>>> q == ('this is a long string that should be b'
... 'roken into shorter lines'
... )
True
```

See also:

filldedent (page 2184), rawlines (page 2185)

sympy.utilities.misc.translate(s, a=None, b=None, c=None)

Return s where characters have been replaced or deleted.

Syntax

translate(s, None, deletechars):

all characters in deletechars are deleted

translate(s, map [,deletechars]):

all characters in deletechars (if provided) are deleted then the replacements defined by map are made; if the keys of map are strings then the longer ones are handled first. Multicharacter deletions should have a value of "."

translate(s, oldchars, newchars, deletechars)

all characters in deletechars are deleted then each character in oldchars is replaced with the corresponding character in newchars
Examples

```python
>>> from sympy.utilities.misc import translate
>>> abc = 'abc'
'bc'
>>> translate(abc, None, 'a')
'bc'
>>> translate(abc, {'a': 'x'}, 'c')
'xb'
>>> translate(abc, {'abc': 'x', 'a': 'y'})
'x'
```

```python
>>> translate('abcd', 'ac', 'AC', 'd')
'AbC'
```

There is no guarantee that a unique answer will be obtained if keys in a mapping overlap are the same length and have some identical sequences at the beginning/end:

```python
>>> translate(abc, {'ab': 'x', 'bc': 'y'}) in ('xc', 'ay')
True
```

PKGDATA

pkgdata is a simple, extensible way for a package to acquire data file resources.
The getResource function is equivalent to the standard idioms, such as the following minimal implementation:

```python
import sys, os

def getResource(identifier, pkgname=__name__):
    pkgpath = os.path.dirname(sys.modules[pkgname].__file__)
    path = os.path.join(pkgpath, identifier)
    return open(os.path.normpath(path), mode='rb')
```

When a __loader__ is present on the module given by __name__, it will defer getResource to its get_data implementation and return it as a file-like object (such as StringIO).

```python
sympy.utilities.pkgdata.get_resource(identifier, pkgname='sympy.utilities.pkgdata')
```

Acquire a readable object for a given package name and identifier. An IOError will be raised if the resource cannot be found.

For example:

```python
mydata = get_resource('mypkgdata.jpg').read()
```

Note that the package name must be fully qualified, if given, such that it would be found in sys.modules.

In some cases, getResource will return a real file object. In that case, it may be useful to use its name attribute to get the path rather than use it as a file-like object. For example, you may be handing data off to a C API.
Source Code Inspection

This module adds several functions for interactive source code inspection.

\texttt{sympy.utilities.source.get\_class(lookup\_view)}

Convert a string version of a class name to the object.

For example, \texttt{get\_class('sympy.core.Basic')} will return class \texttt{Basic} located in module \texttt{sympy.core}

\texttt{sympy.utilities.source.get\_mod\_func(callback)}

splits the string path to a class into a string path to the module and the name of the class.

Examples

\begin{verbatim}
>>> from sympy.utilities.source import get_mod_func
>>> get_mod_func('sympy.core.basic.Basic')
('sympy.core.basic', 'Basic')
\end{verbatim}

Timing Utilities

Simple tools for timing functions' execution, when IPython is not available.

\texttt{sympy.utilities.timeutils.timed(func, setup='pass', limit=None)}

Adaptively measure execution time of a function.

Interactive

Helper module for setting up interactive SymPy sessions.

Session

Tools for setting up interactive sessions.

\texttt{sympy.interactive.session.enable\_automatic\_int\_sympification(shell)}

Allow IPython to automatically convert integer literals to \texttt{Integer}.

\texttt{sympy.interactive.session.enable\_automatic\_symbols(shell)}

Allow IPython to automatically create symbols (isympy -a).

\texttt{sympy.interactive.session.init\_ipython\_session(shell=None, argv=[],
auto\_symbols=False,
auto\_int\_to\_Integer=False)}

Construct new IPython session.

\texttt{sympy.interactive.session.init\_python\_session()}

Construct new Python session.
Initialize an embedded IPython or Python session. The IPython session is initiated with the –pylab option, without the numpy imports, so that Matplotlib plotting can be interactive.

**Parameters**

- **pretty_print**: boolean
  
  If True, use pretty_print to stringify; if False, use sstrrepr to stringify.

- **order**: string or None
  
  There are a few different settings for this parameter: lex (default), which is lexicographic order; grlex, which is graded lexicographic order; grevlex, which is reversed graded lexicographic order; old, which is used for compatibility reasons and for long expressions; None, which sets it to lex.

- **use_unicode**: boolean or None
  
  If True, use unicode characters; if False, do not use unicode characters.

- **use_latex**: boolean or None
  
  If True, use latex rendering if IPython GUI’s; if False, do not use latex rendering.

- **quiet**: boolean
  
  If True, init_session will not print messages regarding its status; if False, init_session will print messages regarding its status.

- **auto_symbols**: boolean
  
  If True, IPython will automatically create symbols for you. If False, it will not. The default is False.

- **auto_int_to_Integer**: boolean
  
  If True, IPython will automatically wrap int literals with Integer, so that things like 1/2 give Rational(1, 2). If False, it will not. The default is False.

- **ipython**: boolean or None
  
  If True, printing will initialize for an IPython console; if False, printing will initialize for a normal console; The default is None, which automatically determines whether we are in an ipython instance or not.

- **str_printer**: function, optional, default=None
  
  A custom string printer function. This should mimic sympy.printing.sstrrepr().

- **pretty_printer**: function, optional, default=None
  
  A custom prettyprinter function.
A custom pretty printer. This should mimic sympy.printing.pretty().

latex_printer: function, optional, default=None

A custom LaTeX printer. This should mimic sympy.printing.latex().

argv: list of arguments for IPython

See sympy.bin.isympy for options that can be used to initialize IPython.

Examples

```python
>>> from sympy import init_session, Symbol, sin, sqrt
>>> sin(x)
NameError: name 'x' is not defined
>>> init_session()
>>> sin(x)
sin(x)
>>> sqrt(5)
\sqrt{5}
>>> init_session(pretty_print=False)
>>> sqrt(5)
sqrt(5)
>>> y + x + y**2 + x**2
x**2 + x + y**2 + y
>>> init_session(order='grlex')
>>> y + x + y**2 + x**2
x**2 + y**2 + x + y
>>> init_session(order='grevlex')
>>> y * x**2 + x * y**2
x**2*y + x*y**2
>>> init_session(order='old')
>>> x**2 + y**2 + x + y
x + y + x**2 + y**2
>>> theta = Symbol('theta')
>>> theta
theta
>>> init_session(use_unicode=True)
>>> theta
θ
```

See also:

sympy.interactive.printing.init_printing (page 2192)
for examples and the rest of the parameters.

sympy.interactive.session.int_to_Integer(s)
Wrap integer literals with Integer.

This is based on the decistmt example from https://docs.python.org/3/library/tokenize.html.

Only integer literals are converted. Float literals are left alone.

5.8. Topics 2191
Examples

```python
>>> from sympy import Integer # noqa: F401
>>> from sympy.interactive.session import int_to_Integer
>>> s = '1.2 + 1/2 - 0x12 + a1'
>>> int_to_Integer(s)
'1.2 +Integer (1 )/Integer (2 )-Integer (0x12 )+a1 '
>>> s = 'print (1/2) '
>>> int_to_Integer(s)
'print (Integer (1 )/Integer (2 ))'
>>> exec(s)
0.5
>>> exec(int_to_Integer(s))
1/2
```

Printing

Tools for setting up printing in interactive sessions.

```python
sympy.interactive.printing.init_printing(pretty_print=True, order=None,
                                         use_unicode=None, use_latex=None,
                                         wrap_line=None, num_columns=None,
                                         no_global=False, ip=None, euler=False,
                                         forecolor=None, backcolor='Transparent',
                                         fontsize='10pt', latex_mode='plain',
                                         print_builtin=True, str_printer=None,
                                         pretty_printer=None, latex_printer=None,
                                         scale=1.0, **settings)
```

Initializes pretty-printer depending on the environment.

**Parameters**

- **pretty_print**: bool, default=True
  - If True, use `pretty_print()` (page 2212) to stringify or the provided pretty printer; if False, use `sstrrepr()` (page 2253) to stringify or the provided string printer.

- **order**: string or None, default='lex'
  - There are a few different settings for this parameter: 'lex' (default), which is lexicographic order; 'grlex', which is graded lexicographic order; 'grevlex', which is reversed graded lexicographic order; 'old', which is used for compatibility reasons and for long expressions; None, which sets it to lex.

- **use_unicode**: bool or None, default=None
  - If True, use unicode characters; if False, do not use unicode characters; if None, make a guess based on the environment.

- **use_latex**: string, bool, or None, default=None
  - If True, use default LaTeX rendering in GUI interfaces (png and mathjax); if False, do not use LaTeX rendering; if None, make a guess based on the environment; if 'png', enable LaTeX rendering with an
external LaTeX compiler, falling back to matplotlib if external compilation fails; if 'matplotlib', enable LaTeX rendering with matplotlib; if 'mathjax', enable LaTeX text generation, for example MathJax rendering in IPython notebook or text rendering in LaTeX documents; if 'svg', enable LaTeX rendering with an external latex compiler, no fallback

wrap_line : bool

If True, lines will wrap at the end; if False, they will not wrap but continue as one line. This is only relevant if pretty_print is True.

num_columns : int or None, default=None

If int, number of columns before wrapping is set to num_columns; if None, number of columns before wrapping is set to terminal width. This is only relevant if pretty_print is True.

no_global : bool, default=False

If True, the settings become system wide; if False, use just for this console/session.

ip : An interactive console

This can either be an instance of IPython, or a class that derives from code.InteractiveConsole.

euler : bool, optional, default=False

Loads the euler package in the LaTeX preamble for handwritten style fonts (https://www.ctan.org/pkg/euler).

forecolor : string or None, optional, default=None

DVI setting for foreground color. None means that either ‘Black’, ‘White’, or ‘Gray’ will be selected based on a guess of the IPython terminal color setting. See notes.

backcolor : string, optional, default='Transparent'

DVI setting for background color. See notes.

fontsize : string or int, optional, default='10pt'

A font size to pass to the LaTeX documentclass function in the preamble. Note that the options are limited by the documentclass. Consider using scale instead.

latex_mode : string, optional, default='plain'

The mode used in the LaTeX printer. Can be one of: {'inline'|'plain'|'equation'|'equation*'}.

print_builtin : boolean, optional, default=True

If True then floats and integers will be printed. If False the printer will only print SymPy types.

str_printer : function, optional, default=None

A custom string printer function. This should mimic sstrrepr() (page 2253).

pretty_printer : function, optional, default=None
A custom pretty printer. This should mimic \texttt{pretty()} (page 2212).

\texttt{latex\_printer} : function, optional, default=None

A custom LaTeX printer. This should mimic \texttt{latex()} (page 2245).

\texttt{scale} : float, optional, default=1.0

Scale the LaTeX output when using the 'png' or 'svg' backends. Useful for high dpi screens.

\texttt{settings} :

Any additional settings for the \texttt{latex} and \texttt{pretty} commands can be used to fine-tune the output.

\section*{Examples}

\begin{verbatim}
>>> from sympy.interactive import init_printing
>>> from sympy import Symbol, sqrt
>>> from sympy.abc import x, y
>>> sqrt(5)
sqrt(5)
>>> init_printing(pretty_print=True)
>>> sqrt(5)
\sqrt{5}

\theta

>>> theta = Symbol('theta')
>>> init_printing(use_unicode=True)
>>> theta
\theta

>>> init_printing(use_unicode=False)
>>> theta
theta
>>> init_printing(order='lex')
>>> str(y + x + y**2 + x**2)
x**2 + x + y**2 + y
>>> init_printing(order='grlex')
>>> str(y + x + y**2 + x**2)
x**2 + x + y**2 + y
>>> init_printing(order='grevlex')
>>> str(y * x**2 + x * y**2)
x**2*y + x*y**2
>>> init_printing(order='old')
>>> str(x**2 + y**2 + x + y)
x**2 + x + y**2 + y
>>> init_printing(num_columns=10)
>>> x**2 + x + y**2 + y
x + y +
x**2 + y**2
\end{verbatim}
Notes

The foreground and background colors can be selected when using 'png' or 'svg' LaTeX rendering. Note that before the init_printing command is executed, the LaTeX rendering is handled by the IPython console and not SymPy.

The colors can be selected among the 68 standard colors known to dvips, for a list see [R568]. In addition, the background color can be set to 'Transparent' (which is the default value).

When using the 'Auto' foreground color, the guess is based on the colors variable in the IPython console, see [R569]. Hence, if that variable is set correctly in your IPython console, there is a high chance that the output will be readable, although manual settings may be needed.

References

[R568], [R569]

Parsing

Parsing Functions Reference

Converts the string s to a SymPy expression, in local_dict.

Parameters

s : str
   The string to parse.

local_dict : dict, optional
   A dictionary of local variables to use when parsing.

global_dict : dict, optional
   A dictionary of global variables. By default, this is initialized with from sympy import *; provide this parameter to override this behavior (for instance, to parse “Q & S”).

5.8. Topics
transformations : tuple or str

A tuple of transformation functions used to modify the tokens of the parsed expression before evaluation. The default transformations convert numeric literals into their SymPy equivalents, convert undefined variables into SymPy symbols, and allow the use of standard mathematical factorial notation (e.g. x!). Selection via string is available (see below).

evaluate : bool, optional

When False, the order of the arguments will remain as they were in the string and automatic simplification that would normally occur is suppressed. (see examples)

Examples

```python
>>> from sympy.parsing.sympy_parser import parse_expr
>>> parse_expr("1/2")
1/2
>>> type(_)
<class 'sympy.core.numbers.Half'>
>>> from sympy.parsing.sympy_parser import standard_transformations,
    ... implicit_multiplication_application
>>> transformations = (standard_transformations +
    ... (implicit_multiplication_application,))
>>> parse_expr("2x", transformations=transformations)
2*x
```

When evaluate=False, some automatic simplifications will not occur:

```python
>>> parse_expr("2**3"), parse_expr("2**3", evaluate=False)
(8, 2**3)
```

In addition the order of the arguments will not be made canonical. This feature allows one to tell exactly how the expression was entered:

```python
>>> a = parse_expr('1 + x', evaluate=False)
>>> b = parse_expr('x + 1', evaluate=0)
>>> a == b
False
>>> a.args
(1, x)
>>> b.args
(x, 1)
```

Note, however, that when these expressions are printed they will appear the same:

```python
>>> assert str(a) == str(b)
```

As a convenience, transformations can be seen by printing transformations:

```python
>>> from sympy.parsing.sympy_parser import transformations
```
The `T` object provides a way to select these transformations:

```python
>>> from sympy.parsing.sympy_parser import T
```

If you print it, you will see the same list as shown above.

```python
>>> str(T) == str(transformations)
True
```

Standard slicing will return a tuple of transformations:

```python
>>> T[:5] == standard_transformations
True
```

So `T` can be used to specify the parsing transformations:

```python
>>> parse_expr("2x", transformations=T[:5])
Traceback (most recent call last):
... SyntaxError: invalid syntax
>>> parse_expr("2x", transformations=T[:6])
2*x
>>> parse_expr('.3', transformations=T[3, 11])
3/10
>>> parse_expr('.3x', transformations=T[:])
3*x/10
```

As a further convenience, strings ‘implicit’ and ‘all’ can be used to select 0-5 and all the transformations, respectively.

```python
>>> parse_expr('.3x', transformations='all')
3*x/10
```

See also:

- `stringify_expr` (page 2197), `eval_expr` (page 2198), `standard_transformations` (page 2199), `implicit_multiplication_application` (page 2200)
sympy.parsing.sympy_parser.stringify_expr\(s: str, local\_dict: Dict[str, Any],
global\_dict: Dict[str, Any],
transformations:
Tuple[Callable[[List[Tuple[int, str]], Dict[str, Any], Dict[str, Any]],
List[Tuple[int, str]]], ...]) \rightarrow str\

Converts the string \(s\) to Python code, in local\_dict
Generally, parse\_expr should be used.

sympy.parsing.sympy_parser.eval_expr\(code, local\_dict: Dict[str, Any], global\_dict: Dict[str, Any]\)

Evaluate Python code generated by stringify\_expr.
Generally, parse\_expr should be used.

sympy.parsing.maxima.parse_maxima\(str, globals=None, name\_dict={}\)

sympy.parsing.mathematica.parse_mathematica\(s\)

Translate a string containing a Wolfram Mathematica expression to a SymPy expression.
If the translator is unable to find a suitable SymPy expression, the FullForm of the Mathematica expression will be output, using SymPy Function objects as nodes of the syntax tree.

**Examples**

```python
>>> from sympy.parsing.mathematica import parse_mathematica
>>> parse_mathematica("Sin[x]^2 Tan[y]")
\sin(x)**2*tan(y)
>>> e = parse_mathematica("F[7,5,3]")
>>> e
F(7, 5, 3)
>>> from sympy import Function, Max, Min
>>> e.replace(Function("F"), lambda *x: Max(*x)*Min(*x))
21
```

Both standard input form and Mathematica full form are supported:

```python
>>> parse_mathematica("x*(a + b)")
x*(a + b)
>>> parse_mathematica("Times[x, Plus[a, b]]")
x*(a + b)
```

To get a matrix from Wolfram’s code:

```python
>>> m = parse_mathematica("\{\{a, b\}, \{c, d\}\}\")
>>> m
((a, b), (c, d))
>>> from sympy import Matrix
>>> Matrix(m)
Matrix([[a, b], [c, d]])
```
If the translation into equivalent SymPy expressions fails, an SymPy expression equivalent to Wolfram Mathematica’s “FullForm” will be created:

```python
>>> parse_mathematica("x_.")
Optional(Pattern(x, Blank()))
```

```python
>>> parse_mathematica("Plus @@ {x, y, z}"
Apply(Plus, (x, y, z))
```

```python
>>> parse_mathematica("f[x_, 3] := x^3 /; x > 0"
SetDelayed(f(Pattern(x, Blank()), 3), Condition(x**3, x > 0))
```

**Parsing Transformations Reference**

A transformation is a function that accepts the arguments tokens, local_dict, global_dict and returns a list of transformed tokens. They can be used by passing a list of functions to `parse_expr()` (page 2195) and are applied in the order given.

```python
sympy.parsing.sympy_parser.standard_transformations:
Tuple[Callable[[List[Tuple[int, str]], Dict[str, Any], Dict[str, Any]],
List[Tuple[int, str]]], ...] = (<function lambda_notation>, <function auto_symbol>, <function repeated_decimals>, <function auto_number>, <function factorial_notation>)
```

Standard transformations for `parse_expr()` (page 2195). Inserts calls to `Symbol` (page 1028), `Integer` (page 1038), and other SymPy datatypes and allows the use of standard factorial notation (e.g. x!).

```python
sympy.parsing.sympy_parser.split_symbols(tokens: List[Tuple[int, str]], local_dict:
Dict[str, Any], global_dict: Dict[str, Any])
```

Splits symbol names for implicit multiplication.

Intended to let expressions like xyz be parsed as x*y*z. Does not split Greek character names, so theta will not become t*h*e*t*a. Generally this should be used with `implicit_multiplication`.

```python
sympy.parsing.sympy_parser.split_symbols_custom(predicate: Callable[[str], bool])
```

Creates a transformation that splits symbol names.

Predicate should return True if the symbol name is to be split.

For instance, to retain the default behavior but avoid splitting certain symbol names, a predicate like this would work:

```python
>>> from sympy.parsing.sympy_parser import (parse_expr, _token_splittable, ...
standard_transformations, implicit_multiplication, ...
split_symbols_custom)
>>> def can_split(symbol):
... if symbol not in ('list', 'of', 'unsplittable', 'names'):
... return _token_splittable(symbol)
... return False
...
>>> transformation = split_symbols_custom(can_split)
>>> parse_expr('unsplittable', transformations=standard_transformations + ...
(unsplittable, implicit_multiplication))
```
sympy.parsing.sympy_parser.implicit_multiplication(tokens: List[Tuple[int, str]], local_dict: Dict[str, Any], global_dict: Dict[str, Any]) \to List[Tuple[int, str]]

Makes the multiplication operator optional in most cases.

Use this before implicit_application() (page 2200), otherwise expressions like \sin 2x will be parsed as \(x \times \sin(2)\) rather than \(\sin(2 \cdot x)\).

Examples

```python
>>> from sympy.parsing.sympy_parser import (parse_expr,
... standard_transformations, implicit_multiplication)
>>> transformations = standard_transformations + (implicit_multiplication,)
>>> parse_expr('3 x y', transformations=transformations)
3*x*y
```

sympy.parsing.sympy_parser.implicit_application(tokens: List[Tuple[int, str]], local_dict: Dict[str, Any], global_dict: Dict[str, Any]) \to List[Tuple[int, str]]

Makes parentheses optional in some cases for function calls.

Use this after implicit_multiplication() (page 2199), otherwise expressions like \sin 2x will be parsed as \(x \times \sin(2)\) rather than \(\sin(2 \cdot x)\).

Examples

```python
>>> from sympy.parsing.sympy_parser import (parse_expr,
... standard_transformations, implicit_application)
>>> transformations = standard_transformations + (implicit_application,)
>>> parse_expr('cot z + csc z', transformations=transformations)
cot(z) + csc(z)
```

sympy.parsing.sympy_parser.function_exponentiation(tokens: List[Tuple[int, str]], local_dict: Dict[str, Any], global_dict: Dict[str, Any])

Allows functions to be exponentiated, e.g. \(\cos^2(x)\).

Examples

```python
>>> from sympy.parsing.sympy_parser import (parse_expr,
... standard_transformations, function_exponentiation)
>>> transformations = standard_transformations + (function_exponentiation,)
>>> parse_expr('\sin^{*4}(x)', transformations=transformations)
\sin(x)^{**4}
```
sympy.parsing.sympy_parser.implicit_multiplication_application(result: List[Tuple[int, str]], local_dict: Dict[str, Any], global_dict: Dict[str, Any]) → List[Tuple[int, str]]

Allows a slightly relaxed syntax.

- Parentheses for single-argument method calls are optional.
- Multiplication is implicit.
- Symbol names can be split (i.e. spaces are not needed between symbols).
- Functions can be exponentiated.

**Examples**

```python
from sympy.parsing.sympy_parser import (parse_expr,
... standard_transformations, implicit_multiplication_application)
>>> parse_expr("10sin**2 x**2 + 3xyz + tan theta",
... transformations=(standard_transformations +
... (implicit_multiplication_application,)))
3*x*y*z + 10*sin(x**2)**2 + tan(theta)
```

sympy.parsing.sympy_parser.rationalize(tokens: List[Tuple[int, str]], local_dict: Dict[str, Any], global_dict: Dict[str, Any])

Converts floats into Rational. Run AFTER auto_number.

sympy.parsing.sympy_parser.convert_xor(tokens: List[Tuple[int, str]], local_dict: Dict[str, Any], global_dict: Dict[str, Any])

Treats XOR, ^, as exponentiation, **.

These are included in sympy.parsing.sympy_parser.standard_transformations (page 2199) and generally don’t need to be manually added by the user.

sympy.parsing.sympy_parser.lambda_notation(tokens: List[Tuple[int, str]], local_dict: Dict[str, Any], global_dict: Dict[str, Any])

Substitutes “lambda” with its SymPy equivalent Lambda(). However, the conversion does not take place if only “lambda” is passed because that is a syntax error.

sympy.parsing.sympy_parser.auto_symbol(tokens: List[Tuple[int, str]], local_dict: Dict[str, Any], global_dict: Dict[str, Any])

 Inserts calls to Symbol/Function for undefined variables.

sympy.parsing.sympy_parser.repeated_decimals(tokens: List[Tuple[int, str]], local_dict: Dict[str, Any], global_dict: Dict[str, Any])

Allows 0.2[1] notation to represent the repeated decimal 0.2111... (19/90)

Run this before auto_number.
SymPy documentation, Release 1.12.1

sympy.parsing.sympy_parser.auto_number(tokens: List[Tuple[int, str]], local_dict: Dict[str, Any], global_dict: Dict[str, Any])

Converts numeric literals to use SymPy equivalents.
Complex numbers use \text{i}, integer literals use Integer, and float literals use Float.

sympy.parsing.sympy_parser.factorial_notation(tokens: List[Tuple[int, str]], local_dict: Dict[str, Any], global_dict: Dict[str, Any])

Allows standard notation for factorial.

**Experimental \LaTeX** Parsing

\LaTeX** parsing was ported from latex2sympy. While functional and its API should remain stable, the parsing behavior or backend may change in future releases.

**\LaTeX** Parsing Caveats

The current implementation is experimental. The behavior, parser backend and API might change in the future. Unlike some of the other parsers, \LaTeX is designed as a type-setting language, not a computer algebra system and so can contain typographical conventions that might be interpreted multiple ways.

In its current definition, the parser will at times will fail to fully parse the expression, but not throw a warning:

```python
parse_latex(r'x - ')
```

Will simply find \(x\). What is covered by this behavior will almost certainly change between releases, and become stricter, more relaxed, or some mix.

**\LaTeX** Parsing Functions Reference

sympy.parsing.latex.parse_latex(s)

Converts the string \(s\) to a SymPy Expr

**Parameters**

- **s**: str

  The \LaTeX string to parse. In Python source containing \LaTeX, raw strings (denoted with \texttt{r"}, like this one) are preferred, as \LaTeX makes liberal use of the \textbackslash character, which would trigger escaping in normal Python strings.
Examples

```python
>>> from sympy.parsing.latex import parse_latex
>>> expr = parse_latex(r"\frac{1 + \sqrt{a}}{b}")
>>> expr
(sqrt(a) + 1)/b
>>> expr.evalf(4, subs=dict(a=5, b=2))
1.618
```

LaTeX Parsing Exceptions Reference

class sympy.parsing.latex.LaTeXParsingError

SymPy Expression Reference

class sympy.parsing.sym_expr.SymPyExpression(source_code=None, mode=None)

Class to store and handle SymPy expressions

This class will hold SymPy Expressions and handle the API for the conversion to and from different languages.

It works with the C and the Fortran Parser to generate SymPy expressions which are stored here and which can be converted to multiple language’s source code.

Notes

The module and its API are currently under development and experimental and can be changed during development.

The Fortran parser does not support numeric assignments, so all the variables have been initialized to zero.

The module also depends on external dependencies:

- LFortran which is required to use the Fortran parser
- Clang which is required for the C parser

Examples

Example of parsing C code:

```python
>>> from sympy.parsing.sym_expr import SymPyExpression
>>> src = ...'
... int a,b;
... float c = 2, d =4;
... 
... a = SymPyExpression(src, 'c')
>>> a.return_expr()
[Declaration(Variable(a, type=intc)),
 (continues on next page)
An example of variable definition:

```python
>>> from sympy.parsing.sympy_expr import SymPyExpression
>>> src2 = '''
... integer :: a, b, c, d
... real :: p, q, r, s
... '''
>>> p = SymPyExpression()
>>> p.convert_to_expr(src2, 'f')
>>> p.convert_to_c()
['int a = 0', 'int b = 0', 'int c = 0', 'int d = 0', 'double p = 0.0',
 'double q = 0.0', 'double r = 0.0', 'double s = 0.0']
```

An example of Assignment:

```python
>>> from sympy.parsing.sympy_expr import SymPyExpression
>>> src3 = '''
... integer :: a, b, c, d, e
... d = a + b - c
... e = b * d + c * e / a
... '''
>>> p = SymPyExpression(src3, 'f')
>>> p.convert_to_python()
['a = 0', 'b = 0', 'c = 0', 'd = 0', 'e = 0', 'd = a + b - c', 'e = b*d + c*e/a']
```

An example of function definition:

```python
>>> from sympy.parsing.sympy_expr import SymPyExpression
>>> src = '''
... integer function f(a,b)
... integer, intent(in) :: a, b
... integer :: r
... end function
... '''
>>> a = SymPyExpression(src, 'f')
>>> a.convert_to_python()
['def f(a, b):
 f = 0
 r = 0
 return f']
```

c\text{convert}\_\text{to}\_c()\

Returns a list with the c source code for the SymPy expressions
Examples

```python
from sympy.parsing.sympy_expr import SymPyExpression

src2 = '''
... integer :: a, b, c, d
... real :: p, q, r, s
... c = a/b
... d = c/a
... s = p/q
... r = q/p
...'''

>>> p = SymPyExpression()
>>> p.convert_to_expr(src2, 'f')
```

```python
['int a = 0', 'int b = 0', 'int c = 0', 'int d = 0', 'double p = 0.0',
 'double q = 0.0', 'double r = 0.0', 'double s = 0.0', 'c = a/b;',
 'd = c/a;', 's = p/q;', 'r = q/p;']
```

**convert_to_expr** *(src_code, mode)*

Converts the given source code to SymPy Expressions

Examples

```python
from sympy.parsing.sympy_expr import SymPyExpression

src3 = '''
... integer function f(a,b) result(r)
... integer, intent(in) :: a, b
... integer :: x
... r = a + b -x
... end function
...'''

>>> p = SymPyExpression()
>>> p.convert_to_expr(src3, 'f')
```

```python
[FunctionDefinition(integer, name=f, parameters=(Variable(a),
 Variable(b)), body=CodeBlock(Declaration(Variable(r, type=integer, value=0)),
 Declaration(Variable(x, type=integer, value=0)),
 Assignment(Variable(r), a + b - x),
 Return(Variable(r)) ))]
```
Attributes

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>src_code</td>
<td>(String) the source code or filename of the source code that is to be converted</td>
</tr>
<tr>
<td>mode</td>
<td>the mode to determine which parser is to be used according to the language of the source code for Fortran or C for C/C++</td>
</tr>
</tbody>
</table>

**convert_to_fortran()**

Returns a list with the fortran source code for the SymPy expressions

**Examples**

```python
>>> from sympy.parsing.sym_expr import SymPyExpression
>>> src2 = '''
... integer :: a, b, c, d
... real :: p, q, r, s
... c = a/b
... d = c/a
... s = p/q
... r = q/p
...'''
>>> p = SymPyExpression(src2, 'f')
>>> p.convert_to_fortran()
[' integer*4 a', ' integer*4 b', ' integer*4 c', ' integer*4 d', ' real*8 p', ' real*8 q', ' real*8 r', ' real*8 s', ' c = a/b', ' d = c/a', ' s = p/q', ' r = q/p']
```

**convert_to_python()**

Returns a list with Python code for the SymPy expressions

**Examples**

```python
>>> from sympy.parsing.sym_expr import SymPyExpression
>>> src2 = '''
... integer :: a, b, c, d
... real :: p, q, r, s
... c = a/b
... d = c/a
... s = p/q
... r = q/p
...'''
>>> p = SymPyExpression(src2, 'f')
>>> p.convert_to_python()
['a = 0', 'b = 0', 'c = 0', 'd = 0', 'p = 0.0', 'q = 0.0', 'r = 0.0', 's = 0.0', 'c = a/b', 'd = c/a', 's = p/q', 'r = q/p']
```

**return_expr()**

Returns the expression list
Examples

```python
from sympy.parsing.sym_expr import SymPyExpression

src3 = '''
... integer function f(a,b)
... integer, intent(in) :: a, b
... integer :: r
... r = a+b
... f = r
... end function
...'''

p = SymPyExpression()

p.convert_to_expr(src3, 'f')
p.return_expr()

[FunctionDefinition(integer, name=f, parameters=(Variable(a), Variable(b)),
  body=CodeBlock(Declaration(Variable(f, type=integer, value=0)),
  Declaration(Variable(r, type=integer, value=0)),
  Assignment(Variable(f), Variable(r)),
  Return(Variable(f)))
  ]

Runtime Installation

The currently-packaged LaTeX parser backend is partially generated with ANTLR4, but to use the parser, you only need the antlr4 Python package available.

Depending on your package manager, you can install the right package with, for example, pip:

```
$ pip install antlr4-python3-runtime==4.11
```

or conda:

```
$ conda install -c conda-forge antlr-python-runtime==4.11
```

The C parser depends on clang and the Fortran parser depends on LFortran. You can install these packages using:

```
$ conda install -c conda-forge lfortran clang
```

Printing

See the Printing (page 19) section in tutorial for introduction into printing.

This guide documents the printing system in SymPy and how it works internally.
**Printer Class**

Printing subsystem driver

SymPy’s printing system works the following way: Any expression can be passed to a designated Printer who then is responsible to return an adequate representation of that expression.

**The basic concept is the following:**

1. Let the object print itself if it knows how.
2. Take the best fitting method defined in the printer.
3. As fall-back use the emptyPrinter method for the printer.

**Which Method is Responsible for Printing?**

The whole printing process is started by calling `.doprint(expr)` on the printer which you want to use. This method looks for an appropriate method which can print the given expression in the given style that the printer defines. While looking for the method, it follows these steps:

1. **Let the object print itself if it knows how.**

   The printer looks for a specific method in every object. The name of that method depends on the specific printer and is defined under `Printer.printmethod`. For example, StrPrinter calls `_sympystr` and LatexPrinter calls `_latex`. Look at the documentation of the printer that you want to use. The name of the method is specified there.

   This was the original way of doing printing in sympy. Every class had its own latex, mathml, str and repr methods, but it turned out that it is hard to produce a high quality printer, if all the methods are spread out that far. Therefore all printing code was combined into the different printers, which works great for built-in SymPy objects, but not that good for user defined classes where it is inconvenient to patch the printers.

2. **Take the best fitting method defined in the printer.**

   The printer loops through expr classes (class + its bases), and tries to dispatch the work to `_print_<EXPR_CLASS>`

   e.g., suppose we have the following class hierarchy:

   ```
   Basic  
   |     
   Atom  
   |     
   Number  
   |     
   Rational
   ```

   then, for `expr=Rational(...)`, the Printer will try to call printer methods in the order as shown in the figure below:

   ```
   p._print(expr)  
   |-- p._print_Rational(expr)
   ```

   (continues on next page)
if \_.print\_.Rational method exists in the printer, then it is called, and the result is returned back. Otherwise, the printer tries to call \_.print\_.Number and so on.

3. **As a fall-back use the emptyPrinter method for the printer.**

   As fall-back self.emptyPrinter will be called with the expression. If not defined in the Printer subclass this will be the same as str(expr).

Example of Custom Printer

In the example below, we have a printer which prints the derivative of a function in a shorter form.

```python
class MyLatexPrinter(LatexPrinter):
    """Print derivative of a function of symbols in a shorter form.\n    """
    def _print_Derivative(self, expr):
        function, *vars = expr.args
        if not isinstance(type(function), UndefinedFunction) or \
            not all(isinstance(i, Symbol) for i in vars):
            return super()._print_Derivative(expr)

        # If you want the printer to work correctly for nested
        # expressions then use self.print() instead of str() or latex().
        # See the example of nested modulo below in the custom printing
        # method section.
        return "{}\_\{{}\}".format(
            self._print(Symbol(function.func.__name__)),
            ''.join(self._print(i) for i in vars))

def print_my_latex(expr):
    """Most of the printers define their own wrappers for print().
    These wrappers usually take printer settings. Our printer does not have
    any settings.\n    """
    print(MyLatexPrinter().doprint(expr))
```

```
y = Symbol("y")
x = Symbol("x")
```
f = Function("f")
expr = f(x, y).diff(x, y)

# Print the expression using the normal latex printer and our custom
# printer.
print_latex(expr)
print_my_latex(expr)

The output of the code above is:

\frac{\partial^2}{\partial x \partial y} f\{x,y \right\}
f_{xy}

Example of Custom Printing Method

In the example below, the latex printing of the modulo operator is modified. This is done by
overriding the method _latex of Mod.

```python
>>> from sympy import Symbol, Mod, Integer, print_latex

>>> # Always use printer._print()
>>> class ModOp(Mod):
...     def _latex(self, printer):
...         a, b = [printer._print(i) for i in self.args]
...         return r"\operatorname{Mod}\{\left(%s, %s\right)}" % (a, b)
```

Comparing the output of our custom operator to the builtin one:

```python
>>> x = Symbol('x')
>>> m = Symbol('m')
>>> print_latex(Mod(x, m))
x \bmod m
>>> print_latex(ModOp(x, m))
\operatorname{Mod}{\left(x, m\right)}
```

Common mistakes

It’s important to always use self._print(obj) to print subcomponents of an expression when
customizing a printer. Mistakes include:

1. Using self.doprint(obj) instead:

```python
>>> # This example does not work properly, as only the outermost call
>>> # may use
>>> # doprint.
>>> class ModOpWrong(Mod):
...     def _latex(self, printer):
...         a, b = [printer.doprint(i) for i in self.args]
...         return r"\operatorname{Mod}\{\left(%s, %s\right)}" % (a, b)
```
This fails when the mode argument is passed to the printer:

```
>>> print_latex(ModOp(x, m), mode='inline')  # ok
$\text{operatorname}{\left(x, m\right)}$
>>> print_latex(ModOpModeWrong(x, m), mode='inline')  # bad
$\text{operatorname}{\left(x, m\right)}$
```

2. Using `str(obj)` instead:

```
>>> class ModOpNestedWrong(Mod):
...     def _latex_(self, printer):
...         a, b = [str(i) for i in self.args]
...         return r"\text{operatorname}{\left(%s, %s\right)}" % (a, b)
```

This fails on nested objects:

```
>>> # Nested modulo.
>>> print_latex(ModOp(ModOp(x, m), Integer(7)))  # ok
$\text{operatorname}{\left(\text{operatorname}{\left(x, m\right)}, 7\right)}$
>>> print_latex(ModOpNestedWrong(ModOpNestedWrong(x, m), Integer(7)))  # bad
$\text{operatorname}{\left(\text{operatorname}{\left(x, m\right)}, 7\right)}$
```

3. Using LaTeXPrinter()._print(obj) instead.

```
>>> from sympy.printing.latex import LaTeXPrinter
>>> class ModOpSettingsWrong(Mod):
...     def _latex_(self, printer):
...         a, b = [LaTeXPrinter()._print(i) for i in self.args]
...         return r"\text{operatorname}{\left(%s, %s\right)}" % (a, b)
```

This causes all the settings to be discarded in the subobjects. As an example, the `full_prec` setting which shows floats to full precision is ignored:

```
>>> from sympy import Float
>>> print_latex(ModOp(Float(1) * x, m), full_prec=True)  # ok
$\text{operatorname}{\left(1.00000000000000 x, m\right)}$
>>> print_latex(ModOpSettingsWrong(Float(1) * x, m), full_prec=True)  # bad
$\text{operatorname}{\left(1.0 x, m\right)}$
```

The main class responsible for printing is Printer (see also its source code):

```
class sympy.printing.printer.Printer(settings=None)
Generic printer
Its job is to provide infrastructure for implementing new printers easily.
If you want to define your custom Printer or your custom printing method for your custom
class then see the example above: printer_example (page 2209).

printmethod: str = None

_print(expr, **kwargs) → str
Internal dispatcher
Tries the following concepts to print an expression:
```
1. Let the object print itself if it knows how.
2. Take the best fitting method defined in the printer.
3. As fall-back use the emptyPrinter method for the printer.

```python
doprint(expr)
   Returns printer's representation for expr (as a string)
```

```python
classmethod set_global_settings(**settings)
   Set system-wide printing settings.
```

**PrettyPrinter Class**

The pretty printing subsystem is implemented in `sympy.printing.pretty.pretty` by the `PrettyPrinter` class deriving from `Printer`. It relies on the modules `sympy.printing.pretty.stringPict` and `sympy.printing.pretty.pretty_symbology` for rendering nice-looking formulas.

The module `stringPict` provides a base class `stringPict` and a derived class `prettyForm` that ease the creation and manipulation of formulas that span across multiple lines.

The module `pretty_symbology` provides primitives to construct 2D shapes (hline, vline, etc) together with a technique to use unicode automatically when possible.

```python
class sympy.printing.pretty.pretty.PrettyPrinter(settings=None)
   Printer, which converts an expression into 2D ASCII-art figure.
```

```python
printmethod: str = '_pretty'
```

```python
sympy.printing.pretty.pretty.pretty(expr, *, order=None, full_prec='auto',
   use_unicode=True, wrap_line=False,
   num_columns=None,
   use_unicode_sqrt_char=True,
   root_notation=True, mat_symbol_style='plain',
   imaginary_unit='i', perm_cyclic=True)
```

Returns a string containing the prettified form of expr.

For information on keyword arguments see pretty_print function.

```python
sympy.printing.pretty.pretty.pretty_print(expr, **kwargs)
```

Prints expr in pretty form.

`pprint` is just a shortcut for this function.

**Parameters**

- `expr`: expression
  - The expression to print.
- `wrap_line`: bool, optional (default=True)
  - Line wrapping enabled/disabled.
- `num_columns`: int or None, optional (default=None)
  - Number of columns before line breaking (default to None which reads the terminal width), useful when using SymPy without terminal.
- `use_unicode`: bool or None, optional (default=None)
Use unicode characters, such as the Greek letter pi instead of the string pi.

**full_prec** : bool or string, optional (default="auto")

Use full precision.

**order** : bool or string, optional (default=None)

Set to ‘none’ for long expressions if slow; default is None.

**use_unicode_sqrt_char** : bool, optional (default=True)

Use compact single-character square root symbol (when unambiguous).

**root_notation** : bool, optional (default=True)

Set to ‘False’ for printing exponents of the form 1/n in fractional form. By default exponent is printed in root form.

**mat_symbol_style** : string, optional (default="plain")

Set to “bold” for printing MatrixSymbols using a bold mathematical symbol face. By default the standard face is used.

**imaginary_unit** : string, optional (default="i")

Letter to use for imaginary unit when use_unicode is True. Can be “i” (default) or “j”.

### C code printers

This class implements C code printing, i.e. it converts Python expressions to strings of C code (see also **C89CodePrinter**).

Usage:

```python
>>> from sympy.printing import print_ccode
>>> from sympy.functions import sin, cos, Abs, gamma
>>> from sympy import x

>>> print_ccode(sin(x)**2 + cos(x)**2, standard='C89')
pow(sin(x), 2) + pow(cos(x), 2)

>>> print_ccode(2*x + cos(x), assign_to="result", standard='C89')
result = 2*x + cos(x);

>>> print_ccode(Abs(x**2), standard='C89')
fabs(pow(x, 2))

>>> print_ccode(gamma(x**2), standard='C99')
tgamma(pow(x, 2))
```

```python
sympy.printing.c.known_functions_C89 = {'Abs': [(<function <lambda>>, 'fabs'), (<function <lambda>>, 'abs')], 'acos': 'acos', 'asin': 'asin', 'atan': 'atan', 'atan2': 'atan2', 'ceiling': 'ceil', 'cos': 'cos', 'cosh': 'cosh', 'exp': 'exp', 'floor': 'floor', 'log': 'log', 'sin': 'sin', 'sinh': 'sinh', 'sqrt': 'sqrt', 'tan': 'tan', 'tanh': 'tanh'}
```
SymPy Documentation, Release 1.12.1

```python
sympy.printing.c.known_functions_C99 = {'Abs': [(<function <lambda>>, 'fabs'), (<function <lambda>>, 'abs')], 'Cbrt': 'cbrt', 'Max': 'fmax', 'Min': 'fmin', 'acos': 'acos', 'acosh': 'acosh', 'asin': 'asin', 'asinh': 'asinh', 'atan': 'atan', 'atan2': 'atan2', 'atanh': 'atanh', 'ceiling': 'ceil', 'cos': 'cos', 'cosh': 'cosh', 'erf': 'erf', 'erfc': 'erfc', 'exp': 'exp', 'exp2': 'exp2', 'expm1': 'expm1', 'floor': 'floor', 'fma': 'fma', 'gamma': 'tgamma', 'hypot': 'hypot', 'log': 'log', 'log10': 'log10', 'log1p': 'log1p', 'log2': 'log2', 'loggamma': 'lgamma', 'sin': 'sin', 'sind': 'sind', 'sqrt': 'sqrt', 'tan': 'tan', 'tanh': 'tanh'}
```

class sympy.printing.c.C89CodePrinter(settings=None)

A printer to convert Python expressions to strings of C code

```python
printmethod: str = '_ccode'
indent_code(code)
    Accepts a string of code or a list of code lines
```

class sympy.printing.c.C99CodePrinter(settings=None)

```python
printmethod: str = '_ccode'
sympy.printing.c.ccode(expr, assign_to=None, standard='c99', **settings)
    Converts an expr to a string of c code
```

**Parameters**

- **expr**: Expr
  A SymPy expression to be converted.

- **assign_to**: optional
  When given, the argument is used as the name of the variable to which the expression is assigned. Can be a string, Symbol, MatrixSymbol, or Indexed type. This is helpful in case of line-wrapping, or for expressions that generate multi-line statements.

- **standard**: str, optional
  String specifying the standard. If your compiler supports a more modern standard you may set this to 'c99' to allow the printer to use more math functions. [default='c89'].

- **precision**: integer, optional
  The precision for numbers such as pi [default=17].

- **user_functions**: dict, optional
  A dictionary where the keys are string representations of either FunctionClass or UndefinedFunction instances and the values are their desired C string representations. Alternatively, the dictionary value can be a list of tuples i.e. [(argument_test, cfunction_string)] or [(argument_test, cfunction_formater)]. See below for examples.

- **dereference**: iterable, optional
  An iterable of symbols that should be dereferenced in the printed code expression. These would be values passed by address to the function. For example, if dereference=[a], the resulting code would print (*a) instead of a.
human : bool, optional

If True, the result is a single string that may contain some constant declarations for the number symbols. If False, the same information is returned in a tuple of (symbols_to_declare, not_supported_functions, code_text). [default=True].

contract : bool, optional

If True, Indexed instances are assumed to obey tensor contraction rules and the corresponding nested loops over indices are generated. Setting contract=False will not generate loops, instead the user is responsible to provide values for the indices in the code. [default=True].

Examples

```python
>>> from sympy import ccode, symbols, Rational, sin, ceiling, Abs,
     ... Function
>>> x, tau = symbols("x, tau")
>>> expr = (2*tau)**Rational(7, 2)
>>> ccode(expr)
'8*M_SQRT2*pow(tau, 7.0/2.0)'
>>> ccode(expr, math_macros={})
'8*sqrt(2)*pow(tau, 7.0/2.0)'
>>> ccode(sin(x), assign_to="s")
's = sin(x);'
>>> from sympy.codegen.ast import real, float80
>>> ccode(expr, type_aliases={real: float80})
'8*M_SQRT2l*powl(tau, 7.0L/2.0L)'
Simple custom printing can be defined for certain types by passing a dictionary of \{"type" : "function"\} to the user_functions kwarg. Alternatively, the dictionary value can be a list of tuples i.e. [(argument_test, cfunction_string)].

```python
>>> custom_functions = {
    ... "ceiling": "CEIL",
    ... "Abs": [(lambda x: not x.is_integer, "fabs"),
              (lambda x: x.is_integer, "ABS")],
    ... "func": "f"
    ... }
>>> func = Function('func')
>>> ccode(func(Abs(x) + ceiling(x)), standard='C89', user_functions=custom_functions)
'f(fabs(x) + CEIL(x))'
```
or if the C-function takes a subset of the original arguments:

```python
>>> ccode(2**x + 3**x, standard='C99', user_functions={
    ... 'Pow': [
              (lambda b, e: b == 2, lambda b, e: 'exp2(%s)' % e),
              (lambda b, e: b != 2, 'pow')]
    ... })
'exp2(x) + pow(3, x)'
```

Piecewise expressions are converted into conditionals. If an assign_to variable is provided an if statement is created, otherwise the ternary operator is used. Note that if
the Piecewise lacks a default term, represented by (expr, True) then an error will be thrown. This is to prevent generating an expression that may not evaluate to anything.

```python
>>> from sympy import Piecewise
>>> expr = Piecewise((x + 1, x > 0), (x, True))
>>> print(ccode(expr, tau, standard='C89'))
if (x > 0) {
    tau = x + 1;
} else {
    tau = x;
}
```

Support for loops is provided through Indexed types. With contract=True these expressions will be turned into loops, whereas contract=False will just print the assignment expression that should be looped over:

```python
>>> from sympy import Eq, IndexedBase, Idx
>>> len_y = 5
>>> y = IndexedBase('y', shape=(len_y,))
>>> t = IndexedBase('t', shape=(len_y,))
>>> Dy = IndexedBase('Dy', shape=(len_y-1,))
>>> i = Idx('i', len_y-1)
>>> e = Eq(Dy[i], (y[i+1] - y[i])/(t[i+1] - t[i]))
>>> ccode(e.rhs, assign_to=e.lhs, contract=False, standard='C89')
'Dy[i] = (y[i + 1] - y[i])/(t[i + 1] - t[i]);'
```

Matrices are also supported, but a MatrixSymbol of the same dimensions must be provided to assign_to. Note that any expression that can be generated normally can also exist inside a Matrix:

```python
>>> from sympy import Matrix, MatrixSymbol
>>> mat = Matrix([x**2, Piecewise((x + 1, x > 0), (x, True)), sin(x)])
>>> A = MatrixSymbol('A', 3, 1)
>>> print(ccode(mat, A, standard='C89'))
A[0] = pow(x, 2);
if (x > 0) {
    A[1] = x + 1;
} else {
    A[1] = x;
} A[2] = sin(x);
```

The `sympy.printing.c.print_ccode` function:

Prints C representation of the given expression.
**C++ code printers**

This module contains printers for C++ code, i.e. functions to convert SymPy expressions to strings of C++ code.

Usage:

```python
>>> from sympy.printing import cxxcode
>>> from sympy.functions import Min, gamma
>>> from sympy.abc import x

>>> print(cxxcode(Min(gamma(x) - 1, x), standard='C++11'))
std::min(x, std::tgamma(x) - 1)
```

```python
class sympy.printing.cxx.CXX98CodePrinter(settings=None)
    printmethod: str = '_cxxcode'
class sympy.printing.cxx.CXX11CodePrinter(settings=None)
    printmethod: str = '_cxxcode'
sympy.printing.codeprinter.cxxcode(expr, assign_to=None, standard='c++11', **settings)
```

C++ equivalent of `ccode()` (page 2214).

**RCodePrinter**

This class implements R code printing (i.e. it converts Python expressions to strings of R code).

Usage:

```python
>>> from sympy.printing import print_rcode
>>> from sympy.functions import sin, cos, Abs
>>> from sympy.abc import x

>>> print_rcode(sin(x)**2 + cos(x)**2)
sin(x)^2 + cos(x)^2
>>> print_rcode(2*x + cos(x), assign_to="result")
result = 2*x + cos(x);
>>> print_rcode(Abs(x**2))
abs(x^2)
```

```python
sympy.printing.rcode.known_functions = {'Abs': 'abs', 'Max': 'max', 'Min': 'min', 'acos': 'acos', 'acosh': 'acosh', 'asin': 'asin', 'asinh': 'asinh', 'atan': 'atan', 'atan2': 'atan2', 'atanh': 'atanh', 'beta': 'beta', 'cos': 'cos', 'cosh': 'cosh', 'digamma': 'digamma', 'erf': 'erf', 'exp': 'exp', 'factorial': 'factorial', 'floor': 'floor', 'gamma': 'gamma', 'log': 'log', 'sign': 'sign', 'sin': 'sin', 'sinh': 'sinh', 'sqrt': 'sqrt', 'tan': 'tan', 'tanh': 'tanh', 'trigamma': 'trigamma'}
class sympy.printing.rcode.RCodePrinter(settings={})
    printmethod: str = '_rcode'
```

A printer to convert SymPy expressions to strings of R code.
indent_code(code)
   Accepts a string of code or a list of code lines

sympy.printing.rcode.rcode(expr, assign_to=None, **settings)
   Converts an expr to a string of r code

Parameters
expr : Expr
   A SymPy expression to be converted.
assign_to : optional
   When given, the argument is used as the name of the variable to which the expression is assigned. Can be a string, Symbol, MatrixSymbol, or Indexed type. This is helpful in case of line-wrapping, or for expressions that generate multi-line statements.
precision : integer, optional
   The precision for numbers such as pi [default=15].
user_functions : dict, optional
   A dictionary where the keys are string representations of either FunctionClass or UndefinedFunction instances and the values are their desired R string representations. Alternatively, the dictionary value can be a list of tuples i.e. [(argument_test, rfunction_string)] or [(argument_test, rfunction_formater)]. See below for examples.
human : bool, optional
   If True, the result is a single string that may contain some constant declarations for the number symbols. If False, the same information is returned in a tuple of (symbols_toDeclare, not_supported_functions, code_text). [default=True].
contract: bool, optional
   If True, Indexed instances are assumed to obey tensor contraction rules and the corresponding nested loops over indices are generated. Setting contract=False will not generate loops, instead the user is responsible to provide values for the indices in the code. [default=True].

Examples

>>> from sympy import rcode, symbols, Rational, sin, ceiling, Abs, Function
>>> x, tau = symbols("x, tau")
>>> rcode((2*tau)**Rational(7, 2))
'8*sqrt(2)*tau^(7.0/2.0)'
>>> rcode(sin(x), assign_to="s")
's = sin(x);'

Simple custom printing can be defined for certain types by passing a dictionary of {"type" : "function"} to the user_functions kwarg. Alternatively, the dictionary value can be a list of tuples i.e. [(argument_test, cfunction_string)].
```python
custom_functions = {
    "ceiling": "CEIL",
    "Abs": [(lambda x: not x.is_integer, "fabs"),
             (lambda x: x.is_integer, "ABS")],
    "func": "f"
}

func = Function('func')
rcode(func(abs(x) + ceiling(x)), user_functions=custom_functions)
'f(fabs(x) + CEIL(x))'
```

or if the R-function takes a subset of the original arguments:

```python
rcode(2**x + 3**x, user_functions={'Pow': [
    (lambda b, e: b == 2, lambda b, e: 'exp2(%s)' % e),
    (lambda b, e: b != 2, 'pow')
]},
'exp2(x) + pow(3, x)'
```

Piecewise expressions are converted into conditionals. If an assign_to variable is provided an if statement is created, otherwise the ternary operator is used. Note that if the Piecewise lacks a default term, represented by (expr, True) then an error will be thrown. This is to prevent generating an expression that may not evaluate to anything.

```python
from sympy import Piecewise
expr = Piecewise((x + 1, x > 0), (x, True))
print(rkode(expr, assign_to=tau))
tau = ifelse(x > 0, x + 1, x);
```

Support for loops is provided through Indexed types. With contract=True these expressions will be turned into loops, whereas contract=False will just print the assignment expression that should be looped over:

```python
from sympy import Eq, IndexedBase, Idx
len_y = 5
y = IndexedBase('y', shape=(len_y,))
t = IndexedBase('t', shape=(len_y,))
Dy = IndexedBase('Dy', shape=(len_y-1,))
i = Idx('i', len_y-1)
e=Eq(Dy[i], (y[i+1] - y[i])/(t[i+1] - t[i]))
rcode(e.rhs, assign_to=e.lhs, contract=False)
'Dy[i] = (y[i + 1] - y[i])/(t[i + 1] - t[i]);'
```

Matrices are also supported, but a MatrixSymbol of the same dimensions must be provided to assign_to. Note that any expression that can be generated normally can also exist inside a Matrix:

```python
from sympy import Matrix, MatrixSymbol
mat = Matrix([[2**2, Piecewise((x + 1, x > 0), (x, True)), sin(x)]
mat = Matrix([[2**2, Piecewise((x + 1, x > 0), (x, True)), sin(x)]
A = MatrixSymbol('A', 3, 1)
print(rkode(mat, A))
A[0] = x^2;
A[1] = ifelse(x > 0, x + 1, x);
A[2] = sin(x);
```

sympy.printing.rcode.print_rkode(expr, **settings)
Prints R representation of the given expression.

**Fortran Printing**

The `fcode` function translates a SymPy expression into Fortran code. The main purpose is to take away the burden of manually translating long mathematical expressions. Therefore the resulting expression should also require no (or very little) manual tweaking to make it compilable. The optional arguments of `fcode` can be used to fine-tune the behavior of `fcode` in such a way that manual changes in the result are no longer needed.

```python
sympy.printing.fortran.fcode(expr, assign_to=None, **settings)
```

Converts an expr to a string of fortran code

**Parameters**

- `expr` : Expr
  A SymPy expression to be converted.

- `assign_to` : optional
  When given, the argument is used as the name of the variable to which the expression is assigned. Can be a string, Symbol, MatrixSymbol, or Indexed type. This is helpful in case of line-wrapping, or for expressions that generate multi-line statements.

- `precision` : integer, optional
  DEPRECATED. Use type_mappings instead. The precision for numbers such as pi [default=17].

- `user_functions` : dict, optional
  A dictionary where keys are FunctionClass instances and values are their string representations. Alternatively, the dictionary value can be a list of tuples i.e. [(argument_test, cfunction_string)]. See below for examples.

- `human` : bool, optional
  If True, the result is a single string that may contain some constant declarations for the number symbols. If False, the same information is returned in a tuple of (symbols_to_declare, not_supported_functions, code_text). [default=True].

- `contract` : bool, optional
  If True, Indexed instances are assumed to obey tensor contraction rules and the corresponding nested loops over indices are generated. Setting contract=False will not generate loops, instead the user is responsible to provide values for the indices in the code. [default=True].

- `source_format` : optional
  The source format can be either ‘fixed’ or ‘free’. [default=’fixed’]

- `standard` : integer, optional
  The Fortran standard to be followed. This is specified as an integer. Acceptable standards are 66, 77, 90, 95, 2003, and 2008. Default
is 77. Note that currently the only distinction internally is between standards before 95, and those 95 and after. This may change later as more features are added.

**name_mangling** : bool, optional

If True, then the variables that would become identical in case-insensitive Fortran are mangled by appending different number of _ at the end. If False, SymPy will not interfere with naming of variables. [default=True]

### Examples

```python
>>> from sympy import fcode, symbols, Rational, sin, ceiling, floor

>>> x, tau = symbols("x, tau")

>>> fcode((2*tau)**Rational(7, 2))
' 8*sqrt(2.0d0)*tau**(7.0d0/2.0d0)'

>>> fcode(sin(x), assign_to="s")
' s = sin(x)'
```

Custom printing can be defined for certain types by passing a dictionary of “type” : “function“ to the user_functions kwarg. Alternatively, the dictionary value can be a list of tuples i.e. [(argument_test, cfunction_string)].

```python
>>> custom_functions = {
...     "ceiling": "CEIL",
...     "floor": [(lambda x: not x.is_integer, "FLOOR1"),
...               (lambda x: x.is_integer, "FLOOR2")]
... }

>>> fcode(floor(x) + ceiling(x), user_functions=custom_functions)
' CEIL(x) + FLOOR1(x)'
```

Piecewise expressions are converted into conditionals. If an assign_to variable is provided an if statement is created, otherwise the ternary operator is used. Note that if the Piecewise lacks a default term, represented by (expr, True) then an error will be thrown. This is to prevent generating an expression that may not evaluate to anything.

```python
>>> from sympy import Piecewise

>>> expr = Piecewise((x + 1, x > 0), (x, True))

>>> print(fcode(expr, tau))
    if (x > 0) then
        tau = x + 1
    else
        tau = x
    end if
```

Support for loops is provided through Indexed types. With contract=True these expressions will be turned into loops, whereas contract=False will just print the assignment expression that should be looped over:

```python
>>> from sympy import Eq, IndexedBase, Idx

>>> len_y = 5

>>> y = IndexedBase('y', shape=(len_y,))
```

(continues on next page)
Matrices are also supported, but a MatrixSymbol of the same dimensions must be provided to assign_to. Note that any expression that can be generated normally can also exist inside a Matrix:

```python
>>> from sympy import Matrix, MatrixSymbol
>>> mat = Matrix([[x**2, Piecewise((x + 1, x > 0), (x, True)), sin(x))])
>>> A = MatrixSymbol('A', 3, 1)
>>> print(fcode(mat, A))
A(1, 1) = x**2
    if (x > 0) then
A(2, 1) = x + 1
    else
A(2, 1) = x
    end if
A(3, 1) = sin(x)
```
In case of line wrapping, it is handy to include the assignment so that lines are wrapped properly when the assignment part is added.

```python
>>> print(fcode(expr, assign_to="var"))
var = -715.0d0/65536.0d0*x**18 - 429.0d0/32768.0d0*x**16 - 33.0d0/2048.0d0*x**14 - 21.0d0/1024.0d0*x**12 - 7.0d0/256.0d0*x**10 - 5.0d0/128.0d0*x**8 - 1.0d0/16.0d0*x**6 - 1.0d0/8.0d0*x**4 - 1.0d0/2.0d0*x**2 + 1
```

For piecewise functions, the `assign_to` option is mandatory:

```python
>>> print(fcode(Piecewise((x,x<1),(x**2,True)), assign_to="var"))
if (x < 1) then
  var = x
else
  var = x**2
end if
```

Note that by default only top-level piecewise functions are supported due to the lack of a conditional operator in Fortran 77. Inline conditionals can be supported using the `merge` function introduced in Fortran 95 by setting of the kwarg `standard=95`:

```python
>>> print(fcode(Piecewise((x,x<1),(x**2,True)), standard=95))
merge(x, x**2, x < 1)
```

Loops are generated if there are Indexed objects in the expression. This also requires use of the `assign_to` option.

```python
>>> A, B = map(IndexedBase, ['A', 'B'])
>>> m = Symbol('m', integer=True)
>>> i = Idx('i', m)
>>> print(fcode(2*B[i], assign_to=A[i]))
do i = 1, m
  A(i) = 2*B(i)
end do
```

Repeated indices in an expression with Indexed objects are interpreted as summation. For instance, code for the trace of a matrix can be generated with

```python
>>> print(fcode(A[i, i], assign_to=x))
x = 0
do i = 1, m
  x = x + A(i, i)
end do
```

By default, number symbols such as `pi` and `E` are detected and defined as Fortran parameters. The precision of the constants can be tuned with the precision argument. Parameter definitions are easily avoided using the `N` function.

```python
>>> print(fcode(x - pi**2 - E))
parameter (E = 2.7182818284590452d0)
parameter (pi = 3.1415926535897932d0)
x - pi**2 - E
>>> print(fcode(x - pi**2 - E, precision=25))
```

(continues on next page)
When some functions are not part of the Fortran standard, it might be desirable to introduce the names of user-defined functions in the Fortran expression.

```
>>> print(fcode(1 - gamma(x)**2, user_functions={'gamma': 'mygamma'}))
1 - mygamma(x)**2
```

However, when the user_functions argument is not provided, fcode will generate code which assumes that a function of the same name will be provided by the user. A comment will be added to inform the user of the issue:

```
>>> print(fcode(1 - gamma(x)**2))
C Not supported in Fortran:
C gamma
   1 - gamma(x)**2
```

The printer can be configured to omit these comments:

```
>>> print(fcode(1 - gamma(x)**2, allow_unknown_functions=True))
1 - gamma(x)**2
```

By default the output is human readable code, ready for copy and paste. With the option human=False, the return value is suitable for post-processing with source code generators that write routines with multiple instructions. The return value is a three-tuple containing: (i) a set of number symbols that must be defined as 'Fortran parameters', (ii) a list functions that cannot be translated in pure Fortran and (iii) a string of Fortran code. A few examples:

```
>>> fcode(1 - gamma(x)**2, human=False)
(set(), {gamma(x)}, ' 1 - gamma(x)**2')
>>> fcode(1 - sin(x)**2, human=False)
(set(), set(), ' 1 - sin(x)**2')
>>> fcode(x - pi**2, human=False)
({(pi, '3.1415926535897932d0')}, set(), ' x - pi**2')
```

**SMT-Lib printing**

```python
class sympy.printing.smtlib.SMTLibPrinter(settings: dict | None = None,
symbol_table=None)
```

```
printmethod: str = '_smtlib'
```
SymPy Documentation, Release 1.12.1

```python
_sym_default_settings: dict = {'known_constants': {}, 'known_functions':
    {<class 'sympy.core.add.Add'>: '+', <class 'sympy.core.mul.Mul'>: '*',
     <class 'sympy.core.power.Pow'>: 'pow', <class
     'sympy.core.relational.Equality'>: '=', <class
     'sympy.core.relational.GreaterThan'>: '>=', <class
     'sympy.core.relational.LessThan'>: '<=', <class
     'sympy.core.relational.StrictGreaterThan'>: '>', <class
     'sympy.core.relational.StrictLessThan'>: '<', Abs: 'abs', And: 'and',
     Xor: 'xor', acos: 'arccos', asin: 'arcsin', atan: 'arctan', atan2:
     sinh: 'sinh', tan: 'tan', tanh: 'tanh'}, 'known_types': {<class 'bool'>:
     'Bool', <class 'float'>: 'Real', <class 'int'>: 'Int'}, 'precision':
    None}

sympy.printing.smtlib.smtlib_code(expr, auto_assert=True, auto_declare=True,
    precision=None, symbol_table=None, known_types=None, known_constants=None,
    known_functions=None, prefix_expressions=None, suffix_expressions=None,
    log_warn=None)
```

Converts `expr` to a string of SMTlib code.

**Parameters**

- `expr` : Expr | List[Expr]
  A SymPy expression or system to be converted.

- `auto_assert` : bool, optional
  If false, do not modify `expr` and produce only the S-Expression equiva-
  lent of `expr`. If true, assume `expr` is a system and assert each boolean
  element.

- `auto_declare` : bool, optional
  If false, do not produce declarations for the symbols used in `expr`. If
  true, prepend all necessary declarations for variables used in `expr`
  based on `symbol_table`.

- `precision` : integer, optional
  The `evalf(…)` precision for numbers such as pi.

- `symbol_table` : dict, optional
  A dictionary where keys are `Symbol` or `Function` instances and values
  are their Python type i.e. `bool`, `int`, `float`, or `Callable[...]`. If
  incomplete, an attempt will be made to infer types from `expr`.

- `known_types`: dict, optional
  A dictionary where keys are `bool`, `int`, `float` etc. and values are
  their corresponding SMT type names. If not given, a partial listing
  compatible with several solvers will be used.

- `known_functions`: dict, optional
  A dictionary where keys are `Function`, `Relational`, `BooleanFunction`, or
  `Expr` instances and values are their SMT string representations. If not given, a partial listing optimized
  for dReal solver (but compatible with others) will be used.

---

**5.8. Topics**

---

2225
known_constants: dict, optional

A dictionary where keys are NumberSymbol instances and values are their SMT variable names. When using this feature, extra caution must be taken to avoid naming collisions between user symbols and listed constants. If not given, constants will be expanded inline i.e. 3.14159 instead of MY_SMT_VARIABLE_FOR_PI.

prefix_expressions: list, optional

A list of lists of str and/or expressions to convert into SMTLib and prefix to the output.

suffix_expressions: list, optional

A list of lists of str and/or expressions to convert into SMTLib and postfix to the output.

log_warn: lambda function, optional

A function to record all warnings during potentially risky operations. Soundness is a core value in SMT solving, so it is good to log all assumptions made.

Examples

```python
>>> from sympy import smtlib_code, symbols, sin, Eq
>>> x = symbols('x')
>>> smtlib_code(sin(x).series(x).removeO(), log_warn=print)
Could not infer type of `x`. Defaulting to float.
Non-Boolean expression `x**5/120 - x**3/6 + x` will not be asserted.
Converting to SMTLib verbatim.
'(declare-const x Real)\n(+ x (* (/ -1 6) (pow x 3)) (* (/ 1 120) (pow x 5)))'
```

```python
>>> from sympy import Rational
>>> x, y, tau = symbols("x, y, tau")
>>> smtlib_code((2*tau)**Rational(7, 2), log_warn=print)
Could not infer type of `tau`. Defaulting to float.
Non-Boolean expression `8*sqrt(2)*tau**(7/2)` will not be asserted.
Converting to SMTLib verbatim.
'(declare-const tau Real)\n(* 8 (pow 2 (/ 1 2)) (pow tau (/ 7 2)))'
```

Piecewise expressions are implemented with ite expressions by default. Note that if the Piecewise lacks a default term, represented by (expr, True) then an error will be thrown. This is to prevent generating an expression that may not evaluate to anything.

```python
>>> from sympy import Piecewise
>>> pw = Piecewise((x + 1, x > 0), (x, True))
>>> smtlib_code(Eq(pw, 3), symbol_table={x: float}, log_warn=print)
'(declare-const x Real)\n(= (ite (> x 0) (+ 1 x) x) 3)'
```

Custom printing can be defined for certain types by passing a dictionary of PythonType: “SMT Name” to the known_types, known_constants, and known_functions kwargs.
```python
>>> from typing import Callable
>>> from sympy import Function, Add
>>> f = Function('f')
>>> g = Function('g')
>>> smt_builtin_funcs = {  # functions our SMT solver will understand
...     f: "existing_smtlib_fcn",
...     Add: "sum",
... }
>>> user_def_funcs = {  # functions defined by the user must have their
...     g: Callable[[int], float],
... }
>>> smtlib_code(f(x) + g(x), symbol_table=user_def_funcs, known_
...     functions=smt_builtin_funcs, log_warn=print)
Non-Boolean expression `f(x) + g(x)` will not be asserted. Converting to
SMTLib verbatim.
'(declare-const x Int)\n(declare-fun g (Int) Real)\n(sum (existing_
    smtlib_fcn x) (g x))'
```

**Mathematica code printing**
SymPy Documentation, Release 1.12.1

sympy.printing.mathematica.known_functions = {'Chi': [(<function <lambda>>, 'CoshIntegral')], 'Ci': [(<function <lambda>>, 'CosIntegral')], 'DiracDelta': [(<function <lambda>>, 'DiracDelta')], 'Ei': [(<function <lambda>>, 'ExpIntegralEi')], 'FallingFactorial': [(<function <lambda>>, 'FactorialPower')], 'Heaviside': [(<function <lambda>>, 'HeavisideTheta')], 'KroneckerDelta': [(<function <lambda>>, 'KroneckerDelta')], 'Max': [(<function <lambda>>, 'Max')], 'Min': [(<function <lambda>>, 'Min')], 'RisingFactorial': [(<function <lambda>>, 'Pochhammer')], 'Shi': [(<function <lambda>>, 'SinIntegral')], 'Si': [(<function <lambda>>, 'SinIntegral')], 'acos': [(<function <lambda>>, 'ArcCos')], 'acosh': [(<function <lambda>>, 'ArcCosh')], 'acot': [(<function <lambda>>, 'ArcCot')], 'acoth': [(<function <lambda>>, 'ArcCoth')], 'acsc': [(<function <lambda>>, 'ArcCsc')], 'acsch': [(<function <lambda>>, 'ArcCsch')], 'airyai': [(<function <lambda>>, 'ArcCsch')], 'airybipp': [(<function <lambda>>, 'AiryBiPrime')], 'airybiprime': [(<function <lambda>>, 'AiryBiPrime')], 'appellf1': [(<function <lambda>>, 'AppellF1')], 'asec': [(<function <lambda>>, 'ArcSec')], 'asech': [(<function <lambda>>, 'ArcSech')], 'asin': [(<function <lambda>>, 'ArcSin')], 'asinh': [(<function <lambda>>, 'ArcSin')], 'assoc_laguerre': [(<function <lambda>>, 'LaguerreL')], 'assoc_legendre': [(<function <lambda>>, 'LegendreP')], 'atan': [(<function <lambda>>, 'ArcTan')], 'atan2': [(<function <lambda>>, 'ArcTan')], 'atanh': [(<function <lambda>>, 'ArcTanh')], 'besseli': [(<function <lambda>>, 'BesselI')], 'besselj': [(<function <lambda>>, 'BesselJ')], 'besselk': [(<function <lambda>>, 'BesselK')], 'bessely': [(<function <lambda>>, 'BesselY')], 'beta': [(<function <lambda>>, 'Beta')], 'catalan': [(<function <lambda>>, 'CatalanNumber')], 'chebyshevT': [(<function <lambda>>, 'ChebyshevT')], 'chebyshevU': [(<function <lambda>>, 'ChebyshevU')], 'conjugate': [(<function <lambda>>, 'Conjugate')], 'cos': [(<function <lambda>>, 'Cos')], 'cosh': [(<function <lambda>>, 'Cosh')], 'cot': [(<function <lambda>>, 'Cot')], 'coth': [(<function <lambda>>, 'Coth')], 'csc': [(<function <lambda>>, 'Csc')], 'csch': [(<function <lambda>>, 'Csch')], 'dirichlet_eta': [(<function <lambda>>, 'DirichletE')], 'elliptic_e': [(<function <lambda>>, 'EllipticE')], 'elliptic_f': [(<function <lambda>>, 'EllipticF')], 'elliptic_k': [(<function <lambda>>, 'EllipticK')], 'elliptic_pi': [(<function <lambda>>, 'EllipticPi')], 'erf': [(<function <lambda>>, 'Erf')], 'erf2': [(<function <lambda>>, 'Erf')], 'erf2inv': [(<function <lambda>>, 'InverseErf')], 'erfc': [(<function <lambda>>, 'Erfc')], 'erfcinv': [(<function <lambda>>, 'InverseErf')], 'erfi': [(<function <lambda>>, 'Erfi')], 'erfinv': [(<function <lambda>>, 'InverseErf')], 'exp': [(<function <lambda>>, 'Exp')], 'expint': [(<function <lambda>>, 'ExpIntegralEi')], 'factorial': [(<function <lambda>>, 'Factorial')], 'factorial2': [(<function <lambda>>, 'Factorial2')], 'fresnelc': [(<function <lambda>>, 'FresnelC')], 'fresnels': [(<function <lambda>>, 'Fresnels')], 'gamma': [(<function <lambda>>, 'Gamma')], 'gcd': [(<function <lambda>>, 'GCD')], 'gegenbauer': [(<function <lambda>>, 'GegenbauerC')], 'hankel1': [(<function <lambda>>, 'HankelH1')], 'hankel2': [(<function <lambda>>, 'HankelH2')], 'harmonic': [(<function <lambda>>, 'HarmonicNumber')], 'hermite': [(<function <lambda>>, 'HermiteH')], 'hyper': [(<function <lambda>>, 'HypergeometricPFQ')], 'jacobi': [(<function <lambda>>, 'JacobiP')], 'jn': [(<function <lambda>>, 'SphericalBesselJ')], 'laguerre': [(<function <lambda>>, 'LaguerreL')], 'lcm': [(<function <lambda>>, 'LCM')], 'legendre': [(<function <lambda>>, 'LegendreP')], 'lerchphi': [(<function <lambda>>, 'LerchPhi')], 'li': [(<function <lambda>>, 'LogIntegral')], 'log': [(<function <lambda>>, 'Log')], 'loggamma': [(<function <lambda>>, 'LogGamma')], 'lucas': [(<function <lambda>>, 'LucasL')], 'mathieu': [(<function <lambda>>, 'MathieuC')], 'mathieuprime': [(<function <lambda>>, 'MathieuCPrime')], 'mathieus': [(<function <lambda>>, 'MathieuS')], 'mathieusprime': [(<function <lambda>>, 'MathieuSPrime')], 'meijerg': [(<function <lambda>>, 'MeijerG')], 'polygamma': [(<function <lambda>>, 'Polygamma')], 'polynomial': [(<function <lambda>>, 'Polynomial')], 'riemann_xi': [(<function <lambda>>, 'RiemannXi')], 'sec': [(<function <lambda>>, 'Sec')], 'sech': [(<function <lambda>>, 'Sech')], 'sin': [(<function <lambda>>, 'Sin')], 'sinc': [(<function <lambda>>, 'Sinc')], 'sinh': [(<function <lambda>>, 'Sinh')], 'sqrt': [(<function <lambda>>, 'Sqrt')], 'stieltjes': [(<function <lambda>>, 'StieltjesGamma')], 'subfactorial': [(<function <lambda>>, 'Subfactorial')], 'tan': [(<function <lambda>>, 'Tan')], 'tanh': [(<function <lambda>>, 'Tanh')], 'uppergamma': [(<function <lambda>>, 'Uppergamma')], 'yn': [(<function <lambda>>, 'SphericalBesselY')], 'zeta': [(<function <lambda>>, 'Zeta')]}
class sympy.printing.mathematica.MCodePrinter(settings={})
A printer to convert Python expressions to strings of the Wolfram’s Mathematica code

printmethod: str = '_mcode'

sympy.printing.mathematica.mathematica_code(expr, **settings)
Converts an expr to a string of the Wolfram Mathematica code

Examples

```python
>>> from sympy import mathematica_code as mcode, symbols, sin
>>> x = symbols('x')
>>> mcode(sin(x).series(x).removeO())
'(1/120)*x^5 - 1/6*x^3 + x'
```

Maple code printing

class sympy.printing.maple.MapleCodePrinter(settings=None)
Printer which converts a SymPy expression into a maple code.

printmethod: str = '_maple'

sympy.printing.maple.maple_code(expr, assign_to=None, **settings)
Converts expr to a string of Maple code.

Parameters

- expr: Expr
  A SymPy expression to be converted.

- assign_to: optional
  When given, the argument is used as the name of the variable to which the expression is assigned. Can be a string, Symbol, MatrixSymbol, or Indexed type. This can be helpful for expressions that generate multi-line statements.

- precision: integer, optional
  The precision for numbers such as pi [default=16].

- user_functions: dict, optional
  A dictionary where keys are FunctionClass instances and values are their string representations. Alternatively, the dictionary value can be a list of tuples i.e. [(argument_test, cfunction_string)]. See below for examples.

- human: bool, optional
  If True, the result is a single string that may contain some constant declarations for the number symbols. If False, the same information is returned in a tuple of (symbols_to_declare, not_supported_functions, code_text). [default=True].

5.8. Topics 2229
**contract**: bool, optional

If True, Indexed instances are assumed to obey tensor contraction rules and the corresponding nested loops over indices are generated. Setting contract=False will not generate loops, instead the user is responsible to provide values for the indices in the code. [default=True].

**inline**: bool, optional

If True, we try to create single-statement code instead of multiple statements. [default=True].

```python
from sympy import print_maple_code, symbols
x, y = symbols('x y')
print_maple_code(x, assign_to=y)
```

```
y := x
```

### Javascript Code printing

```python

class sympy.printing.jscode.JavaScriptCodePrinter(settings={})
    # A Printer to convert Python expressions to strings of JavaScript code
    printmethod: str = '_javascript'

indent_code(code)
    Accepts a string of code or a list of code lines

sympy.printing.jscode.jscode(expr, assign_to=None, **settings)
    Converts an expr to a string of javascript code

Parameters

- **expr** : Expr
    A SymPy expression to be converted.

- **assign_to** : optional
    When given, the argument is used as the name of the variable to which the expression is assigned. Can be a string, Symbol,
MatrixSymbol, or Indexed type. This is helpful in case of line-wrapping, or for expressions that generate multi-line statements.

**precision**: integer, optional

The precision for numbers such as pi [default=15].

**user_functions**: dict, optional

A dictionary where keys are FunctionClass instances and values are their string representations. Alternatively, the dictionary value can be a list of tuples i.e. [(argument_test, js_function_string)]. See below for examples.

**human**: bool, optional

If True, the result is a single string that may contain some constant declarations for the number symbols. If False, the same information is returned in a tuple of (symbols_to_declare, not_supported_functions, code_text). [default=True].

**contract**: bool, optional

If True, Indexed instances are assumed to obey tensor contraction rules and the corresponding nested loops over indices are generated. Setting contract=False will not generate loops, instead the user is responsible to provide values for the indices in the code. [default=True].

### Examples

```python
>>> from sympy import jscode, symbols, Rational, sin, ceiling, Abs
>>> x, tau = symbols("x, tau")
>>> jscode((2*tau)**Rational(7, 2))
'8*Math.sqrt(2)*Math.pow(tau, 7/2)'
>>> jscode(sin(x), assign_to="s")
's = Math.sin(x);'
```

Custom printing can be defined for certain types by passing a dictionary of “type”: “function” to the user_functions kwarg. Alternatively, the dictionary value can be a list of tuples i.e. [(argument_test, js_function_string)].

```python
>>> custom_functions = {
...     "ceiling": "CEIL",
...     "Abs": [(lambda x: not x.is_integer, "fabs"),
...             (lambda x: x.is_integer, "ABS")]
... }
>>> jscode(Abs(x) + ceiling(x), user_functions=custom_functions)
'fabs(x) + CEIL(x)'
```

Piecewise expressions are converted into conditionals. If an assign_to variable is provided an if statement is created, otherwise the ternary operator is used. Note that if the Piecewise lacks a default term, represented by (expr, True) then an error will be thrown. This is to prevent generating an expression that may not evaluate to anything.
```python
>>> from sympy import Piecewise
>>> expr = Piecewise((x + 1, x > 0), (x, True))
>>> print(jscode(expr, tau))
if (x > 0) {
    tau = x + 1;
} else {
    tau = x;
}
```

Support for loops is provided through Indexed types. With contract=True these expressions will be turned into loops, whereas contract=False will just print the assignment expression that should be looped over:

```python
>>> from sympy import Eq, IndexedBase, Idx
>>> len_y = 5
>>> y = IndexedBase('y', shape=(len_y,))
>>> t = IndexedBase('t', shape=(len_y,))
>>> Dy = IndexedBase('Dy', shape=(len_y-1,))
>>> i = Idx('i', len_y-1)
>>> e=Eq(Dy[i], (y[i+1]-y[i])/(t[i+1]-t[i]))
>>> jscode(e.rhs, assign_to=e.lhs, contract=False)
'Dy[i] = (y[i + 1] - y[i])/(t[i + 1] - t[i]);'
```

Matrices are also supported, but a MatrixSymbol of the same dimensions must be provided to assign_to. Note that any expression that can be generated normally can also exist inside a Matrix:

```python
>>> from sympy import Matrix, MatrixSymbol
>>> mat = Matrix([x**2, Piecewise((x + 1, x > 0), (x, True)), sin(x)]
>>> A = MatrixSymbol('A', 3, 1)
>>> print(jscode(mat, A))
A[0] = Math.pow(x, 2);
if (x > 0) {
    A[1] = x + 1;
} else {
    A[1] = x;
}
A[2] = Math.sin(x);
```

**Julia code printing**

Built-in mutable sequence.
If no argument is given, the constructor creates a new empty list. The argument must be an iterable if specified.

```python
sympy.printing.julia.known_fcns_src2 = {'Abs': 'abs', 'ceiling': 'ceil', 'conjugate': 'conj', 'hankel1': 'hankelh1', 'hankel2': 'hankelh2', 'im': 'imag', 're': 'real'}
```

```python
class sympy.printing.julia.JuliaCodePrinter(settings={})

A printer to convert expressions to strings of Julia code.

printmethod: str = '_julia'

indent_code(code)

Accepts a string of code or a list of code lines
```

```python
sympy.printing.julia.julia_code(expr, assign_to=None, **settings)

Converts expr to a string of Julia code.
```

**Parameters**

expr : Expr

A SymPy expression to be converted.

assign_to : optional

When given, the argument is used as the name of the variable to which the expression is assigned. Can be a string, Symbol, MatrixSymbol, or Indexed type. This can be helpful for expressions that generate multi-line statements.

precision : integer, optional

The precision for numbers such as pi [default=16].

user_functions : dict, optional

A dictionary where keys are FunctionClass instances and values are their string representations. Alternatively, the dictionary value can be a list of tuples i.e. [(argument_test, cfunction_string)]. See below for examples.

human : bool, optional

If True, the result is a single string that may contain some constant declarations for the number symbols. If False, the same information is returned in a tuple of (symbols_to_declare, not_supported_functions, code_text). [default=True].

contract: bool, optional

If True, Indexed instances are assumed to obey tensor contraction rules and the corresponding nested loops over indices are generated. Setting contract=False will not generate loops, instead the user is responsible to provide values for the indices in the code. [default=True].

inline: bool, optional

If True, we try to create single-statement code instead of multiple statements. [default=True].
Examples

```python
>>> from sympy import julia_code, symbols, sin, pi
>>> x = symbols('x')
>>> julia_code(sin(x).series(x).removeO())
'x .^ 5 / 120 - x .^ 3 / 6 + x'

>>> from sympy import Rational, ceiling
>>> x, y, tau = symbols("x, y, tau")
>>> julia_code((2*tau)**Rational(7, 2))
'8 * sqrt(2) * tau .^ (7 // 2)'

Note that element-wise (Hadamard) operations are used by default between symbols. This is because it's possible in Julia to write "vectorized" code. It is harmless if the values are scalars.

```python
>>> julia_code(sin(pi*x*y), assign_to="s")
's = sin(pi * x .* y)'

If you need a matrix product "*" or matrix power "^", you can specify the symbol as a MatrixSymbol.

```python
>>> from sympy import Symbol, MatrixSymbol
>>> n = Symbol('n', integer=True, positive=True)
>>> A = MatrixSymbol('A', n, n)
>>> julia_code(3*pi*A**3)
'(3 * pi) * A ^ 3'

This class uses several rules to decide which symbol to use a product. Pure numbers use "*", Symbols use ".*" and MatrixSymbols use "^". A HadamardProduct can be used to specify componentwise multiplication ".*" of two MatrixSymbols. There is currently no easy way to specify scalar symbols, so sometimes the code might have some minor cosmetic issues. For example, suppose x and y are scalars and A is a Matrix, then while a human programmer might write "(x^2*y)*A^3", we generate:

```python
>>> julia_code(x**2*y*A**3)
'(x .^ 2 .* y) * A ^ 3'

Matrices are supported using Julia inline notation. When using assign_to with matrices, the name can be specified either as a string or as a MatrixSymbol. The dimensions must align in the latter case.

```python
>>> from sympy import Matrix, MatrixSymbol
>>> mat = Matrix([[x**2, sin(x), ceiling(x)]]
>>> julia_code(mat, assign_to='A')
'A = [x .^ 2 sin(x) ceil(x)]'

Piecewise expressions are implemented with logical masking by default. Alternatively, you can pass "inline=False" to use if-else conditionals. Note that if the Piecewise lacks a default term, represented by (expr, True) then an error will be thrown. This is to prevent generating an expression that may not evaluate to anything.

```python
>>> from sympy import Piecewise
>>> pw = Piecewise((x + 1, x > 0), (x, True))

(continues on next page)
Note that any expression that can be generated normally can also exist inside a Matrix:

```python
>>> mat = Matrix([[x**2, pw, sin(x)]]
`A = [x .^ 2 ((x > 0) ? (x + 1) : (x)) sin(x)]`
```

Custom printing can be defined for certain types by passing a dictionary of “type”: “function” to the `user_functions` keyword. Alternatively, the dictionary value can be a list of tuples i.e., [(argument_test, cfunction_string)]. This can be used to call a custom Julia function.

```python
>>> from sympy import Function
>>> f = Function('f')
>>> g = Function('g')
>>> custom_functions = {
...     "f": "existing_julia_fcn",
...     "g": [(lambda x: x.is_Matrix, "my_mat_fcn"),
...            (lambda x: not x.is_Matrix, "my_fcn")]
... }
>>> mat = Matrix([[1, x]])
>>> julia_code(f(x) + g(x) + g(mat), user_functions=custom_functions)
'existing_julia_fcn(x) + my_fcn(x) + my_mat_fcn([1 x])'
```

Support for loops is provided through Indexed types. With contract=True these expressions will be turned into loops, whereas contract=False will just print the assignment expression that should be looped over:

```python
>>> from sympy import Eq, IndexedBase, Idx
>>> len_y = 5
>>> y = IndexedBase('y', shape=(len_y,))
>>> t = IndexedBase('t', shape=(len_y,))
>>> Dy = IndexedBase('Dy', shape=(len_y-1,))
>>> i = Idx('i', len_y-1)
>>> e = Eq(Dy[i], (y[i+1] - y[i]) / (t[i+1] - t[i]))
>>> julia_code(e.rhs, assign_to=e.lhs, contract=False)
'Dy[i] = (y[i + 1] - y[i]) ./ (t[i + 1] - t[i])'
```

**Octave (and Matlab) Code printing**

```python
```

Built-in mutable sequence.

5.8. Topics 2235
If no argument is given, the constructor creates a new empty list. The argument must be an iterable if specified.

```python
sympy.printing.octave.known_fcns_src2 = {'Abs': 'abs', 'Chi': 'coshint', 'Ci': 'cosint', 'DiracDelta': 'dirac', 'Heaviside': 'heaviside', 'LambertW': 'lambertw', 'Max': 'max', 'Min': 'min', 'Mod': 'mod', 'RisingFactorial': 'pochhammer', 'Shi': 'sinhint', 'Si': 'sinint', 'arg': 'angle', 'binomial': 'bincoeff', 'ceiling': 'ceil', 'chebyshevt': 'chebyshevT', 'chebyshevu': 'chebyshevU', 'conjugate': 'conj', 'im': 'imag', 'laguerre': 'laguerrel', 'li': 'logint', 'loggamma': 'gammaln', 'polygamma': 'psi', 're': 'real'}
```

```python
class sympy.printing.octave.OctaveCodePrinter(settings={})
    A printer to convert expressions to strings of Octave/Matlab code.

    printmethod: str = '_octave'

    indent_code(code)
        Accepts a string of code or a list of code lines

    sympy.printing.octave.octave_code(expr, assign_to=None, **settings)
        Converts expr to a string of Octave (or Matlab) code.
        The string uses a subset of the Octave language for Matlab compatibility.

        Parameters
        expr : Expr
            A SymPy expression to be converted.

        assign_to : optional
            When given, the argument is used as the name of the variable
to which the expression is assigned. Can be a string, Symbol,
MatrixSymbol, or Indexed type. This can be helpful for expressions
that generate multi-line statements.

        precision : integer, optional
            The precision for numbers such as pi [default=16].

        user_functions : dict, optional
            A dictionary where keys are FunctionClass instances and values are
their string representations. Alternatively, the dictionary value can
be a list of tuples i.e. [(argument_test, cfunction_string)]. See below
for examples.

        human : bool, optional
            If True, the result is a single string that may contain some
constant declarations for the number symbols. If False, the
same information is returned in a tuple of (symbols_to_declare,
not_supported_functions, code_text). [default=True].

        contract: bool, optional
            If True, Indexed instances are assumed to obey tensor contraction
rules and the corresponding nested loops over indices are generated.
Setting contract=False will not generate loops, instead the
user is responsible to provide values for the indices in the code. [de-
fault=True].
inline: bool, optional

If True, we try to create single-statement code instead of multiple statements. [default=True].

Examples

```python
>>> from sympy import octave_code, symbols, sin, pi
>>> x = symbols('x')
>>> octave_code(sin(x).series(x).removeO())
'x.^5/120 - x.^3/6 + x'

>>> from sympy import Rational, ceiling
>>> x, y, tau = symbols('x, y, tau')
>>> octave_code((2*tau)**Rational(7, 2))
'8*sqrt(2)*tau.^(7/2)'
```

Note that element-wise (Hadamard) operations are used by default between symbols. This is because it is very common in Octave to write “vectorized” code. It is harmless if the values are scalars.

```python
>>> octave_code(sin(pi*x*y), assign_to='s')
's = sin(pi*x.*y);'
```

If you need a matrix product "**" or matrix power "^", you can specify the symbol as a MatrixSymbol.

```python
>>> from sympy import Symbol, MatrixSymbol
>>> n = Symbol('n', integer=True, positive=True)
>>> A = MatrixSymbol('A', n, n)
>>> octave_code(3*pi*A**3)
'(3*pi)*A^3'
```

This class uses several rules to decide which symbol to use a product. Pure numbers use "*", Symbols use ".*" and MatrixSymbols use "**". A HadamardProduct can be used to specify component-wise multiplication ".*" of two MatrixSymbols. There is currently no easy way to specify scalar symbols, so sometimes the code might have some minor cosmetic issues. For example, suppose x and y are scalars and A is a Matrix, then while a human programmer might write "(x^2*y)*A^3", we generate:

```python
>>> octave_code(x**2*y*A**3)
'(x.^2.*y)*A^3'
```

Matrices are supported using Octave inline notation. When using assign_to with matrices, the name can be specified either as a string or as a MatrixSymbol. The dimensions must align in the latter case.

```python
>>> from sympy import Matrix, MatrixSymbol
>>> mat = Matrix([[x**2, sin(x), ceiling(x)]])
>>> octave_code(mat, assign_to='A')
'A = [x.^2 sin(x) ceil(x)];'
```

Piecewise expressions are implemented with logical masking by default. Alternatively, you can pass "inline=False" to use if-else conditionals. Note that if the Piecewise lacks
a default term, represented by (expr, True) then an error will be thrown. This is to prevent generating an expression that may not evaluate to anything.

```python
>>> from sympy import Piecewise
>>> pw = Piecewise((x + 1, x > 0), (x, True))
>>> octave_code(pw, assign_to=tau)
'tau = ((x > 0).*(x + 1) + ~(x > 0)).*(x));'
```

Note that any expression that can be generated normally can also exist inside a Matrix:

```python
>>> mat = Matrix([[x**2, pw, sin(x)]])
>>> octave_code(mat, assign_to='A')
'A = [x.^2 ((x > 0).*(x + 1) + (~x > 0)).*(x)) sin(x)];'
```

Custom printing can be defined for certain types by passing a dictionary of “type” : “function” to the user_functions kwarg. Alternatively, the dictionary value can be a list of tuples i.e., [argument_test, cfunction_string]]. This can be used to call a custom Octave function.

```python
>>> from sympy import Function
>>> f = Function('f')
>>> g = Function('g')
>>> custom_functions = {
...     "f": "existing_octave_fcn",
...     "g": [(lambda x: x.is_Matrix, "my_mat_fcn"),
...            (lambda x: not x.is_Matrix, "my_fcn")]
... }
>>> mat = Matrix([[1, x]])
>>> octave_code(f(x) + g(x) + g(mat), user_functions=custom_functions)
'existing_octave_fcn(x) + my_fcn(x) + my_mat_fcn([1 x])'
```

Support for loops is provided through Indexed types. With contract=True these expressions will be turned into loops, whereas contract=False will just print the assignment expression that should be looped over:

```python
>>> from sympy import Eq, IndexedBase, Idx
>>> len_y = 5
>>> y = IndexedBase('y', shape=(len_y,))
>>> t = IndexedBase('t', shape=(len_y,))
>>> Dy = IndexedBase('Dy', shape=(len_y-1,))
>>> i = Idx('i', len_y-1)
>>> e = Eq(Dy[i], (y[i+1]-y[i])/(t[i+1]-t[i]))
>>> octave_code(e.rhs, assign_to=e.lhs, contract=False)
'Dy(i) = (y(i + 1) - y(i))./(t(i + 1) - t(i));'
```
Rust code printing

```python
SymPy.printing.rust.known_functions = {'Abs': 'abs', 'Max': 'max', 'Min': 'min', 'Pow': lambda expr: 'pow' if isinstance(expr, 2), (lambda expr: 'sqrt') if isinstance(expr, 2), (lambda expr: 'sqrt().recip') if isinstance(expr, 2), (lambda expr: 'cbrt', 2), (lambda expr: 'exp2', 3), (lambda expr: 'powi', 1), (lambda expr: 'powf', 1), 'acos': 'acos', 'acosh': 'acosh', 'asin': 'asin', 'asinh': 'asinh', 'atan': 'atan', 'atan2': 'atan2', 'atanh': 'atanh', 'ceiling': 'ceil', 'cos': 'cos', 'cosh': 'cosh', 'exp': lambda expr: 'exp', 'floor': 'floor', 'log': 'ln', 'sign': 'signum', 'sin': 'sin', 'sinh': 'sinh', 'sqrt': 'sqrt', 'tan': 'tan', 'tanh': 'tanh'}

class sympy.printing.rust.RustCodePrinter(settings={})
    A printer to convert SymPy expressions to strings of Rust code
    printmethod: str = '_rust_code'
    indent_code(code)
        Accepts a string of code or a list of code lines
    sympy.printing.rust.rust_code(expr, assign_to=None, **settings)
        Converts an expr to a string of Rust code

Parameters
expr : Expr
    A SymPy expression to be converted.
assign_to : optional
    When given, the argument is used as the name of the variable to which the expression is assigned. Can be a string, Symbol, MatrixSymbol, or Indexed type. This is helpful in case of line-wrapping, or for expressions that generate multi-line statements.
precision : integer, optional
    The precision for numbers such as pi [default=15].
user_functions : dict, optional
    A dictionary where the keys are string representations of either FunctionClass or UndefinedFunction instances and the values are their desired C string representations. Alternatively, the dictionary value can be a list of tuples i.e. [(argument_test, cfunction_string)]. See below for examples.
dereference : iterable, optional
    An iterable of symbols that should be dereferenced in the printed code expression. These would be values passed by address to the function. For example, if dereference=[a], the resulting code would print (*a) instead of a.
human : bool, optional
    If True, the result is a single string that may contain some constant declarations for the number symbols. If False, the same information is returned in a tuple of (symbols_toDeclare, not_supportedFunctions, code_text). [default=True].
```
contract: bool, optional

If True, Indexed instances are assumed to obey tensor contraction rules and the corresponding nested loops over indices are generated. Setting contract=False will not generate loops, instead the user is responsible to provide values for the indices in the code. [default=True].

Examples

```python
>>> from sympy import rust_code, symbols, Rational, sin, ceiling, Abs,
                 Function
>>> x, tau = symbols("x, tau")
>>> rust_code((2*tau)**Rational(7, 2))
'8*1.4142135623731*tau.powf(7_f64/2.0)'
>>> rust_code(sin(x), assign_to="s")
's = x.sin();'
```

Simple custom printing can be defined for certain types by passing a dictionary of {"type": "function"} to the user_functions kwarg. Alternatively, the dictionary value can be a list of tuples i.e. [(argument_test, cfunction_string)].

```python
>>> custom_functions = {
...     "ceiling": "CEIL",
...     "Abs": [(lambda x: not x.is_integer, "fabs", 4),
...             (lambda x: x.is_integer, "ABS", 4)],
...     "func": "f"
... }
>>> func = Function('func')
>>> rust_code(func(Abs(x) + ceiling(x)), user_functions=custom_functions)
'(fabs(x) + x.CEIL()).f()'
```

Piecewise expressions are converted into conditionals. If an assign_to variable is provided an if statement is created, otherwise the ternary operator is used. Note that if the Piecewise lacks a default term, represented by (expr, True) then an error will be thrown. This is to prevent generating an expression that may not evaluate to anything.

```python
>>> from sympy import Piecewise
>>> expr = Piecewise((x + 1, x > 0), (x, True))
>>> print(rust_code(expr, tau))
tau = if (x > 0) {
  x + 1
} else {
  x
};
```

Support for loops is provided through Indexed types. With contract=True these expressions will be turned into loops, whereas contract=False will just print the assignment expression that should be looped over:

```python
>>> from sympy import Eq, IndexedBase, Idx
>>> len_y = 5
>>> y = IndexedBase('y', shape=(len_y,))
```
Matrices are also supported, but a MatrixSymbol of the same dimensions must be provided to assign_to. Note that any expression that can be generated normally can also exist inside a Matrix:

```python
>>> from sympy import Matrix, MatrixSymbol
>>> mat = Matrix([[x**2, Piecewise((x + 1, x > 0), (x, True)), sin(x)]])
>>> A = MatrixSymbol('A', 3, 1)
>>> print(rust_code(mat, A))
A = [x.powi(2), if (x > 0) {
   x + 1
} else {
   x
}, x.sin()];
```

### Aesara Code printing

**class** sympy.printing.aesaracode.AesaraPrinter(*args, **kwargs)**

Code printer which creates Aesara symbolic expression graphs.

**Parameters**

- **cache**: dict
  
  Cache dictionary to use. If None (default) will use the global cache. To create a printer which does not depend on or alter global state pass an empty dictionary. Note: the dictionary is not copied on initialization of the printer and will be updated in-place, so using the same dict object when creating multiple printers or making multiple calls to `aesara_code()` (page 2242) or `aesara_function()` (page 2242) means the cache is shared between all these applications.

**Attributes**

- **cache** (dict) A cache of Aesara variables which have been created for SymPy symbol-like objects (e.g. `sympy.core.symbol.Symbol` (page 1028) or `sympy.matrices.expressions.MatrixSymbol` (page 1417)). This is used to ensure that all references to a given symbol in an expression (or multiple expressions) are printed as the same Aesara variable, which is created only once. Symbols are differentiated only by name and type. The format of the cache’s contents should be considered opaque to the user.

- **printmethod**: str = '_aesara'
doprint(expr, dtypes=None, broadcastables=None)

Convert a SymPy expression to a Aesara graph variable.

The dtypes and broadcastables arguments are used to specify the data type, dimension, and broadcasting behavior of the Aesara variables corresponding to the free symbols in expr. Each is a mapping from SymPy symbols to the value of the corresponding argument to aesara.tensor.var.TensorVariable.

See the corresponding documentation page for more information on broadcasting in Aesara.

Parameters
expr : sympy.core.expr.Expr
SymPy expression to print.
dtypes : dict
Mapping from SymPy symbols to Aesara datatypes to use when creating new Aesara variables for those symbols. Corresponds to the dtype argument to aesara.tensor.var.TensorVariable. Defaults to 'floatX' for symbols not included in the mapping.
broadcastables : dict
Mapping from SymPy symbols to the value of the broadcastable argument to aesara.tensor.var.TensorVariable to use when creating Aesara variables for those symbols. Defaults to the empty tuple for symbols not included in the mapping (resulting in a scalar).

Returns
aesara.graph.basic.Variable
A variable corresponding to the expression’s value in a Aesara symbolic expression graph.

sympy.printing.aesaracode.aesara_code(expr, cache=None, **kwargs)

Convert a SymPy expression into a Aesara graph variable.

Parameters
expr : sympy.core.expr.Expr
SymPy expression object to convert.
cache : dict
Cached Aesara variables (see AesaraPrinter.cache (page 2241)). Defaults to the module-level global cache.
dtypes : dict
Passed to AesaraPrinter.doprint() (page 2241).
broadcastables : dict
Passed to AesaraPrinter.doprint() (page 2241).

Returns
aesara.graph.basic.Variable
A variable corresponding to the expression’s value in a Aesara symbolic expression graph.
sympy.printing.aesaracode.aesara_function(inputs, outputs, scalar=False, *
   dim=None, dims=None,
   broadcastables=None, **kwargs)

Create a Aesara function from SymPy expressions.

The inputs and outputs are converted to Aesara variables using `aesara_code()` (page 2242) and then passed to `aesara.function`.

**Parameters**

**inputs**

Sequence of symbols which constitute the inputs of the function.

**outputs**

Sequence of expressions which constitute the outputs(s) of the function. The free symbols of each expression must be a subset of inputs.

**scalar** : bool

Convert 0-dimensional arrays in output to scalars. This will return a Python wrapper function around the Aesara function object.

**cache** : dict

Cached Aesara variables (see `AesaraPrinter.cache` (page 2241)). Defaults to the module-level global cache.

**dtypes** : dict

Passed to `AesaraPrinter.doprint()` (page 2241).

**broadcastables** : dict

Passed to `AesaraPrinter.doprint()` (page 2241).

**dims** : dict

Alternative to `broadcastables` argument. Mapping from elements of inputs to integers indicating the dimension of their associated arrays/tensors. Overrides `broadcastables` argument if given.

**dim** : int

Another alternative to the `broadcastables` argument. Common number of dimensions to use for all arrays/tensors. `aesara_function([x, y], [...], dim=2)` is equivalent to using `broadcastables={x: (False, False), y: (False, False)}`.

**Returns**

callable

A callable object which takes values of inputs as positional arguments and returns an output array for each of the expressions in outputs. If outputs is a single expression the function will return a Numpy array, if it is a list of multiple expressions the function will return a list of arrays. See description of the `squeeze` argument above for the behavior when a single output is passed in a list. The returned object will either be an instance of `aesara.compile.function.types.Function` or a Python wrapper function around one. In both cases, the returned value will have a `aesara_function` attribute which points to the return value of `aesara.function`.

5.8. Topics
Examples

```python
>>> from sympy.abc import x, y, z
>>> from sympy.printing.aesaracode import aesara_function
```

A simple function with one input and one output:

```python
>>> f1 = aesara_function([x], [x**2 - 1], scalar=True)
>>> f1(3)
8.0
```

A function with multiple inputs and one output:

```python
>>> f2 = aesara_function([x, y, z], [(x**z + y**z)**(1/z)], scalar=True)
>>> f2(3, 4, 2)
5.0
```

A function with multiple inputs and multiple outputs:

```python
>>> f3 = aesara_function([x, y], [x**2 + y**2, x**2 - y**2], scalar=True)
>>> f3(2, 3)
[13.0, -5.0]
```

See also:

dim_handling (page 2244)

```python
sympy.printing.aesaracode.dim_handling(inputs, dim=None, dims=None, broadcastables=None)
```

Get value of broadcastables argument to `aesara_code()` (page 2242) from keyword arguments to `aesara_function()` (page 2242).

Included for backwards compatibility.

**Parameters**

- **inputs**
  - Sequence of input symbols.

- **dim**
  - int
  - Common number of dimensions for all inputs. Overrides other arguments if given.

- **dims**
  - dict
  - Mapping from input symbols to number of dimensions. Overrides broadcastables argument if given.

- **broadcastables**
  - dict
  - Explicit value of broadcastables argument to `AesaraPrinter.doprint()` (page 2241). If not None function will return this value unchanged.

**Returns**

- **dict**
  - Dictionary mapping elements of inputs to their “broadcastable” values (tuple of bools).
Gtk

You can print to a gtkmathview widget using the function `print_gtk` located in `sympy.printing.gtk` (it requires to have installed gtkmathview and libgtkmathview-bin in some systems).

GtkMathView accepts MathML, so this rendering depends on the MathML representation of the expression.

Usage:

```python
from sympy import *
print_gtk(x**2 + 2*exp(x**3))
```

```python
sympy.printing.gtk.print_gtk(x, start_viewer=True)
```

Print to Gtkmathview, a gtk widget capable of rendering MathML.

Needs libgtkmathview-bin

**LambdaPrinter**

This classes implements printing to strings that can be used by the `sympy.utilities.lambdify.lambdify()` function.

```python
class sympy.printing.lambdarepr.LambdaPrinter(settings=None)
```

```
printmethod: str = '_lambdacode'
```

```python
sympy.printing.lambdarepr.lambdarepr(expr, **settings)
```

Returns a string usable for lambdifying.

**LatexPrinter**

This class implements LaTeX printing. See `sympy.printing.latex`.

```python
sympy.printing.latex.accepted_latex_functions = ['arcsin', 'arccos', 'arctan', 'sin', 'cos', 'tan', 'cosh', 'sinh', 'tanh', 'sqrt', 'ln', 'log', 'sec', 'csc', 'cot', 'coth', 're', 'im', 'frac', 'root', 'arg']
```

Built-in mutable sequence.

If no argument is given, the constructor creates a new empty list. The argument must be an iterable if specified.

```python
class sympy.printing.latex.LatexPrinter(settings=None)
```

```
printmethod: str = '_latex'
```

```
parenthesize_super(s)
```

Protect superscripts in `s`

If the `parenthesize_super` option is set, protect with parentheses, else wrap in braces.

5.8. Topics
Convert the given expression to LaTeX string representation.

**Parameters**

- **full_prec**: boolean, optional
  If set to True, a floating point number is printed with full precision.

- **fold_frac_powers**: boolean, optional
  Emit $^p/q$ instead of $^{\frac{p}{q}}$ for fractional powers.

- **fold_func_brackets**: boolean, optional
  Fold function brackets where applicable.

- **fold_short_frac**: boolean, optional
  Emit $p / q$ instead of $\frac{p}{q}$ when the denominator is simple enough (at most two terms and no powers). The default value is True for inline mode, False otherwise.

- **inv_trig_style**: string, optional
  How inverse trig functions should be displayed. Can be one of 'abbreviated', 'full', or 'power'. Defaults to 'abbreviated'.

- **itex**: boolean, optional
  Specifies if itex-specific syntax is used, including emitting $$...$$.

- **ln_notation**: boolean, optional
  If set to True, $\ln$ is used instead of default $\log$.

- **long_frac_ratio**: float or None, optional
  The allowed ratio of the width of the numerator to the width of the denominator before the printer breaks off long fractions. If None (the default value), long fractions are not broken up.

- **mat_delim**: string, optional
  The delimiter to wrap around matrices. Can be one of '{', '(', or the empty string ''. Defaults to '{'.

- **mat_str**: string, optional
  Which matrix environment string to emit. 'smallmatrix', 'matrix', 'array', etc. Defaults to 'smallmatrix' for inline mode, 'matrix' for matrices of no more than 10 columns, and 'array' otherwise.

- **mode**: string, optional
Specifies how the generated code will be delimited. mode can be one of 'plain', 'inline', 'equation' or 'equation*'. If mode is set to 'plain', then the resulting code will not be delimited at all (this is the default). If mode is set to 'inline' then inline LaTeX $...$ will be used. If mode is set to 'equation' or 'equation*', the resulting code will be enclosed in the equation or equation* environment (remember to import amsmath for equation*), unless the itex option is set. In the latter case, the $$...$$ syntax is used.

**mul_symbol**: string or None, optional

The symbol to use for multiplication. Can be one of None, 'ldot', 'dot', or 'times'.

**order**: string, optional

Any of the supported monomial orderings (currently 'lex', 'grlex', or 'grevlex'), 'old', and 'none'. This parameter does nothing for :class:`Mul` objects. Setting order to 'old' uses the compatibility ordering for ~. Add defined in Printer. For very large expressions, set the order keyword to 'none' if speed is a concern.

**symbol_names**: dictionary of strings mapped to symbols, optional

Dictionary of symbols and the custom strings they should be emitted as.

**root_notation**: boolean, optional

If set to False, exponents of the form 1/n are printed in fractional form. Default is True, to print exponent in root form.

**mat_symbol_style**: string, optional

Can be either 'plain' (default) or 'bold'. If set to 'bold', a :class:`MatrixSymbol` A will be printed as \textbf{A}, otherwise as A.

**imaginary_unit**: string, optional

String to use for the imaginary unit. Defined options are 'i' (default) and 'j'. Adding r or t in front gives \texttt{r} or \texttt{t}, so 'ri' leads to \texttt{r} which gives i.

**gothic_re_im**: boolean, optional

If set to True, \mathbb{R} and \mathbb{I} is used for re and im, respectively. The default is False leading to re and im.

**decimal_separator**: string, optional

Specifies what separator to use to separate the whole and fractional parts of a floating point number as in 2.5 for the default, period or 2,5 when comma is specified. Lists, sets, and tuple are printed with semicolon separating the elements when comma is chosen. For example, [1; 2; 3] when comma is chosen and [1,2,3] for when period is chosen.

**parenthesize_super**: boolean, optional

If set to False, superscripted expressions will not be parenthesized when powered. Default is True, which parenthesizes the expression when powered.

**min**: Integer or None, optional
Sets the lower bound for the exponent to print floating point numbers in fixed-point format.

**max**: Integer or None, optional

Sets the upper bound for the exponent to print floating point numbers in fixed-point format.

**diff_operator**: string, optional

String to use for differential operator. Default is 'd', to print in italic form. 'rd', 'td' are shortcuts for \mathrm{d} and \text{d}.

**Notes**

Not using a print statement for printing, results in double backslashes for latex commands since that's the way Python escapes backslashes in strings.

```python
>>> from sympy import latex, Rational
>>> from sympy.abc import tau
>>> latex((2*tau)**Rational(7,2))
'8 \sqrt{2} \tau^{\frac{7}{2}}'
>>> print(latex((2*tau)**Rational(7,2)))
8 \sqrt{2} \tau^\frac{7}{2}
```

**Examples**

```python
>>> from sympy import latex, pi, sin, asin, Integral, Matrix, Rational, log
>>> from sympy.abc import x, y, mu, r, tau

Basic usage:

```latex
>>> print(latex((2*mu)**Rational(7,2)))
8 \sqrt{2} \mu^\frac{7}{2}
```

```python
>>> print(latex((2*mu)**Rational(7,2), mode='plain'))
8 \sqrt{2} \mu^\frac{7}{2}
```
\begin{equation*}8 \sqrt{2} \mu^\frac{7}{2}\end{equation*}

```python
>>> print(latex((2*mu)**Rational(7,2), mode='equation'))
\begin{equation*}8 \sqrt{2} \mu^\frac{7}{2}\end{equation*}
```

Fraction options:

```python
>>> print(latex((2*tau)**Rational(7,2), fold_frac_powers=True))
8 \sqrt{2} \tau^{\frac{7}{2}}
>>> print(latex((2*tau)**sin(Rational(7,2))), fold_func_brackets=True))
left(2 \tau\right)^{\sin \frac{7}{2}}
```

Multiplication options:

```python
>>> print(latex((2*tau)**sin(Rational(7,2)), mul_symbol="times"))
left(2 \times \tau\right)^{\sin \frac{7}{2}}
```

Trig options:

```python
>>> print(latex(asin(Rational(7,2))))
\operatorname{asin}{\left(\frac{7}{2} \right)}
>>> print(latex(asin(Rational(7,2)), inv_trig_style="full"))
\arcsin{\left(\frac{7}{2} \right)}
```

Matrix options:

```python
>>> print(latex(Matrix(2, 1, [x, y])))
\left(\begin{matrix}x & y\end{matrix}\right)
>>> print(latex(Matrix(2, 1, [x, y]), mat_str = "array"))
\left(\begin{array}{c}x & y\end{array}\right)
>>> print(latex(Matrix(2, 1, [x, y]), mat_delim="")
\left(\begin{matrix}x & y\end{matrix}\right)
```

Custom printing of symbols:

```python
>>> print(latex(x**2, symbol_names={x: 'x_i'}))
x_{i}^{2}
```

Logarithms:

5.8. Topics 2249
latex() also supports the built-in container types list, tuple, and dict:

```python
>>> print(latex([2/x, y], mode='inline'))
$\left[ 2 / x, \ y\right]$  
```

Unsupported types are rendered as monospaced plaintext:

```python
>>> print(latex(int))
\mathtt{\text{<class 'int'>}}
>>> print(latex("plain \% text"))
\mathtt{\text{plain \% text}}
```

See Example of Custom Printing Method (page 2210) for an example of how to override this behavior for your own types by implementing _latex.

Changed in version 1.7.0: Unsupported types no longer have their str representation treated as valid latex.

**sympy.printing.latex.print_latex(expr, **settings)**

Prints LaTeX representation of the given expression. Takes the same settings as latex().

### MathMLPrinter

This class is responsible for MathML printing. See sympy.printing.mathml.

More info on mathml: https://www.w3.org/TR/MathML2

**class sympy.printing.mathml.MathMLPrinterBase(settings=None)**

Contains common code required for MathMLContentPrinter and MathMLPresentationPrinter.

**doprint(expr)**

Prints the expression as MathML.

**class sympy.printing.mathml.MathMLContentPrinter(settings=None)**

Prints an expression to the Content MathML markup language.

References: https://www.w3.org/TR/MathML2/chapter4.html

**printmethod: str = '_mathml_content'**

**mathml_tag(e)**

Returns the MathML tag for an expression.

**class sympy.printing.mathml.MathMLPresentationPrinter(settings=None)**

Prints an expression to the Presentation MathML markup language.

References: https://www.w3.org/TR/MathML2/chapter3.html

**printmethod: str = '_mathml_presentation'**
mathml_tag(e)

Returns the MathML tag for an expression.

```
sympy.printing.mathml.mathml(expr, printer='content', *, order=None, encoding='utf-8',
fold_frac_powers=False, fold_func_brackets=False,
fold_short_frac=None, inv_trig_style='abbreviated',
ln_notation=False, long_frac_ratio=None, mat_delim='[',
mat_symbol_style='plain', mul_symbol=None,
root_notation=True, symbol_names={},
mul_symbol_mathml_numbers='·')
```

Returns the MathML representation of expr. If printer is presentation then prints Presentation MathML else prints content MathML.

```
sympy.printing.mathml.print_mathml(expr, printer='content', **settings)
```

Prints a pretty representation of the MathML code for expr. If printer is presentation then prints Presentation MathML else prints content MathML.

### Examples

```python
>>> from sympy import print_mathml
>>> from sympy.abc import x
>>> print_mathml(x+1)
<apply>
  <plus/>
  <ci>x</ci>
  <cn>1</cn>
</apply>
```

```python
>>> print_mathml(x+1, printer='presentation')
<mrow>
  <mi>x</mi>
  <mo>+</mo>
  <mn>1</mn>
</mrow>
```

## PythonCodePrinter

Python code printers

This module contains Python code printers for plain Python as well as NumPy & SciPy enabled code.

```python
class sympy.printing.pycode.MpmathPrinter(settings=None)
    Lambda printer for mpmath which maintains precision for floats
```

```python
sympy.printing.pycode.pycode(expr, **settings)
    Converts an expr to a string of Python code
```

### Parameters

- **expr**: Expr
  
  A SymPy expression.

- **fullyQualifiedName**: bool
Whether or not to write out full module names of functions (math.sin vs. sin). default: True.

**standard**: str or None, optional

Only ‘python3’ (default) is supported. This parameter may be removed in the future.

### Examples

```python
>>> from sympy import pycode, tan, Symbol
>>> pycode(tan(Symbol('x')) + 1)
'math.tan(x) + 1'
```

#### PythonPrinter

This class implements Python printing. Usage:

```python
>>> from sympy import print_python, sin
>>> from sympy.abc import x

>>> print_python(5*x**3 + sin(x))
x = Symbol('x')
e = 5*x**3 + sin(x)
```

**srepr**

This printer generates executable code. This code satisfies the identity `eval(srepr(expr)) == expr`.

`srepr()` gives more low level textual output than `repr()`

Example:

```python
>>> repr(5*x**3 + sin(x))
'5*x**3 + sin(x)'

>>> srepr(5*x**3 + sin(x))
>Add(Mul(Integer(5), Pow(Symbol('x'), Integer(3))), sin(Symbol('x')))
```

`srepr()` gives the `repr` form, which is what `repr()` would normally give but for SymPy we don’t actually use `srepr()` for `_repr_` because it’s is so verbose, it is unlikely that anyone would want it called by default. Another reason is that lists call `repr` on their elements, like `print([a, b, c])` calls `repr(a), repr(b), repr(c)`. So if we used `srepr` for `_repr_` any list with SymPy objects would include the `srepr` form, even if we used `str()` or `print()`.

```python
class sympy.printing.repr.ReprPrinter(settings=None)

    printmethod: str = '_sympyrepr'

    emptyPrinter(expr)
        The fallback printer.
```
reprify\((\text{args, sep})\)

Prints each item in \text{args} and joins them with \text{sep}.

```python
sympy.printing.repr.srepr(expr, *, order=None, perm_cyclic=True)
```

return expr in repr form

**StrPrinter**

This module generates readable representations of SymPy expressions.

```python
class sympy.printing.str.StrPrinter(settings=None)
```

**printmethod**: str = '_sympystr'

```python
sympy.printing.str.sstr(expr, *, order=None, full_prec='auto', sympy_integers=False, abbrev=False, perm_cyclic=True, min=None, max=None)
```

Returns the expression as a string.

For large expressions where speed is a concern, use the setting \text{order}='none'. If \text{abbrev}=True setting is used then units are printed in abbreviated form.

**Examples**

```python
>>> from sympy import symbols, Eq, sstr
>>> a, b = symbols('a b')
>>> sstr(Eq(a + b, 0))
'Eq(a + b, 0)'
```

```python
sympy.printing.str.sstrrepr(expr, *, order=None, full_prec='auto', sympy_integers=False, abbrev=False, perm_cyclic=True, min=None, max=None)
```

return expr in mixed str/repr form

i.e. strings are returned in repr form with quotes, and everything else is returned in str form.

This function could be useful for hooking into \text{sys.displayhook}

**Tree Printing**

The functions in this module create a representation of an expression as a tree.

```python
sympy.printing.tree.pprint_nodes(subtrees)
```

Prettyprints systems of nodes.
Examples

```python
>>> from sympy.printing.tree import pprint_nodes
>>> print(pprint_nodes(["a", "b1\nb2", "c"]))
+--a
 | +--b1
 |   | b2
 | +--c
```

`sympy.printing.tree.print_node(node, assumptions=True)`
Returns information about the “node”.
This includes class name, string representation and assumptions.

**Parameters**

- `assumptions` : bool, optional
  
  See the assumptions keyword in `tree`

`sympy.printing.tree.tree(node, assumptions=True)`
Returns a tree representation of “node” as a string.
It uses print_node() together with pprint_nodes() on node.args recursively.

**Parameters**

- `assumptions` : bool, optional
  
  The flag to decide whether to print out all the assumption data (such as `is_integer`, `is_real`) associated with the expression or not.

  Enabling the flag makes the result verbose, and the printed result may not be deterministic because of the randomness used in back-tracing the assumptions.

**See also:**

- `print_tree` (page 2254)

`sympy.printing.tree.print_tree(node, assumptions=True)`
Prints a tree representation of “node”.

**Parameters**

- `assumptions` : bool, optional
  
  The flag to decide whether to print out all the assumption data (such as `is_integer`, `is_real`) associated with the expression or not.

  Enabling the flag makes the result verbose, and the printed result may not be deterministic because of the randomness used in back-tracing the assumptions.
Examples

```python
>>> from sympy.printing import print_tree
>>> from sympy import Symbol
>>> x = Symbol('x', odd=True)
>>> y = Symbol('y', even=True)
```

Printing with full assumptions information:

```python
>>> print_tree(y**x)
Pow: y**x
+-Symbol: y
 | algebraic: True
 | commutative: True
 | complex: True
 | even: True
 | extended_real: True
 | finite: True
 | hermitian: True
 | imaginary: False
 | infinite: False
 | integer: True
 | irrational: False
 | noninteger: False
 | odd: False
 | rational: False
 | real: True
 | transcendental: False
+-Symbol: x
 | algebraic: True
 | commutative: True
 | complex: True
 | even: False
 | extended_nonzero: True
 | extended_real: True
 | finite: True
 | hermitian: True
 | imaginary: False
 | infinite: False
 | integer: True
 | irrational: False
 | noninteger: False
 | nonzero: True
 | odd: True
 | rational: True
 | real: True
 | transcendental: False
 | zero: False
```

Hiding the assumptions:

```python
>>> print_tree(y**x, assumptions=False)
Pow: y**x
```

(continues on next page)
A useful function is `preview`:

```python
from sympy import symbols, preview, Symbol

x, y = symbols("x,y")

preview(x + y, output='png')
```

View expression or LaTeX markup in PNG, DVI, PostScript or PDF form.

If the `expr` argument is an expression, it will be exported to LaTeX and then compiled using the available TeX distribution. The first argument, `expr`, may also be a LaTeX string. The function will then run the appropriate viewer for the given output format or use the user defined one. By default png output is generated.

By default pretty Euler fonts are used for typesetting (they were used to typeset the well known "Concrete Mathematics" book). For that to work, you need the `eulervm.sty` LaTeX style (in Debian/Ubuntu, install the texlive-fonts-extra package). If you prefer default AMS fonts or your system lacks `eulervm` LaTeX package then unset the `euler` keyword argument.

To use viewer auto-detection, lets say for ‘png’ output, issue

```python
from sympy import symbols, preview, Symbol

x, y = symbols("x,y")

preview(x + y, output='png')
```

This will choose ‘pyglet’ by default. To select a different one, do

```python
from sympy import symbols, preview, Symbol

x, y = symbols("x,y")

preview(x + y, output='png', viewer='gimp')
```

The ‘png’ format is considered special. For all other formats the rules are slightly different. As an example we will take ‘dvi’ output format. If you would run

```python
from sympy import symbols, preview, Symbol

x, y = symbols("x,y")

preview(x + y, output='dvi')
```

then ‘view’ will look for available ‘dvi’ viewers on your system (predefined in the function, so it will try evince, first, then kdvi and xdvi). If nothing is found, it will fall back to using a system file association (via open and xdg-open). To always use your system file association without searching for the above readers, use

```python
from sympy import symbols, preview, Symbol

x, y = symbols("x,y")

from sympy.printing.preview import system_default_viewer

preview(x + y, output='dvi', viewer=system_default_viewer)
```

If this still does not find the viewer you want, it can be set explicitly.
This will skip auto-detection and will run user specified ‘superior-dvi-viewer’. If view fails to find it on your system it will gracefully raise an exception.

You may also enter 'file' for the viewer argument. Doing so will cause this function to return a file object in read-only mode, if filename is unset. However, if it was set, then ‘preview’ writes the generated file to this filename instead.

There is also support for writing to a io.BytesIO like object, which needs to be passed to the outputbuffer argument.

The LaTeX preamble can be customized by setting the ‘preamble’ keyword argument. This can be used, e.g., to set a different font size, use a custom documentclass or import certain set of LaTeX packages.

It is also possible to use the standard preamble and provide additional information to the preamble using the extra_preamble keyword argument.

If the value of ‘output’ is different from ‘dvi’ then command line options can be set (‘dvioptions’ argument) for the execution of the ‘dvi’+output conversion tool. These options have to be in the form of a list of strings (see subprocess.Popen).

Additional keyword args will be passed to the latex() (page 2245) call, e.g., the symbol_names flag.

For post-processing the generated TeX File can be written to a file by passing the desired filename to the ‘outputTexFile’ keyword argument. To write the TeX code to a file named “sample.tex” and run the default png viewer to display the resulting bitmap, do
Implementation - Helper Classes/Functions

`sympy.printing.conventions.split_super_sub(text)`

Split a symbol name into a name, superscripts and subscripts.

The first part of the symbol name is considered to be its actual 'name', followed by super- and subscripts. Each superscript is preceded with a “^” character or by “__”. Each subscript is preceded by a “_” character. The three return values are the actual name, a list with superscripts and a list with subscripts.

**Examples**

```python
>>> from sympy.printing.conventions import split_super_sub
>>> split_super_sub('a_x^1')
('a', ['1'], ['x'])
>>> split_super_sub('var_sub1__sup_sub2')
('var', ['sup'], ['sub1', 'sub2'])
```

**CodePrinter**

This class is a base class for other classes that implement code-printing functionality, and additionally lists a number of functions that cannot be easily translated to C or Fortran.

```python
class sympy.printing.codeprinter.CodePrinter(settings=None)
```

The base class for code-printing subclasses.

```python
printmethod: str = '_sympystr'
```

```python
doprint(expr, assign_to=None)
```

Print the expression as code.

**Parameters**

- `expr`: Expression
  - The expression to be printed.

- `assign_to`: Symbol, string, MatrixSymbol, list of strings or Symbols (optional)
  - If provided, the printed code will set the expression to a variable or multiple variables with the name or names given in assign_to.

**exception sympy.printing.codeprinter.AssignmentError**

Raised if an assignment variable for a loop is missing.
Precedence

```python
sympy.printing.precedence.PRECEDENCE = {'Add': 40, 'And': 30, 'Atom': 1000,
'BitwiseAnd': 38, 'BitwiseOr': 36, 'BitwiseXor': 37, 'Func': 70, 'Lambda': 1,
'Mul': 50, 'Not': 100, 'Or': 20, 'Pow': 60, 'Relational': 35, 'Xor': 10}
```

Default precedence values for some basic types.

```python
sympy.printing.precedence.PRECEDENCE_VALUES = {'Add': 40, 'And': 30,
'Equality': 50, 'Equivalent': 10, 'Function': 70, 'HadamardPower': 60,
'HadamardProduct': 50, 'Imply': 10, 'KroneckerProduct': 50, 'MatAdd': 40,
'MatPow': 60, 'MatrixMultiply': 50, 'Mod': 50, 'NegativeInfinity': 40, 'Not':
100, 'Or': 20, 'Pow': 60, 'Relational': 35, 'Sub': 40, 'TensAdd': 40,
'TensMul': 50, 'Unequality': 50, 'Xor': 10}
```

A dictionary assigning precedence values to certain classes. These values are treated
like they were inherited, so not every single class has to be named here.

```python
sympy.printing.precedence.PRECEDENCE_FUNCTIONS = {'Float': <function
precedence_Float>, 'FracElement': <function precedence_FracElement>,
'Integer': <function precedence_Integer>, 'Mul': <function precedence_Mul>,
'PolyElement': <function precedence_PolyElement>, 'Rational': <function
precedence_Rational>, 'UnevaluatedExpr': <function
precedence_UnevaluatedExpr>}
```

Sometimes it's not enough to assign a fixed precedence value to a class. Then a function
can be inserted in this dictionary that takes an instance of this class as argument and
returns the appropriate precedence value.

```python
sympy.printing.precedence.precedence(item)
```

Returns the precedence of a given object.

This is the precedence for StrPrinter.

Pretty-Printing Implementation Helpers

```python
sympy.printing.pretty.pretty_symbology.U(name)
```

Get a unicode character by name or, None if not found.

This exists because older versions of Python use older unicode databases.

```python
sympy.printing.pretty.pretty_symbology.pretty_use_unicode(flag=False)
```

Set whether pretty-printer should use unicode by default

```python
sympy.printing.pretty.pretty_symbology.pretty_try_use_unicode()
```

See if unicode output is available and leverage it if possible

```python
sympy.printing.pretty.pretty_symbology.xstr(*args)
```

The following two functions return the Unicode version of the inputted Greek letter:

```python
sympy.printing.pretty.pretty_symbology.g(l)
```

```python
sympy.printing.pretty.pretty_symbology.G(l)
```

```python
sympy.printing.pretty.pretty_symbology.greek_letters = ['alpha', 'beta',
'gamma', 'delta', 'epsilon', 'zeta', 'eta', 'theta', 'iota', 'kappa', 'lamda',
'mu', 'nu', 'xi', 'omicron', 'pi', 'rho', 'sigma', 'tau', 'upsilon', 'phi',
'chi', 'psi', 'omega']
```
Built-in mutable sequence.

If no argument is given, the constructor creates a new empty list. The argument must be an iterable if specified.

```python
sympy.printing.pretty.pretty_symbology.digit_2txt = {'0': 'ZERO', '1': 'ONE', '2': 'TWO', '3': 'THREE', '4': 'FOUR', '5': 'FIVE', '6': 'SIX', '7': 'SEVEN', '8': 'EIGHT', '9': 'NINE'}
```

```python
sympy.printing.pretty.pretty_symbology.symb_2txt = {')': 'RIGHT PARENTHESIS', '+': 'PLUS SIGN', '-': 'MINUS', '=': 'EQUALS SIGN', '[': 'LEFT SQUARE BRACKET', ']': 'RIGHT SQUARE BRACKET', 'int': 'INTEGRAL', 'sum': 'SUMMATION', '{': 'LEFT CURLY BRACKET', '}': 'RIGHT CURLY BRACKET'}
```

The following functions return the Unicode subscript/superscript version of the character.

```python
sympy.printing.pretty.pretty_symbology.sub = {')': '₍', '+': '₊', '-': '₋', '0': '₀', '1': '₁', '2': '₂', '3': '₃', '4': '₄', '5': '₅', '6': '₆', '7': '₇', '8': '₈', '9': '₉', '=': '₌', 'a': 'ₐ', 'beta': '', 'chi': '', 'e': 'ₑ', 'gamma': '', 'h': 'ₕ', 'i': 'ᵢ', 'k': 'ₖ', 'l': 'ₗ', 'm': 'ₒ', 'n': 'ₙ', 'o': 'ₒ', 'p': 'ₚ', 'phi': '', 'r': 'ᵣ', 'rho': '', 's': 'ₛ', 't': 'ₜ', 'u': 'ᵤ', 'v': 'ᵥ', 'x': 'ₓ'}
```

```python
sympy.printing.pretty.pretty_symbology.sup = {')': '₎', '+': '⁺', '-': '⁻', '0': '₀', '1': '₁', '2': '₂', '3': '₃', '4': '₄', '5': '₅', '6': '₆', '7': '₇', '8': '₈', '9': '₉', '=': '⁼', 'i': 'ⁱ', 'n': 'ⁿ'}
```

The following functions return Unicode vertical objects.

```python
sympy.printing.pretty.pretty_symbology.xobj(symb, length)

Construct spatial object of given length.

return: [] of equal-length strings
```

```python
sympy.printing.pretty.pretty_symbology.vobj(symb, height)

Construct vertical object of a given height

see: xobj
```

```python
sympy.printing.pretty.pretty_symbology.hobj(symb, width)

Construct horizontal object of a given width

see: xobj
```

The following constants are for rendering roots and fractions.

```python
```

```python
sympy.printing.pretty.pretty_symbology.VF(txt)
```

```python
```

The following constants/functions are for rendering atoms and symbols.
SymPy printing pretty_symbology

```python
symy.printing.pretty.pretty_symbology.xsym(sym)
get symbology for a 'character'
symy.printing.pretty.pretty_symbology.atoms_table = {'Complexes': 'ℂ', 'EmptySequence': 'EmptySequence', 'EmptySet': '∅', 'Exp1': 'e', 'ImaginaryUnit': 'i', 'Infinity': '∞', 'Integers': 'ℤ', 'Intersection': '∩', 'Modifier Letter Low Ring': '˳', 'Naturals': 'ℕ', 'Naturals0': 'ℕ₀', 'NegativeInfinity': '-∞', 'Pi': 'π', 'Rationals': 'ℚ', 'Reals': 'ℝ', 'Ring': '∘', 'SymmetricDifference': 'Δ', 'Union': '∪'}
symy.printing.pretty.pretty_symbology.pretty_atom(atom_name, default=None, printer=None)
return pretty representation of an atom
symy.printing.pretty.pretty_symbology.pretty_symbol(symb_name, bold_name=False)
return pretty representation of a symbol
symy.printing.pretty.pretty_symbology.annotated(letter)
Return a stylised drawing of the letter letter, together with information on how to put annotations (super- and subscripts to the left and to the right) on it.
See pretty.py functions _print_meijerg, _print_hyper on how to use this information.
Prettyprinter by Jurjen Bos. (I hate spammers: mail me at pietjepuk314 at the reverse of ku.oc.oohay). All objects have a method that create a "stringPict", that can be used in the str method for pretty printing.

Updates by Jason Gedge (email <my last name> at cs mun ca)
• terminal_string() method
• minor fixes and changes (mostly to prettyForm)

TODO:
• Allow left/center/right alignment options for above/below and top/center/bottom alignment options for left/right

class symy.printing.pretty.stringpict.stringPict(s, baseline=0)
An ASCII picture. The pictures are represented as a list of equal length strings.
above(*args)
Put pictures above this picture. Returns string, baseline arguments for stringPict. Baseline is baseline of bottom picture.
below(*args)
Put pictures under this picture. Returns string, baseline arguments for stringPict. Baseline is baseline of top picture
```
Examples

```python
>>> from sympy.printing.pretty.stringpict import stringPict
>>> print(stringPict("x+3").below(
...
    stringPict.LINE, '3')[0])
x+3
---
3
```

height()

The height of the picture in characters.

left(*args)

Put pictures (left to right) at left. Returns string, baseline arguments for stringPict.

leftslash()

Precede object by a slash of the proper size.

static next(*args)

Put a string of stringPicts next to each other. Returns string, baseline arguments for stringPict.

parens(left='(', right=')', ifascii_nougly=False)

Put parentheses around self. Returns string, baseline arguments for stringPict.

left or right can be None or empty string which means ‘no paren from that side’

render(*args, **kwargs)

Return the string form of self.

Unless the argument line_break is set to False, it will break the expression in a form that can be printed on the terminal without being broken up.

right(*args)

Put pictures next to this one. Returns string, baseline arguments for stringPict. (Multiline) strings are allowed, and are given a baseline of 0.

Examples

```python
>>> from sympy.printing.pretty.stringpict import stringPict
>>> print(stringPict("10").right(" + ",stringPict("1\r-\r2",1))[0])
10 + -
2
```

root(n=None)

Produce a nice root symbol. Produces ugly results for big n inserts.

static stack(*args)

Put pictures on top of each other, from top to bottom. Returns string, baseline arguments for stringPict. The baseline is the baseline of the second picture. Everything is centered. Baseline is the baseline of the second picture. Strings are allowed. The special value stringPict.LINE is a row of ‘-’ extended to the width.
terminal_width()
Return the terminal width if possible, otherwise return 0.

width()
The width of the picture in characters.

class sympy.printing.pretty.stringpict.prettyForm(s, baseline=0, binding=0, unicode=None)
Extension of the stringPict class that knows about basic math applications, optimizing double minus signs.

“Binding” is interpreted as follows:

<table>
<thead>
<tr>
<th>Binding</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ATOM</td>
<td>this is an atom: never needs to be parenthesized</td>
</tr>
<tr>
<td>FUNC</td>
<td>this is a function application: parenthesize if added (?)</td>
</tr>
<tr>
<td>DIV</td>
<td>this is a division: make wider division if divided</td>
</tr>
<tr>
<td>POW</td>
<td>this is a power: only parenthesize if exponent</td>
</tr>
<tr>
<td>MUL</td>
<td>this is a multiplication: parenthesize if powered</td>
</tr>
<tr>
<td>ADD</td>
<td>this is an addition: parenthesize if multiplied or powered</td>
</tr>
<tr>
<td>NEG</td>
<td>this is a negative number: optimize if added, parenthesize if multiplied or powered</td>
</tr>
<tr>
<td>OPEN</td>
<td>this is an open object: parenthesize if added, multiplied, or powered (example: Piecewise)</td>
</tr>
</tbody>
</table>

static apply(function, *args)
Functions of one or more variables.

dotprint

sympy.printing.dot.dotprint(expr, styles=((<class 'sympy.core.basic.Basic'>, {'color': 'blue', 'shape': 'ellipse'}), (<class 'sympy.core.expr.Expr'>, {'color': 'black'})), atom=<function <lambda>>, maxdepth=None, repeat=True, labelfunc=<class 'str'>, **kwargs)

DOT description of a SymPy expression tree

Parameters
styles : list of lists composed of (Class, mapping), optional
Styles for different classes.
The default is

{(Basic, {'color': 'blue', 'shape': 'ellipse'}), (Expr, {'color': 'black'})}

atom : function, optional
Function used to determine if an arg is an atom.
A good choice is lambda x: not x.args.
The default is lambda x: not isinstance(x, Basic).

maxdepth : integer, optional
The maximum depth.
The default is None, meaning no limit.

**repeat** : boolean, optional
Whether to use different nodes for common subexpressions.
The default is True.
For example, for $x + x*y$ with repeat=True, it will have two nodes
for $x$; with repeat=False, it will have one node.

**Warning:** Even if a node appears twice in the same object
like $x$ in $\text{Pow}(x, x)$, it will still only appear once. Hence, with
repeat=False, the number of arrows out of an object might not
equal the number of args it has.

**labelfunc** : function, optional
A function to create a label for a given leaf node.
The default is str.
Another good option is srepr.
For example with str, the leaf nodes of $x + 1$ are labeled, x and 1.
With srepr, they are labeled Symbol('x') and Integer(1).

**kwargs** : optional
Additional keyword arguments are included as styles for the graph.

**Examples**

```python
>>> from sympy import dotprint
>>> from sympy.abc import x
>>> print(dotprint(x+2))
digraph{
  # Graph style
  "ordering"="out"
  "rankdir"="TD"
  
  # Nodes #
  
  "Add(Integer(2), Symbol('x'))()" ["color"="black", "label"="Add", "shape"="ellipse"];
  "Integer(2)_(0,)" ["color"="black", "label"="2", "shape"="ellipse"];
  "Symbol('x')_(1,)" ["color"="black", "label"="x", "shape"="ellipse"];

  # Edges #
  
  (continues on next page)
```

Geometry

Introduction

The geometry module for SymPy allows one to create two-dimensional geometrical entities, such as lines and circles, and query for information about these entities. This could include asking the area of an ellipse, checking for collinearity of a set of points, or finding the intersection between two lines. The primary use case of the module involves entities with numerical values, but it is possible to also use symbolic representations.

Available Entities

The following entities are currently available in the geometry module:

- Point (page 2277)
- Line (page 2303), Segment (page 2308), Ray (page 2305)
- Ellipse (page 2328), Circle (page 2344)
- Polygon (page 2348), RegularPolygon (page 2359), Triangle (page 2368)

Most of the work one will do will be through the properties and methods of these entities, but several global methods exist:

- intersection(entity1, entity2)
- are_similar(entity1, entity2)
- convex_hull(points)

For a full API listing and an explanation of the methods and their return values please see the list of classes at the end of this document.
Example Usage

The following Python session gives one an idea of how to work with some of the geometry module.

```python
>>> from sympy import *
>>> from sympy.geometry import *
>>> x = Point(0, 0)
>>> y = Point(1, 1)
>>> z = Point(2, 2)
>>>zp = Point(1, 0)
>>> Point.is_collinear(x, y, z)
True
>>> Point.is_collinear(x, y, zp)
False
>>> t = Triangle(zp, y, x)
>>> t.area
1/2
>>> t.medians[x]
Segment2D(Point2D(0, 0), Point2D(1, 1/2))
>>> m = t.medians
>>> intersection(m[x], m[y], m[zp])
[Point2D(2/3, 1/3)]
>>> c = Circle(x, 5)
>>> l = Line(Point(5, -5), Point(5, 5))
>>> c.is_tangent(l) # is l tangent to c?
True
>>> l = Line(x, y)
>>> c.is_tangent(l) # is l tangent to c?
False
>>> intersection(c, l)
[Point2D(-5*sqrt(2)/2, -5*sqrt(2)/2), Point2D(5*sqrt(2)/2, 5*sqrt(2)/2)]
```

Intersection of medians

```python
>>> from sympy import symbols
>>> from sympy.geometry import Point, Triangle, intersection

>>> a, b = symbols("a,b", positive=True)

>>> x = Point(0, 0)
>>> y = Point(a, 0)
>>> z = Point(2*a, b)
>>> t = Triangle(x, y, z)

>>> t.area
a*b/2
>>> t.medians[x]
Segment2D(Point2D(0, 0), Point2D(3*a/2, b/2))
```
An in-depth example: Pappus’ Hexagon Theorem

From Wikipedia ([WikiPappus]):

Given one set of collinear points \(A, B, C\), and another set of collinear points \(a, b, c\), then the intersection points \(X, Y, Z\) of line pairs \(Ab\) and \(aB\), \(Ac\) and \(aC\), \(Bc\) and \(bC\) are collinear.

```python
>>> from sympy import *
>>> from sympy.geometry import *

>>> l1 = Line(Point(0, 0), Point(5, 6))
>>> l2 = Line(Point(0, 0), Point(2, -2))

>>> def subs_point(l, val):
...     """Take an arbitrary point and make it a fixed point.""
...     t = Symbol('t', real=True)
...     ap = l.arbitrary_point()
...     return Point(ap.x.subs(t, val), ap.y.subs(t, val))

>>> p11 = subs_point(l1, 5)
>>> p12 = subs_point(l1, 6)
>>> p13 = subs_point(l1, 11)

>>> p21 = subs_point(l2, -1)
>>> p22 = subs_point(l2, 2)
>>> p23 = subs_point(l2, 13)

>>> ll1 = Line(p11, p22)
>>> ll2 = Line(p11, p23)
>>> ll3 = Line(p12, p21)
>>> ll4 = Line(p12, p23)
>>> ll5 = Line(p13, p21)
>>> ll6 = Line(p13, p22)

>>> pp1 = intersection(ll1, ll3)[0]
>>> pp2 = intersection(ll2, ll5)[0]
>>> pp3 = intersection(ll4, ll6)[0]

>>> Point.is_collinear(pp1, pp2, pp3)
True
```
References

Miscellaneous Notes

• The area property of Polygon and Triangle may return a positive or negative value, depending on whether or not the points are oriented counter-clockwise or clockwise, respectively. If you always want a positive value be sure to use the abs function.

• Although Polygon can refer to any type of polygon, the code has been written for simple polygons. Hence, expect potential problems if dealing with complex polygons (overlapping sides).

• Since SymPy is still in its infancy some things may not simplify properly and hence some things that should return True (e.g., Point.is_collinear) may not actually do so. Similarly, attempting to find the intersection of entities that do intersect may result in an empty result.

Future Work

Truth Setting Expressions

When one deals with symbolic entities, it often happens that an assertion cannot be guaranteed. For example, consider the following code:

```python
>>> from sympy import *
>>> from sympy.geometry import *
>>> x, y, z = map(Symbol, 'xyz')
>>> p1, p2, p3 = Point(x, y), Point(y, z), Point(2*x*y, y)
>>> Point.is_collinear(p1, p2, p3)
False
```

Even though the result is currently False, this is not always true. If the quantity $z - y - 2 * y * z + 2 * y ^ 2 == 0$ then the points will be collinear. It would be really nice to inform the user of this because such a quantity may be useful to a user for further calculation and, at the very least, being nice to know. This could be potentially done by returning an object (e.g., GeometryResult) that the user could use. This actually would not involve an extensive amount of work.

Three Dimensions and Beyond

Currently a limited subset of the geometry module has been extended to three dimensions, but it certainly would be a good addition to extend more. This would probably involve a fair amount of work since many of the algorithms used are specific to two dimensions.
Geometry Visualization

The plotting module is capable of plotting geometric entities. See *Plotting Geometric Entities* (page 2956) in the plotting module entry.

Submodules

Entities

class sympy.geometry.entity.GeometryEntity(*args, **kwargs)

The base class for all geometrical entities.

This class does not represent any particular geometric entity, it only provides the implementation of some methods common to all subclasses.

property ambient_dimension

What is the dimension of the space that the object is contained in?

property bounds

Return a tuple (xmin, ymin, xmax, ymax) representing the bounding rectangle for the geometric figure.

encloses(o)

Return True if o is inside (not on or outside) the boundaries of self.

The object will be decomposed into Points and individual Entities need only define an encloses_point method for their class.

Examples

```python
>>> from sympy import RegularPolygon, Point, Polygon
>>> t = Polygon(*RegularPolygon(Point(0, 0), 1, 3).vertices)
>>> t2 = Polygon(*RegularPolygon(Point(0, 0), 2, 3).vertices)
>>> t2.encloses(t)
True
>>> t.encloses(t2)
False
```

See also:

* sympy.geometry.ellipse.Ellipse.encloses_point  (page 2332),  sympy.geometry.polygon.Polygon.encloses_point  (page 2353)

intersection(o)

Returns a list of all of the intersections of self with o.
Notes

An entity is not required to implement this method.

If two different types of entities can intersect, the item with higher index in ordering of classes should implement intersections with anything having a lower index.

See also:

sympy.geometry.util.intersection (page 2272)

is_similar(other)

Is this geometrical entity similar to another geometrical entity?
Two entities are similar if a uniform scaling (enlarging or shrinking) of one of the entities will allow one to obtain the other.

Notes

This method is not intended to be used directly but rather through the are_similar function found in util.py. An entity is not required to implement this method. If two different types of entities can be similar, it is only required that one of them be able to determine this.

See also:

scale (page 2271)

parameter_value(other, t)

Return the parameter corresponding to the given point. Evaluating an arbitrary point of the entity at this parameter value will return the given point.

Examples

```python
>>> from sympy import Line, Point
>>> from sympy import t
>>> a = Point(0, 0)
>>> b = Point(2, 2)
>>> Line(a, b).parameter_value((1, 1), t)
{t: 1/2}
>>> Line(a, b).arbitrary_point(t).subs(_)
Point2D(1, 1)
```

reflect(line)

Reflects an object across a line.

Parameters

- **line**: Line
Examples

```python
>>> from sympy import pi, sqrt, Line, RegularPolygon
>>> l = Line((0, pi), slope=sqrt(2))
>>> pent = RegularPolygon((1, 2), 1, 5)
>>> rpent = pent.reflect(l)
>>> rpent
RegularPolygon(Point2D(-2*sqrt(2)*pi/3 - 1/3 + 4*sqrt(2)/3, 2/3 + 2*sqrt(2)/3 + 2*pi/3), -1, 5, -atan(2*sqrt(2)) + 3*pi/5)
```

```python
>>> from sympy import pi, Line, Circle, Point
>>> l = Line((0, pi), slope=1)
>>> circ = Circle(Point(0, 0), 5)
>>> rcirc = circ.reflect(l)
>>> rcirc
Circle(Point2D(-pi, pi), -5)
```

**rotate**(angle, pt=None)

Rotate angle radians counterclockwise about Point pt.

The default pt is the origin, Point(0, 0)

Examples

```python
>>> from sympy import Point, RegularPolygon, Polygon, pi
>>> t = Polygon(*RegularPolygon(Point(0, 0), 1, 3).vertices)
>>> t  # vertex on x axis
Triangle(Point2D(1, 0), Point2D(-1/2, sqrt(3)/2), Point2D(-1/2, -sqrt(3)/2))
>>> t.rotate(pi/2)  # vertex on y axis now
Triangle(Point2D(0, 1), Point2D(-sqrt(3)/2, -1/2), Point2D(sqrt(3)/2, -1/2))
```

See also: 

* **scale** (page 2271), **translate** (page 2272)

**scale**(x=1, y=1, pt=None)

Scale the object by multiplying the x,y-coordinates by x and y.

If pt is given, the scaling is done relative to that point; the object is shifted by -pt, scaled, and shifted by pt.
Examples

```python
>>> from sympy import RegularPolygon, Point, Polygon
>>> t = Polygon(*RegularPolygon(Point(0, 0), 1, 3).vertices)
>>> t
Triangle(Point2D(1, 0), Point2D(-1/2, sqrt(3)/2), Point2D(-1/2, -sqrt(3)/2))
>>> t.scale(2)
Triangle(Point2D(2, 0), Point2D(-1, sqrt(3)/2), Point2D(-1, -sqrt(3)/2))
>>> t.scale(2, 2)
Triangle(Point2D(2, 0), Point2D(-1, sqrt(3)), Point2D(-1, -sqrt(3)))
```

See also:

`rotate` (page 2271), `translate` (page 2272)

**translate** (x=0, y=0)

Shift the object by adding to the x,y-coordinates the values x and y.

```
translate(x=0, y=0)
```

Examples

```python
>>> from sympy import RegularPolygon, Point, Polygon
>>> t = Polygon(*RegularPolygon(Point(0, 0), 1, 3).vertices)
>>> t
Triangle(Point2D(1, 0), Point2D(-1/2, sqrt(3)/2), Point2D(-1/2, -sqrt(3)/2))
>>> t.translate(2)
Triangle(Point2D(3, 0), Point2D(3/2, sqrt(3)/2), Point2D(3/2, -sqrt(3)/2))
>>> t.translate(2, 2)
Triangle(Point2D(3, 2), Point2D(3/2, sqrt(3)/2 + 2), Point2D(3/2, 2 - sqrt(3)/2))
```

See also:

`rotate` (page 2271), `scale` (page 2271)

**utility**

```python
sympy.geometry.util.intersection(*entities, pairwise=False, **kwargs)
```

The intersection of a collection of GeometryEntity instances.

**Parameters**

- `entities` : sequence of GeometryEntity
- `pairwise` (keyword argument) : Can be either True or False

**Returns**

- `intersection` : list of GeometryEntity

**Raises**

- `NotImplementedError`

When unable to calculate intersection.
Notes

The intersection of any geometrical entity with itself should return a list with one item: the entity in question. An intersection requires two or more entities. If only a single entity is given then the function will return an empty list. It is possible for intersection to miss intersections that one knows exists because the required quantities were not fully simplified internally. Reals should be converted to Rationals, e.g. Rational(str(real_num)) or else failures due to floating point issues may result.

Case 1: When the keyword argument ‘pairwise’ is False (default value): In this case, the function returns a list of intersections common to all entities.

Case 2: When the keyword argument ‘pairwise’ is True: In this case, the functions returns a list intersections that occur between any pair of entities.

Examples

```python
from sympy import Ray, Circle, intersection

c = Circle((0, 1), 1)
intersection(c, c.center)
[]
right = Ray((0, 0), (1, 0))
up = Ray((0, 0), (0, 1))
intersection(c, right, up)
[Point2D(0, 0)]
intersection(c, right, up, pairwise=True)
[Point2D(0, 0), Point2D(0, 2)]
left = Ray((1, 0), (0, 0))
intersection(right, left)
[Segment2D(Point2D(0, 0), Point2D(1, 0))]
```

See also:

- `sympy.geometry.entity.GeometryEntity.intersection` (page 2269)
- `sympy.geometry.util.convex_hull(*args, polygon=True)`

The convex hull surrounding the Points contained in the list of entities.

Parameters

- **args**: a collection of Points, Segments and/or Polygons

Returns

- **convex_hull**: Polygon if polygon is True else as a tuple $(U, L)$ where $L$ and $U$ are the lower and upper hulls, respectively.
Optional Parameters

**polygon**

[Boolean. If True, returns a Polygon, if false a tuple, see below.] Default is True.

Notes

This can only be performed on a set of points whose coordinates can be ordered on the number line.

Examples

```python
>>> from sympy import convex_hull
>>> points = [(1, 1), (1, 2), (3, 1), (-5, 2), (15, 4)]
>>> convex_hull(*points)
Polygon(Point2D(-5, 2), Point2D(1, 1), Point2D(3, 1), Point2D(15, 4))
>>> convex_hull(*points, **dict(polygon=False))
([Point2D(-5, 2), Point2D(15, 4)],
 [Point2D(-5, 2), Point2D(1, 1), Point2D(3, 1), Point2D(15, 4)])
```

See also:

* sympy.geometry.point.Point (page 2277), sympy.geometry.polygon.Polygon (page 2348)

References

[R535], [R536]

sympy.geometry.util.are_similar(e1, e2)

Are two geometrical entities similar.

Can one geometrical entity be uniformly scaled to the other?

Parameters

- **e1**: GeometryEntity
- **e2**: GeometryEntity

Returns

- **are_similar**: boolean

Raises

- **GeometryError**

    When $e_1$ and $e_2$ cannot be compared.
Notes

If the two objects are equal then they are similar.

Examples

```python
from sympy import Point, Circle, Triangle, are_similar

c1, c2 = Circle(Point(0, 0), 4), Circle(Point(1, 4), 3)
t1 = Triangle(Point(0, 0), Point(1, 0), Point(0, 1))
t2 = Triangle(Point(0, 0), Point(2, 0), Point(0, 2))
t3 = Triangle(Point(0, 0), Point(3, 0), Point(0, 1))
are_similar(t1, t2)
True
are_similar(t1, t3)
False
```

See also:

`sympy.geometry.entity.GeometryEntity.is_similar` (page 2270)

`sympy.geometry.util.centroid(*args)`

Find the centroid (center of mass) of the collection containing only Points, Segments or Polygons. The centroid is the weighted average of the individual centroid where the weights are the lengths (of segments) or areas (of polygons). Overlapping regions will add to the weight of that region.

If there are no objects (or a mixture of objects) then None is returned.

Examples

```python
from sympy import Point, Segment, Polygon

from sympy.geometry.util import centroid

p = Polygon((0, 0), (10, 0), (10, 10))
q = p.translate(0, 20)
 centroid(p, q)
Point2D(1, 2 - sqrt(2))

p, q = Segment((0, 0), (2, 0)), Segment((0, 0), (2, 2))
 centroid(p, q)
Point2D(1/2)

Stacking 3 polygons on top of each other effectively triples the weight of that polygon:

```python
p = Polygon((0, 0), (1, 0), (1, 1), (0, 1))
q = Polygon((1, 0), (3, 0), (3, 1), (1, 1))
 centroid(p, q)
Point2D(3/2, 1/2)
 centroid(p, p, p, q) # centroid x-coord shifts left
Point2D(11/10, 1/2)
```
Stacking the squares vertically above and below p has the same effect:

```
>>> centroid(p, p.translate(0, 1), p.translate(0, -1), q)
Point2D(11/10, 1/2)
```

**See also:**

- `sympy.geometry.point.Point` (page 2277)
- `sympy.geometry.line.Segment` (page 2308)
- `sympy.geometry.polygon.Polygon` (page 2348)

`sympy.geometry.util.idiff(eq, y, x, n=1)`

Return dy/dx assuming that eq == 0.

**Parameters**

- `y`: the dependent variable or a list of dependent variables (with y first)
- `x`: the variable that the derivative is being taken with respect to
- `n`: the order of the derivative (default is 1)

**Examples**

```
>>> from sympy import x, y, a
>>> from sympy.geometry.util import idiff

>>> circ = x**2 + y**2 - 4
>>> idiff(circ, y, x)
-x/y
>>> idiff(circ, y, x, 2).simplify()
(-x**2 - y**2)/y**3
```

Here, a is assumed to be independent of x:

```
>>> idiff(x + a + y, y, x)
-1
```

Now the x-dependence of a is made explicit by listing a after y in a list.

```
>>> idiff(x + a + y, [y, a], x)
-Derivative(a, x) - 1
```

**See also:**

- `sympy.core.function.Derivative` (page 1088)
  represents unevaluated derivatives
- `sympy.core.function.diff` (page 1094)
  explicitly differentiates wrt symbols
Points

class sympy.geometry.point.Point(*args, **kwargs)
A point in a n-dimensional Euclidean space.

**Parameters**
- **coords**: sequence of n-coordinate values. In the special
case where n=2 or 3, a Point2D or Point3D will be created as appro-
priate.
- **evaluate**: if True (default), all floats are turn into
effect types.
- **dim**: number of coordinates the point should have. If coordinates
are unspecified, they are padded with zeros.
- **on_morph**: indicates what should happen when the number of
coordinates of a point need to be changed by adding or removing ze-
ros. Possible values are 'warn', 'error', or 'ignore' (default). No warning
or error is given when *args is empty and dim is given. An error is
always raised when trying to remove nonzero coordinates.

**Raises**
- **TypeError**: When instantiating with anything but a Point or sequence

**Examples**

```python
>>> from sympy import Point
>>> from sympy.abc import x
>>> Point(1, 2, 3)
Point3D(1, 2, 3)
>>> Point([1, 2])
Point2D(1, 2)
>>> Point(0, x)
Point2D(0, x)
>>> Point(dim=4)
Point(0, 0, 0, 0)
```

Floats are automatically converted to Rational unless the evaluate flag is False:

```python
>>> Point(0.5, 0.25)
Point2D(1/2, 1/4)
>>> Point(0.5, 0.25, evaluate=False)
Point2D(0.5, 0.25)
```

**See also:**

*sympy.geometry.line.Segment (page 2308)*
Connects two Points
Attributes

| length | origin: A *Point* representing the origin of the appropriately-dimensioned space. |

**static affine_rank(*args)**

The affine rank of a set of points is the dimension of the smallest affine space containing all the points. For example, if the points lie on a line (and are not all the same) their affine rank is 1. If the points lie on a plane but not a line, their affine rank is 2. By convention, the empty set has affine rank -1.

**property ambient_dimension**

Number of components this point has.

**classmethod are_coplanar(*points)**

Return True if there exists a plane in which all the points lie. A trivial True value is returned if len(points) < 3 or all Points are 2-dimensional.

**Parameters**

A set of points

**Returns**

boolean

**Raises**

* ValueError : if less than 3 unique points are given

**Examples**

```python
>>> from sympy import Point3D
>>> p1 = Point3D(1, 2, 2)
>>> p2 = Point3D(2, 7, 2)
>>> p3 = Point3D(0, 0, 2)
>>> p4 = Point3D(1, 1, 2)
>>> Point3D.are_coplanar(p1, p2, p3, p4)
True
>>> p5 = Point3D(0, 1, 3)
>>> Point3D.are_coplanar(p1, p2, p3, p5)
False
```

**canberra_distance(p)**

The Canberra Distance from self to point p.

Returns the weighted sum of horizontal and vertical distances to point p.

**Parameters**

p : Point

**Returns**

canberra_distance : The weighted sum of horizontal and vertical distances to point p. The weight used is the sum of absolute values of the coordinates.
Defines a point in the (affine) plane.

**Attributes**

- `x`:
  - The horizontal coordinate of the point.
- `y`:
  - The vertical coordinate of the point.

**Methods**

- `canberra_distance(other)`:
  - Return the Canberra distance between vectors
    - Raises `ValueError` when both vectors are zero.

**Examples**

```python
>>> from sympy import Point
>>> p1, p2 = Point(1, 1), Point(3, 3)
>>> p1.canberra_distance(p2)
1
>>> p1, p2 = Point(0, 0), Point(3, 3)
>>> p1.canberra_distance(p2)
2
See also:

sympy.geometry.point.Point.distance (page 2279)
```

**distance(other)**

The Euclidean distance between self and another GeometricEntity.

**Returns**

- `distance` : number or symbolic expression.

**Raises**

- `TypeError` : if `other` is not recognized as a GeometricEntity or is a GeometricEntity for which distance is not defined.

**Examples**

```python
>>> from sympy import Point, Line
>>> p1, p2 = Point(1, 1), Point(4, 5)
>>> l = Line((3, 1), (2, 2))
>>> p1.distance(p2)
5
>>> p1.distance(l)
sqrt(2)
```

The computed distance may be symbolic, too:

```python
>>> from sympy.abc import x, y
>>> p3 = Point(x, y)
>>> p3.distance((0, 0))
sqrt(x**2 + y**2)
```

**See also:**

sympy.geometry.line.Segment.length (page 2310), sympy.geometry.point. Point.taxicab_distance (page 2283)

**dot(p)**

Return dot product of self with another Point.
equals($other$)
 Returns whether the coordinates of self and other agree.

intersection($other$)
 The intersection between this point and another GeometryEntity.

Parameters
    $other$ : GeometryEntity or sequence of coordinates

Returns
    intersection : list of Points

Notes
 The return value will either be an empty list if there is no intersection, otherwise it will contain this point.

Examples

```python
>>> from sympy import Point
>>> p1, p2, p3 = Point(0, 0), Point(1, 1), Point(0, 0)
>>> p1.intersection(p2)
[]
>>> p1.intersection(p3)
[Point2D(0, 0)]
```

is_collinear(*$args$)
 Returns $True$ if there exists a line that contains $self$ and $points$. Returns $False$ otherwise. A trivially True value is returned if no points are given.

Parameters
    $args$ : sequence of Points

Returns
    is_collinear : boolean

Examples

```python
>>> from sympy import Point
>>> from sympy.abc import x
>>> p1, p2 = Point(0, 0), Point(1, 1)
>>> p3, p4, p5 = Point(2, 2), Point(x, x), Point(1, 2)
>>> Point.is_collinear(p1, p2, p3, p4)
True
>>> Point.is_collinear(p1, p2, p3, p5)
False
```

See also:

`sympy.geometry.line.Line` (page 2303)
**is_concyclic(***args**)

Do `self` and the given sequence of points lie in a circle?

Returns True if the set of points are concyclic and False otherwise. A trivial value of True is returned if there are fewer than 2 other points.

**Parameters**

- **args**: sequence of Points

**Returns**

- **is_concyclic**: boolean

**Examples**

```python
>>> from sympy import Point

Define 4 points that are on the unit circle:

```py
>>> p1, p2, p3, p4 = Point(1, 0), (0, 1), (-1, 0), (0, -1)
```

```py
>>> p1.is_concyclic() == p1.is_concyclic(p2, p3, p4) == True
```

Define a point not on that circle:

```py
>>> p = Point(1, 1)
```

```py
>>> p.is_concyclic(p1, p2, p3) == False
```

**property is_nonzero**

True if any coordinate is nonzero, False if every coordinate is zero, and None if it cannot be determined.

**is_scalar_multiple**(p)

Returns whether each coordinate of `self` is a scalar multiple of the corresponding coordinate in point `p`.

**property is_zero**

True if every coordinate is zero, False if any coordinate is not zero, and None if it cannot be determined.

**property length**

Treating a Point as a Line, this returns 0 for the length of a Point.
Examples

```python
>>> from sympy import Point
>>> p = Point(0, 1)
>>> p.length
0
```

`midpoint(p)`
The midpoint between self and point p.

**Parameters**

- `p`: Point

**Returns**

- `midpoint`: Point

Examples

```python
>>> from sympy import Point
>>> p1, p2 = Point(1, 1), Point(13, 5)
>>> p1.midpoint(p2)
Point2D(7, 3)
```

See also:

`sympy.geometry.line.Segment.midpoint` (page 2310)

property `origin`
A point of all zeros of the same ambient dimension as the current point

property `orthogonal_direction`
Returns a non-zero point that is orthogonal to the line containing self and the origin.

Examples

```python
>>> from sympy import Line, Point
>>> a = Point(1, 2, 3)
>>> a.orthogonal_direction
Point3D(-2, 1, 0)
>>> b = _
>>> Line(b, b.origin).is_perpendicular(Line(a, a.origin))
True
```

static `project(a, b)`
Project the point a onto the line between the origin and point b along the normal direction.

**Parameters**

- `a`: Point
- `b`: Point

**Returns**

- `p`: Point
Examples

```python
>>> from sympy import Line, Point
>>> a = Point(1, 2)
>>> b = Point(2, 5)
>>> z = a.origin
>>> p = Point.project(a, b)
>>> Line(p, a).is_perpendicular(Line(p, b))
True
>>> Point.is_collinear(z, p, b)
True
```

See also:

- `sympy.geometry.line.LinearEntity.projection` (page 2301)

**taxicab_distance(p)**

The Taxicab Distance from self to point p.

Returns the sum of the horizontal and vertical distances to point p.

**Parameters**

- `p`: Point

**Returns**

- `taxicab_distance`: The sum of the horizontal and vertical distances to point p.

Examples

```python
>>> from sympy import Point
>>> p1, p2 = Point(1, 1), Point(4, 5)
>>> p1.taxicab_distance(p2)
7
```

See also:

- `sympy.geometry.point.Point.distance` (page 2279)

**property unit**

Return the Point that is in the same direction as `self` and a distance of 1 from the origin.

**class** `sympy.geometry.point.Point2D(*args, _nocheck=False, **kwargs)`

A point in a 2-dimensional Euclidean space.

**Parameters**

- `coords`: A sequence of 2 coordinate values.

**Raises**

- `TypeError`: When trying to add or subtract points with different dimensions.
- `TypeError`: When trying to create a point with more than two dimensions. When `intersection` is called with object other than a Point.
Examples

```python
from sympy import Point2D
from sympy.abc import x

Point2D(1, 2)
Point2D([1, 2])
Point2D(0, x)

Point2D(1, 2)
Point2D(1/2, 1/4)
Point2D(0.5, 0.25, evaluate=False)
```

Floats are automatically converted to Rational unless the evaluate flag is False:

```
See also:

sympy.geometry.line.Segment (page 2308)
Connects two Points

Attributes

<table>
<thead>
<tr>
<th>x</th>
<th>y</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
</tr>
</tbody>
</table>

property bounds
Return a tuple (xmin, ymin, xmax, ymax) representing the bounding rectangle for the geometric figure.

property coordinates
Returns the two coordinates of the Point.

Examples

```python
from sympy import Point2D

p = Point2D(0, 1)

p.coordinates (0, 1)
```

rotate(angle, pt=None)
Rotate angle radians counterclockwise about Point pt.
Examples

```python
>>> from sympy import Point2D, pi
>>> t = Point2D(1, 0)
>>> t.rotate(pi/2)
Point2D(0, 1)
>>> t.rotate(pi/2, (2, 0))
Point2D(2, -1)
```

See also:

`translate` (page 2285), `scale` (page 2285)

`scale`(x=1, y=1, pt=None)
Scale the coordinates of the Point by multiplying by x and y after subtracting pt - default is (0, 0) – and then adding pt back again (i.e. pt is the point of reference for the scaling).

Examples

```python
>>> from sympy import Point2D
>>> t = Point2D(1, 1)
>>> t.scale(2)
Point2D(2, 1)
>>> t.scale(2, 2)
Point2D(2, 2)
```

See also:

`rotate` (page 2284), `translate` (page 2285)

`transform`(matrix)
Return the point after applying the transformation described by the 3x3 Matrix, matrix.

See also:

sympy.geometry.point.Point2D.rotate (page 2284), sympy.geometry.point.Point2D.scale (page 2285), sympy.geometry.point.Point2D.translate (page 2285)

`translate`(x=0, y=0)
Shift the Point by adding x and y to the coordinates of the Point.

Examples

```python
>>> from sympy import Point2D
>>> t = Point2D(0, 1)
>>> t.translate(2)
Point2D(2, 1)
>>> t.translate(2, 2)
Point2D(2, 3)
```
See also:

`sympy.geometry.point.Point2D.rotate` (page 2284), `scale` (page 2285)

**property x**

Returns the X coordinate of the Point.

**Examples**

```python
>>> from sympy import Point2D
>>> p = Point2D(0, 1)
>>> p.x
0
```

**property y**

Returns the Y coordinate of the Point.

**Examples**

```python
>>> from sympy import Point2D
>>> p = Point2D(0, 1)
>>> p.y
1
```

**class sympy.geometry.point.Point3D(coords, _nocheck=False, **kwargs)**

A point in a 3-dimensional Euclidean space.

**Parameters**

- **coords**
  A sequence of 3 coordinate values.

**Raises**

- **TypeError**
  When trying to add or subtract points with different dimensions.
  When `intersection` is called with object other than a Point.

**Examples**

```python
>>> from sympy import Point3D
>>> from sympy.abc import x
>>> Point3D(1, 2, 3)
Point3D(1, 2, 3)
>>> Point3D([1, 2, 3])
Point3D(1, 2, 3)
>>> Point3D((0, x, 3))
Point3D(0, x, 3)
```
Floats are automatically converted to Rational unless the evaluate flag is False:

```python
>>> Point3D(0.5, 0.25, 2)
Point3D(1/2, 1/4, 2)
>>> Point3D(0.5, 0.25, 3, evaluate=False)
Point3D(0.5, 0.25, 3)
```

**Attributes**

```python
tax
y
z
length
```

**static are_collinear(**points**)**

Is a sequence of points collinear?

Test whether or not a set of points are collinear. Returns True if the set of points are collinear, or False otherwise.

**Parameters**

- **points**: sequence of Point

**Returns**

- **are_collinear**: boolean

**Examples**

```python
>>> from sympy import Point3D
>>> from sympy.abc import x
>>> p1, p2 = Point3D(0, 0, 0), Point3D(1, 1, 1)
>>> p3, p4, p5 = Point3D(2, 2, 2), Point3D(x, x, x), Point3D(1, 2, 6)
>>> Point3D.are_collinear(p1, p2, p3, p4)
True
>>> Point3D.are_collinear(p1, p2, p3, p5)
False
```

**See also:**

- `sympy.geometry.line.Line3D` (page 2319)

**property coordinates**

Returns the three coordinates of the Point.
Examples

```python
>>> from sympy import Point3D
>>> p = Point3D(0, 1, 2)
>>> p.coordinates
(0, 1, 2)
```

direction_cosine(point)

Gives the direction cosine between 2 points

Parameters

- `p` : Point3D

Returns

list

Examples

```python
>>> from sympy import Point3D
>>> p1 = Point3D(1, 2, 3)
>>> p1.direction_cosine(Point3D(2, 3, 5))
[sqrt(6)/6, sqrt(6)/6, sqrt(6)/3]
```

direction_ratio(point)

Gives the direction ratio between 2 points

Parameters

- `p` : Point3D

Returns

list

Examples

```python
>>> from sympy import Point3D
>>> p1 = Point3D(1, 2, 3)
>>> p1.direction_ratio(Point3D(2, 3, 5))
[1, 1, 2]
```

intersection(other)

The intersection between this point and another GeometryEntity.

Parameters

- `other` : GeometryEntity or sequence of coordinates

Returns

- `intersection` : list of Points
Notes

The return value will either be an empty list if there is no intersection, otherwise it will contain this point.

Examples

```python
>>> from sympy import Point3D
>>> p1, p2, p3 = Point3D(0, 0, 0), Point3D(1, 1, 1), Point3D(0, 0, 0)
>>> p1.intersection(p2)
[]
>>> p1.intersection(p3)
[Point3D(0, 0, 0)]
```

scale\((x=1, y=1, z=1, pt=None)\)

Scale the coordinates of the Point by multiplying by \(x\) and \(y\) after subtracting \(pt\) - default is \((0, 0)\) - and then adding \(pt\) back again (i.e. \(pt\) is the point of reference for the scaling).

Examples

```python
>>> from sympy import Point3D
>>> t = Point3D(1, 1, 1)
>>> t.scale(2)
Point3D(2, 1, 1)
>>> t.scale(2, 2)
Point3D(2, 2, 1)
```

See also:

translate (page 2289)

transform\((\text{matrix})\)

Return the point after applying the transformation described by the 4x4 Matrix, \(\text{matrix}\).

See also:

sympy.geometry.point.Point3D.scale (page 2289), sympy.geometry.point.Point3D.translate (page 2289)

translate\((x=0, y=0, z=0)\)

Shift the Point by adding \(x\) and \(y\) to the coordinates of the Point.
Examples

```python
>>> from sympy import Point3D
>>> t = Point3D(0, 1, 1)
>>> t.translate(2)
Point3D(2, 1, 1)
>>> t.translate(2, 2)
Point3D(2, 3, 1)
>>> t + Point3D(2, 2, 2)
Point3D(2, 3, 3)
```

See also:

`sacle` (page 2289)

**property x**

Returns the X coordinate of the Point.

Examples

```python
>>> from sympy import Point3D
>>> p = Point3D(0, 1, 3)
>>> p.x
0
```

**property y**

Returns the Y coordinate of the Point.

Examples

```python
>>> from sympy import Point3D
>>> p = Point3D(0, 1, 2)
>>> p.y
1
```

**property z**

Returns the Z coordinate of the Point.

Examples

```python
>>> from sympy import Point3D
>>> p = Point3D(0, 1, 1)
>>> p.z
1
```
Lines

class sympy.geometry.line.LinearEntity(p1, p2=None, **kwargs)
A base class for all line entities (Line, Ray and Segment) in n-dimensional Euclidean space.

Notes

This is an abstract class and is not meant to be instantiated.

See also:
sympy.geometry.entity.GeometryEntity (page 2269)

Attributes

| ambient_dimension
| direction
| length
| p1
| p2
| points

property ambient_dimension
A property method that returns the dimension of LinearEntity object.

Parameters

p1 : LinearEntity

Returns
dimension : integer

Examples

```python
>>> from sympy import Point, Line
>>> p1, p2 = Point(0, 0), Point(1, 1)
>>> l1 = Line(p1, p2)
>>> l1.ambient_dimension
2

>>> from sympy import Point, Line
>>> p1, p2 = Point(0, 0, 0), Point(1, 1, 1)
>>> l1 = Line(p1, p2)
>>> l1.ambient_dimension
3
```

angle_between(l2)
Return the non-reflex angle formed by rays emanating from the origin with directions the same as the direction vectors of the linear entities.
**Parameters**

- \( l_1 \) : LinearEntity
- \( l_2 \) : LinearEntity

**Returns**

- \( \text{angle} \) : angle in radians

**Notes**

From the dot product of vectors \( v_1 \) and \( v_2 \) it is known that:

\[
\text{dot}(v_1, v_2) = |v_1|*|v_2|*\cos(A)
\]

where \( A \) is the angle formed between the two vectors. We can get the directional vectors of the two lines and readily find the angle between the two using the above formula.

**Examples**

```python
>>> from sympy import Line
>>> e = Line((0, 0), (1, 0))
>>> ne = Line((0, 0), (1, 1))
>>> sw = Line((1, 1), (0, 0))
>>> ne.angle_between(e)
pi/4
>>> sw.angle_between(e)
3*pi/4
```

To obtain the non-obtuse angle at the intersection of lines, use the `smallest_angle_between` method:

```python
>>> sw.smallest_angle_between(e)
pi/4
```

**See also:**

- `is_perpendicular` (page 2296), `Ray2D.closing_angle` (page 2316)

**arbitrary_point** *(parameter='t')*

A parameterized point on the Line.

**Parameters**

- `parameter` : str, optional
  The name of the parameter which will be used for the parametric point. The default value is 't'. When this parameter is 0, the first
point used to define the line will be returned, and when it is 1 the
second point will be returned.

**Returns**

point : Point

**Raises**

ValueError

When parameter already appears in the Line's definition.

**Examples**

```python
>>> from sympy import Point, Line
>>> p1, p2 = Point(1, 0), Point(5, 3)
>>> l1 = Line(p1, p2)
>>> l1.arbitrary_point()
Point2D(4*t + 1, 3*t)
>>> from sympy import Point3D, Line3D
>>> p1, p2 = Point3D(1, 0, 0), Point3D(5, 3, 1)
>>> l1 = Line3D(p1, p2)
>>> l1.arbitrary_point()
Point3D(4*t + 1, 3*t, t)
```

See also:

`sympy.geometry.point.Point` (page 2277)

**static are_concurrent(**lines)**

Is a sequence of linear entities concurrent?

Two or more linear entities are concurrent if they all intersect at a single point.

**Parameters**

lines

A sequence of linear entities.

**Returns**

**True** : if the set of linear entities intersect in one point

**False** : otherwise.

**Examples**

```python
>>> from sympy import Point, Line
>>> p1, p2 = Point(0, 0), Point(3, 5)
>>> p3, p4 = Point(-2, -2), Point(0, 2)
>>> l1, l2, l3 = Line(p1, p2), Line(p1, p3), Line(p1, p4)
>>> Line.are_concurrent(l1, l2, l3)
True
>>> l4 = Line(p2, p3)
>>> Line.are_concurrent(l2, l3, l4)
False
>>> from sympy import Point3D, Line3D
```

(continues on next page)
See also:

`sympy.geometry.util.intersection` (page 2272)

**bisectors**(other)

Returns the perpendicular lines which pass through the intersections of self and other that are in the same plane.

**Parameters**
- **line**: Line3D

**Returns**
- list: two Line instances

**Examples**

```python
>>> from sympy import Point3D, Line3D
>>> r1 = Line3D(Point3D(0, 0, 0), Point3D(1, 0, 0))
>>> r2 = Line3D(Point3D(0, 0, 0), Point3D(0, 1, 0))
>>> r1.bisectors(r2)
[Line3D(Point3D(0, 0, 0), Point3D(1, 1, 0)), Line3D(Point3D(0, 0, 0), Point3D(1, -1, 0))]
```

**contains**(other)

Subclasses should implement this method and should return True if other is on the boundaries of self; False if not on the boundaries of self; None if a determination cannot be made.

**property direction**

The direction vector of the LinearEntity.

**Returns**
- **p**: a Point; the ray from the origin to this point is the direction of self
Examples

```python
>>> from sympy import Line
>>> a, b = (1, 1), (1, 3)
>>> Line(a, b).direction
Point2D(0, 2)
>>> Line(b, a).direction
Point2D(0, -2)
```

This can be reported so the distance from the origin is 1:

```python
>>> Line(b, a).direction.unit
Point2D(0, -1)
```

See also:

`sympy.geometry.point.Point.unit` (page 2283)

intersection(other)

The intersection with another geometrical entity.

Parameters

- `o`: Point or LinearEntity

Returns

- `intersection`: list of geometrical entities

Examples

```python
>>> from sympy import Point, Line, Segment
>>> p1, p2, p3 = Point(0, 0), Point(1, 1), Point(7, 7)
>>> l1 = Line(p1, p2)
>>> l1.intersection(p3)
[Point2D(7, 7)]
>>> p4, p5 = Point(5, 0), Point(0, 3)
>>> l2 = Line(p4, p5)
>>> l1.intersection(l2)
[Point2D(15/8, 15/8)]
>>> p6, p7 = Point(0, 5), Point(2, 6)
>>> s1 = Segment(p6, p7)
>>> l1.intersection(s1)
[]
```

```python
>>> from sympy import Point3D, Line3D, Segment3D
>>> p1, p2, p3 = Point3D(0, 0, 0), Point3D(1, 1, 1), Point3D(7, 7, 7)
>>> l1 = Line3D(p1, p2)
>>> l1.intersection(p3)
[Point3D(7, 7, 7)]
>>> l1 = Line3D(Point3D(4, 19, 12), Point3D(5, 25, 17))
>>> l2 = Line3D(Point3D(-3, -15, -19), direction_ratio=[2, 8, 8])
>>> l1.intersection(l2)
[Point3D(1, 1, -3)]
>>> p6, p7 = Point3D(0, 5, 2), Point3D(2, 6, 3)
>>> s1 = Segment3D(p6, p7)
```
>>> l1.intersection(s1)
[]

See also:

sympy.geometry.point.Point (page 2277)

is_parallel(l2)
Are two linear entities parallel?

Parameters

l1 : LinearEntity
l2 : LinearEntity

Returns

True : if l1 and l2 are parallel,
False : otherwise.

Examples

>>> from sympy import Point, Line
>>> p1, p2 = Point(0, 0), Point(1, 1)
>>> p3, p4 = Point(3, 4), Point(6, 7)
>>> l1, l2 = Line(p1, p2), Line(p3, p4)
>>> Line.is_parallel(l1, l2)
True
>>> p5 = Point(6, 6)
>>> l3 = Line(p3, p5)
>>> Line.is_parallel(l1, l3)
False

See also:

coefficients (page 2314)

is_perpendicular(l2)
Are two linear entities perpendicular?

Parameters

l1 : LinearEntity
l2 : LinearEntity
Returns

- **True**: if \( l_1 \) and \( l_2 \) are perpendicular,
- **False**: otherwise.

Examples

```python
>>> from sympy import Point, Line
>>> p1, p2, p3 = Point(0, 0), Point(1, 1), Point(-1, 1)
>>> l1, l2 = Line(p1, p2), Line(p1, p3)
>>> l1.is_perpendicular(l2)
True
>>> p4 = Point(5, 3)
>>> l3 = Line(p1, p4)
>>> l1.is_perpendicular(l3)
False
```

See also:

- `coefficients` (page 2314)
- `is_similar(other)`
  Return True if self and other are contained in the same line.

Examples

```python
>>> from sympy import Point, Line
>>> p1, p2, p3 = Point(0, 1), Point(3, 4), Point(2, 3)
>>> l1 = Line(p1, p2)
>>> l2 = Line(p1, p3)
>>> l1.is_similar(l2)
True
```
Examples

```python
>>> from sympy import Point, Line
>>> p1, p2 = Point(0, 0), Point(3, 5)
>>> l1 = Line(p1, p2)
>>> l1.length
oo
```

**property p1**
The first defining point of a linear entity.

**Examples**

```python
>>> from sympy import Point, Line
>>> p1, p2 = Point(0, 0), Point(5, 3)
>>> l = Line(p1, p2)
>>> l.p1
Point2D(0, 0)
```

See also:
* [sympy.geometry.point.Point](page2277)

**property p2**
The second defining point of a linear entity.

**Examples**

```python
>>> from sympy import Point, Line
>>> p1, p2 = Point(0, 0), Point(5, 3)
>>> l = Line(p1, p2)
>>> l.p2
Point2D(5, 3)
```

See also:
* [sympy.geometry.point.Point](page2277)

**parallel_line(p)**
Create a new Line parallel to this linear entity which passes through the point `p`.

**Parameters**
- `p`: Point

**Returns**
- `line`: Line
Examples

```python
>>> from sympy import Point, Line
>>> p1, p2, p3 = Point(0, 0), Point(2, 3), Point(-2, 2)
>>> l1 = Line(p1, p2)
>>> l2 = l1.parallel_line(p3)
>>> p3 in l2
True
>>> l1.is_parallel(l2)
True
>>> from sympy import Line3D
>>> p1, p2, p3 = Point3D(0, 0, 0), Point3D(2, 3, 4), Point3D(-2, 2, 0)
>>> l1 = Line3D(p1, p2)
>>> l2 = l1.parallel_line(p3)
>>> p3 in l2
True
>>> l1.is_parallel(l2)
True
```

See also:

`is_parallel` (page 2296)

`perpendicular_line(p)`
Create a new Line perpendicular to this linear entity which passes through the point `p`.

Parameters
- `p`: Point

Returns
- `line`: Line

Examples

```python
>>> from sympy import Point3D, Line3D
>>> p1, p2, p3 = Point3D(0, 0, 0), Point3D(2, 3, 4), Point3D(-2, 2, 0)
>>> L = Line3D(p1, p2)
>>> P = L.perpendicular_line(p3); P
Line3D(Point3D(-2, 2, 0), Point3D(4/29, 6/29, 8/29))
>>> L.is_perpendicular(P)
True
```

In 3D the, the first point used to define the line is the point through which the perpendicular was required to pass; the second point is (arbitrarily) contained in the given line:

```python
>>> P.p2 in L
True
```

See also:

`sympy.geometry.line.LinearEntity.is_perpendicular` (page 2296),
`perpendicular_segment` (page 2299)
perpendicular_segment\((p)\)
Create a perpendicular line segment from \(p\) to this line.
The endpoints of the segment are \(p\) and the closest point in the line containing self.
(If self is not a line, the point might not be in self.)

**Parameters**
\(p\) : Point

**Returns**
segment : Segment

**Notes**
Returns \(p\) itself if \(p\) is on this linear entity.

**Examples**

```python
>>> from sympy import Point, Line
>>> p1, p2, p3 = Point(0, 0), Point(1, 1), Point(0, 2)
>>> l1 = Line(p1, p2)
>>> s1 = l1.perpendicular_segment(p3)
>>> l1.is_perpendicular(s1)
True
>>> p3 in s1
True
>>> l1.perpendicular_segment(Point(4, 0))
Segment2D(Point2D(4, 0), Point2D(2, 2))
```

**See also:**
perpendicular_line (page 2299)

**property points**
The two points used to define this linear entity.

**Returns**
points : tuple of Points
Examples

```python
>>> from sympy import Point, Line
>>> p1, p2 = Point(0, 0), Point(5, 11)
>>> l1 = Line(p1, p2)
>>> l1.points
(Point2D(0, 0), Point2D(5, 11))
```

See also:
`sympy.geometry.point.Point` (page 2277)

`projection(other)`
Project a point, line, ray, or segment onto this linear entity.

**Parameters**

- `other`: Point or LinearEntity (Line, Ray, Segment)

**Returns**

- `projection`: Point or LinearEntity (Line, Ray, Segment)

The return type matches the type of the parameter `other`.

**Raises**

- `GeometryError`

When method is unable to perform projection.

Notes

A projection involves taking the two points that define the linear entity and projecting those points onto a Line and then reforming the linear entity using these projections. A point P is projected onto a line L by finding the point on L that is closest to P. This point is the intersection of L and the line perpendicular to L that passes through P.

Examples

```python
>>> from sympy import Point, Line, Segment, Rational
>>> p1, p2, p3 = Point(0, 0), Point(1, 1), Point(Rational(1, 2), 0)
>>> l1 = Line(p1, p2)
>>> l1.projection(p3)
Point2D(1/4, 1/4)
>>> p4, p5 = Point(10, 0), Point(12, 1)
>>> s1 = Segment(p4, p5)
>>> l1.projection(s1)
Segment2D(Point2D(5, 5), Point2D(13/2, 13/2))
>>> p1, p2, p3 = Point(0, 0, 1), Point(1, 1, 2), Point(2, 0, 1)
>>> l1 = Line(p1, p2)
>>> l1.projection(p3)
Point3D(2/3, 2/3, 5/3)
>>> p4, p5 = Point(10, 0, 1), Point(12, 1, 3)
>>> s1 = Segment(p4, p5)
```

(continues on next page)
l1.projection(s1)
Segment3D(Point3D(10/3, 10/3, 13/3), Point3D(5, 5, 6))

See also:
sympy.geometry.point.Point (page 2277), perpendicular_line (page 2299)

random_point(seed=None)
A random point on a LinearEntity.

Returns
point : Point

Examples

from sympy import Point, Line, Ray, Segment
p1, p2 = Point(0, 0), Point(5, 3)
line = Line(p1, p2)
r = line.random_point(seed=42)  # seed value is optional
r.n(3)
Point2D(-0.72, -0.432)
r in line
True
Ray(p1, p2).random_point(seed=42).n(3)
Point2D(0.72, 0.432)
Segment(p1, p2).random_point(seed=42).n(3)
Point2D(3.2, 1.92)

See also:
sympy.geometry.point.Point (page 2277)

smallest_angle_between(l2)
Return the smallest angle formed at the intersection of the lines containing the linear entities.

Parameters
l1 : LinearEntity
l2 : LinearEntity

Returns
angle : angle in radians

Examples

from sympy import Point, Line
p1, p2, p3 = Point(0, 0), Point(0, 4), Point(2, -2)
l1, l2 = Line(p1, p2), Line(p1, p3)
l1.smallest_angle_between(l2)
pi/4
class sympy.geometry.line.Line(*args, **kwargs)

An infinite line in space.

A 2D line is declared with two distinct points, point and slope, or an equation. A 3D line may be defined with a point and a direction ratio.

Parameters

- `p1` : Point
- `p2` : Point
- `slope` : SymPy expression
- `direction_ratio` : list
- `equation` : equation of a line

Notes

`Line` will automatically subclass to `Line2D` or `Line3D` based on the dimension of `p1`. The `slope` argument is only relevant for `Line2D` and the `direction_ratio` argument is only relevant for `Line3D`.

The order of the points will define the direction of the line which is used when calculating the angle between lines.

Examples

```python
>>> from sympy import Line, Segment, Point, Eq
>>> from sympy.abc import x, y, a, b

>>> L = Line(Point(2, 3), Point(3, 5))
>>> L
Line2D(Point2D(2, 3), Point2D(3, 5))
>>> L.points
(Point2D(2, 3), Point2D(3, 5))
>>> L.equation()
-2*x + y + 1
>>> L.coefficients
(-2, 1, 1)
```

Instantiate with keyword slope:

```python
>>> Line(Point(0, 0), slope=0)
Line2D(Point2D(0, 0), Point2D(1, 0))
```

Instantiate with another linear object

```python
>>> s = Segment((0, 0), (0, 1))
>>> Line(s).equation()
x
```
The line corresponding to an equation in the for \( ax + by + c = 0 \), can be entered:

```python
>>> Line(3*x + y + 18)
Line2D(Point2D(0, -18), Point2D(1, -21))
```

If \( x \) or \( y \) has a different name, then they can be specified, too, as a string (to match the name) or symbol:

```python
>>> Line(Eq(3*a + b, -18), x='a', y=b)
Line2D(Point2D(0, -18), Point2D(1, -21))
```

See also:

sympy.geometry.point.Point (page 2277), sympy.geometry.line.Line2D (page 2313), sympy.geometry.line.Line3D (page 2319)

`contains(other)`

Return True if \( other \) is on this Line, or False otherwise.

Examples

```python
>>> from sympy import Line, Point
>>> p1, p2 = Point(0, 1), Point(3, 4)
>>> l = Line(p1, p2)
>>> l.contains(p1)
True
>>> l.contains((0, 1))
True
>>> l.contains((0, 0))
False
>>> a = (0, 0, 0)
>>> b = (1, 1, 1)
>>> c = (2, 2, 2)
>>> l1 = Line(a, b)
>>> l2 = Line(b, a)
>>> l1 == l2
False
>>> l1 in l2
True
```

distance\((other)\)

Finds the shortest distance between a line and a point.

 Raises

\( \text{NotImplementedError} \) is raised if \``other``\ is not a Point
Examples

```python
>>> from sympy import Point, Line
>>> p1, p2 = Point(0, 0), Point(1, 1)
>>> s = Line(p1, p2)
>>> s.distance(Point(-1, 1))
sqrt(2)
>>> s.distance((-1, 2))
3*sqrt(2)/2
>>> p1, p2 = Point(0, 0, 0), Point(1, 1, 1)
>>> s = Line(p1, p2)
>>> s.distance(Point(-1, 1, 1))
2*sqrt(6)/3
>>> s.distance((-1, 1, 1))
2*sqrt(6)/3

equals(other)

Returns True if self and other are the same mathematical entities

plot_interval(parameter='t')

The plot interval for the default geometric plot of line. Gives values that will produce
a line that is +/- 5 units long (where a unit is the distance between the two points
that define the line).

Parameters

parameter : str, optional
Default value is ‘t’.

Returns

plot_interval : list (plot interval)
[parameter, lower_bound, upper_bound]
```

```
class sympy.geometry.line.Ray(p1, p2=None, **kwargs)

A Ray is a semi-line in the space with a source point and a direction.

Parameters

p1 : Point
The source of the Ray

p2 : Point or radian value
This point determines the direction in which the Ray propagates. If
given as an angle it is interpreted in radians with the positive direc-
tion being ccw.
```
Notes

Ray will automatically subclass to Ray2D or Ray3D based on the dimension of p1.

Examples

```python
>>> from sympy import Ray, Point, pi
>>> r = Ray(Point(2, 3), Point(3, 5))
>>> r
Ray2D(Point2D(2, 3), Point2D(3, 5))
>>> r.points
(Point2D(2, 3), Point2D(3, 5))
>>> r.source
Point2D(2, 3)
>>> r.xdirection
oo
>>> r.ydirection
oo
>>> r.slope
2
>>> Ray(Point(0, 0), angle=pi/4).slope
1
```

See also:
sympy.geometry.line.Ray2D (page 2315), sympy.geometry.line.Ray3D (page 2320), sympy.geometry.point.Point (page 2277), sympy.geometry.line.Line (page 2303)

Attributes

- **source**
  - contains(other)
    - Is other GeometryEntity contained in this Ray?

Examples

```python
>>> from sympy import Ray, Point, Segment
>>> p1, p2 = Point(0, 0), Point(4, 4)
>>> r = Ray(p1, p2)
>>> r.contains(p1)
True
>>> r.contains((1, 1))
True
>>> r.contains((1, 3))
False
>>> s = Segment((1, 1), (2, 2))
>>> r.contains(s)
```

(continues on next page)
True
>>> s = Segment((1, 2), (2, 5))
>>> r.contains(s)
False
>>> r1 = Ray((2, 2), (3, 3))
>>> r.contains(r1)
True
>>> r1 = Ray((2, 2), (3, 5))
>>> r.contains(r1)
False

distance(other)
Find the shortest distance between the ray and a point.

Raises
NotImplementedError is raised if `other` is not a Point

Examples

```python
>>> from sympy import Point, Ray
>>> p1, p2 = Point(0, 0), Point(1, 1)
>>> s = Ray(p1, p2)
>>> s.distance(Point(-1, -1))
sqrt(2)
>>> s.distance((-1, 2))
3*sqrt(2)/2
>>> p1, p2 = Point(0, 0, 0), Point(1, 1, 2)
>>> s = Ray(p1, p2)
>>> s
Ray3D(Point3D(0, 0, 0), Point3D(1, 1, 2))
>>> s.distance(Point(-1, -1, 2))
4*sqrt(3)/3
>>> s.distance((-1, -1, 2))
4*sqrt(3)/3
```
equals(other)
Returns True if self and other are the same mathematical entities

plot_interval(parameter='t')
The plot interval for the default geometric plot of the Ray. Gives values that will produce a ray that is 10 units long (where a unit is the distance between the two points that define the ray).

Parameters
- parameter : str, optional
  Default value is ‘t’.

Returns
- plot_interval : list
  [parameter, lower_bound, upper_bound]
Examples

```python
>>> from sympy import Ray, pi
>>> r = Ray((0, 0), angle=pi/4)
>>> r.plot_interval()
[t, 0, 10]
```

**property source**
The point from which the ray emanates.

Examples

```python
>>> from sympy import Point, Ray
>>> p1, p2 = Point(0, 0), Point(4, 1)
>>> r1 = Ray(p1, p2)
>>> r1.source
Point2D(0, 0)
>>> p1, p2 = Point(0, 0, 0), Point(4, 1, 5)
>>> r1 = Ray(p2, p1)
>>> r1.source
Point3D(4, 1, 5)
```

See also:

* sympy.geometry.point.Point (page 2277)

class sympy.geometry.line.Segment(p1, p2, **kwargs)
A line segment in space.

**Parameters**

- `p1`: Point
- `p2`: Point

**Notes**

If 2D or 3D points are used to define `Segment`, it will be automatically subclassed to `Segment2D` or `Segment3D`.

Examples

```python
>>> from sympy import Point, Segment
>>> Segment((1, 0), (1, 1)) # tuples are interpreted as pts
Segment2D(Point2D(1, 0), Point2D(1, 1))
>>> s = Segment(Point(4, 3), Point(1, 1))
>>> s.points
(Point2D(4, 3), Point2D(1, 1))
>>> s.slope
2/3
>>> s.length
(continues on next page)```
sqrt(13)

>>> s.midx
Point2D(5/2, 2)

>>> Segment(((1, 0, 0), (1, 1, 1)))  # tuples are interpreted as pts
Segment3D(Point3D(1, 0, 0), Point3D(1, 1, 1))

>>> s = Segment(Point(4, 3, 9), Point(1, 1, 7)); s
Segment3D(Point3D(4, 3, 9), Point3D(1, 1, 7))

>>> s.points
(Point3D(4, 3, 9), Point3D(1, 1, 7))

>>> s.length
sqrt(17)

>>> s.midx
Point3D(5/2, 2, 8)

See also:

sympy.geometry.line.Segment2D (page 2317),  
sympy.geometry.line.Segment3D (page 2322),  
sympy.geometry.point.Point (page 2277),  
sympy.geometry.line.Line (page 2303)

Attributes

<table>
<thead>
<tr>
<th>length</th>
<th>(number or SymPy expression)</th>
</tr>
</thead>
<tbody>
<tr>
<td>midpoint</td>
<td>(Point)</td>
</tr>
</tbody>
</table>

contains(other)

Is the other GeometryEntity contained within this Segment?

Examples

```python
>>> from sympy import Point, Segment
>>> p1, p2 = Point(0, 1), Point(3, 4)
>>> s = Segment(p1, p2)
>>> s.contains(s2)
True
```

```python
>>> from sympy import Point3D, Segment3D
>>> p1, p2 = Point3D(0, 1, 1), Point3D(3, 4, 5)
>>> s = Segment3D(p1, p2)
>>> s.contains(s2)
True
```

distance(other)

Finds the shortest distance between a line segment and a point.

Raises

NotImplementedError is raised if `other` is not a Point

5.8. Topics
Examples

```python
>>> from sympy import Point, Segment
>>> p1, p2 = Point(0, 1), Point(3, 4)
>>> s = Segment(p1, p2)
>>> s.distance(Point(10, 15))
sqrt(170)
>>> s.distance((0, 12))
sqrt(73)
>>> from sympy import Point3D, Segment3D
>>> p1, p2 = Point3D(0, 0, 3), Point3D(1, 1, 4)
>>> s = Segment3D(p1, p2)
>>> s.distance(Point3D(10, 15, 12))
sqrt(341)
>>> s.distance((10, 15, 12))
sqrt(341)
```

equals(other)

Returns True if self and other are the same mathematical entities

**property length**

The length of the line segment.

**See also:**

*sympy.geometry.point.Point.distance* (page 2279)

**property midpoint**

The midpoint of the line segment.
Examples

```python
>>> from sympy import Point, Segment
>>> p1, p2 = Point(0, 0), Point(4, 3)
>>> s1 = Segment(p1, p2)
>>> s1.midpoint
Point2D(2, 3/2)
```

```python
>>> from sympy import Point3D, Segment3D
>>> p1, p2 = Point3D(0, 0, 0), Point3D(4, 3, 3)
>>> s1 = Segment3D(p1, p2)
>>> s1.midpoint
Point3D(2, 3/2, 3/2)
```

See also:

`sympy.geometry.point.Point.midpoint` (page 2282)

**perpendicular_bisector** *(p=None)*

The perpendicular bisector of this segment.

If no point is specified or the point specified is not on the bisector then the bisector is returned as a Line. Otherwise a Segment is returned that joins the point specified and the intersection of the bisector and the segment.

**Parameters**

- **p**: Point

**Returns**

- **bisector**: Line or Segment

Examples

```python
>>> from sympy import Point, Segment
>>> p1, p2, p3 = Point(0, 0), Point(6, 6), Point(5, 1)
>>> s1 = Segment(p1, p2)
>>> s1.perpendicular_bisector()
Line2D(Point2D(3, 3), Point2D(-3, 9))
```

```python
>>> s1.perpendicular_bisector(p3)
Segment2D(Point2D(5, 1), Point2D(3, 3))
```

See also:

`LinearEntity.perpendicular_segment` (page 2299)

**plot_interval** *(parameter='t')*

The plot interval for the default geometric plot of the Segment gives values that will produce the full segment in a plot.

**Parameters**

- **parameter** : str, optional

  Default value is ‘t’.

**Returns**

- **plot_interval**: list
Examples

```python
>>> from sympy import Point, Segment
>>> p1, p2 = Point(0, 0), Point(5, 3)
>>> s1 = Segment(p1, p2)
>>> s1.plot_interval()
[t, 0, 1]
```

class sympy.geometry.line.LinearEntity2D(p1, p2=None, **kwargs)

A base class for all line entities (line, ray and segment) in a 2-dimensional Euclidean space.

Notes

This is an abstract class and is not meant to be instantiated.

See also:
sympy.geometry.entity.GeometryEntity (page 2269)

Attributes

- p1
- p2
- coefficients
- slope
- points

property bounds

Return a tuple (xmin, ymin, xmax, ymax) representing the bounding rectangle for the geometric figure.

perpendicular_line(p)

Create a new Line perpendicular to this linear entity which passes through the point p.

Parameters

- p : Point

Returns

- line : Line
Examples

```python
>>> from sympy import Point, Line
>>> p1, p2, p3 = Point(0, 0), Point(2, 3), Point(-2, 2)
>>> L = Line(p1, p2)
>>> P = L.perpendicular_line(p3); P
Line2D(Point2D(-2, 2), Point2D(-5, 4))
>>> L.is_perpendicular(P)
True
```

In 2D, the first point of the perpendicular line is the point through which was required to pass; the second point is arbitrarily chosen. To get a line that explicitly uses a point in the line, create a line from the perpendicular segment from the line to the point:

```python
>>> Line(L.perpendicular_segment(p3))
Line2D(Point2D(-2, 2), Point2D(4/13, 6/13))
```

See also:

- `sympy.geometry.line.LinearEntity.is_perpendicular` (page 2296), `perpendicular_segment` (page 2299)

**property slope**

The slope of this linear entity, or infinity if vertical.

Returns

- **slope**: number or SymPy expression

Examples

```python
>>> from sympy import Point, Line
>>> p1, p2 = Point(0, 0), Point(3, 5)
>>> l1 = Line(p1, p2)
>>> l1.slope
5/3
>>> p3 = Point(0, 4)
>>> l2 = Line(p1, p3)
>>> l2.slope
oo
```

See also:

- `coefficients` (page 2314)

**class** `sympy.geometry.line.Line2D(p1, pt=None, slope=None, **kwargs)`

An infinite line in space 2D.

A line is declared with two distinct points or a point and slope as defined using keyword `slope`.

**Parameters**

- **p1**: Point
- **pt**: Point

---

5.8. Topics 2313
**Examples**

```python
>>> from sympy import Line, Segment, Point
>>> L = Line(Point(2, 3), Point(3, 5))
>>> L
Line2D(Point2D(2, 3), Point2D(3, 5))
>>> L.points
(Point2D(2, 3), Point2D(3, 5))
>>> L.equation()
-2*x + y + 1
>>> L.coefficients
(-2, 1, 1)
```

Instantiate with keyword `slope`:

```python
>>> Line(Point(0, 0), slope=0)
Line2D(Point2D(0, 0), Point2D(1, 0))
```

Instantiate with another linear object

```python
>>> s = Segment((0, 0), (0, 1))
>>> Line(s).equation()
x
```

See also:

* sympy.geometry.point.Point (page 2277)*

**property coefficients**

The coefficients $(a, b, c)$ for $ax + by + c = 0$.

**Examples**

```python
>>> from sympy import Point, Line
>>> from sympy.abc import x, y
>>> p1, p2 = Point(0, 0), Point(5, 3)
>>> l = Line(p1, p2)
>>> l.coefficients
(-3, 5, 0)

>>> p3 = Point(x, y)
>>> l2 = Line(p1, p3)
>>> l2.coefficients
(-y, x, 0)
```

See also:

* sympy.geometry.line.Line2D.equation (page 2314)*
The equation of the line: \( ax + by + c \).

**Parameters**
- **x**: str, optional
  - The name to use for the x-axis, default value is ‘x’.
- **y**: str, optional
  - The name to use for the y-axis, default value is ‘y’.

**Returns**
- **equation**: SymPy expression

**Examples**

```python
from sympy import Point, Line
p1, p2 = Point(1, 0), Point(5, 3)
l1 = Line(p1, p2)
l1.equation()
```

```
-3*x + 4*y + 3
```

**See also:**
- `sympy.geometry.line.Line2D.coefficients` (page 2314)

**class** sympy.geometry.line.Ray2D(p1, pt=None, angle=None, **kwargs)**

A Ray is a semi-line in the space with a source point and a direction.

**Parameters**
- **p1**: Point
  - The source of the Ray
- **p2**: Point or radian value
  - This point determines the direction in which the Ray propagates. If given as an angle it is interpreted in radians with the positive direction being ccw.

**Examples**

```python
from sympy import Point, pi, Ray
r = Ray(Point(2, 3), Point(3, 5))
r.points
r.source
r.xdirection
r.ydirection
```

(continues on next page)
SymPy Documentation, Release 1.12.1

(continued from previous page)

```python
>>> r.slope
2
>>> Ray(Point(0, 0), angle=pi/4).slope
1
```

<th>Attribute</th>
</tr>
</thead>
<tbody>
<tr>
<td>source</td>
</tr>
<tr>
<td>xdirection</td>
</tr>
<tr>
<td>ydirection</td>
</tr>
</tbody>
</table>

**closing_angle**(r2)

Return the angle by which r2 must be rotated so it faces the same direction as r1.

**Parameters**

- **r1**: Ray2D
- **r2**: Ray2D

**Returns**

- **angle**: angle in radians (ccw angle is positive)

**Examples**

```python
>>> from sympy import Ray, pi
>>> r1 = Ray((0, 0), (1, 0))
>>> r2 = r1.rotate(-pi/2)
>>> angle = r1.closing_angle(r2); angle
pi/2
>>> r2.rotate(angle).direction.unit == r1.direction.unit
True
>>> r2.closing_angle(r1)
-pi/2
```

**See also:**

`LinearEntity.angle_between` (page 2291)

**property xdirection**

The x direction of the ray.

Positive infinity if the ray points in the positive x direction, negative infinity if the ray points in the negative x direction, or 0 if the ray is vertical.
Examples

```python
>>> from sympy import Point, Ray
>>> p1, p2, p3 = Point(0, 0), Point(1, 1), Point(0, -1)
>>> r1, r2 = Ray(p1, p2), Ray(p1, p3)
>>> r1.xdirection
oo
>>> r2.xdirection
0
```

See also:

`ydirection` (page 2317)

**property ydirection**

The y direction of the ray.

Positive infinity if the ray points in the positive y direction, negative infinity if the ray points in the negative y direction, or 0 if the ray is horizontal.

Examples

```python
>>> from sympy import Point, Ray
>>> p1, p2, p3 = Point(0, 0), Point(-1, -1), Point(-1, 0)
>>> r1, r2 = Ray(p1, p2), Ray(p1, p3)
>>> r1.ydirection
-oo
>>> r2.ydirection
0
```

See also:

`xdirection` (page 2316)

class sympy.geometry.line.Segment2D(p1, p2, **kwargs)

A line segment in 2D space.

**Parameters**

- `p1`: Point
- `p2`: Point

Examples

```python
>>> from sympy import Point, Segment
>>> Segment((1, 0), (1, 1)) # tuples are interpreted as pts
Segment2D(Point2D(1, 0), Point2D(1, 1))
>>> s = Segment(Point(4, 3), Point(1, 1)); s
Segment2D(Point2D(4, 3), Point2D(1, 1))
>>> s.points
(Point2D(4, 3), Point2D(1, 1))
>>> s.slope
2/3
```
See also:
sympy.geometry.point.Point (page 2277), Line (page 2303)

Attributes

<table>
<thead>
<tr>
<th>length</th>
<th>(number or SymPy expression)</th>
</tr>
</thead>
<tbody>
<tr>
<td>midpoint</td>
<td>(Point)</td>
</tr>
</tbody>
</table>

class sympy.geometry.line.LinearEntity3D(p1, p2, **kwargs)

An base class for all linear entities (line, ray and segment) in a 3-dimensional Euclidean space.

Notes

This is a base class and is not meant to be instantiated.

Attributes

<table>
<thead>
<tr>
<th>p1</th>
</tr>
</thead>
<tbody>
<tr>
<td>p2</td>
</tr>
<tr>
<td>direction_ratio</td>
</tr>
<tr>
<td>direction_cosine</td>
</tr>
<tr>
<td>points</td>
</tr>
</tbody>
</table>

property direction_cosine

The normalized direction ratio of a given line in 3D.

Examples

```python
>>> from sympy import Point3D, Line3D
>>> p1, p2 = Point3D(0, 0, 0), Point3D(5, 3, 1)
>>> l = Line3D(p1, p2)
>>> l.direction_cosine
[sqrt(35)/7, 3*sqrt(35)/35, sqrt(35)/35]
>>> sum(i**2 for i in _)
1
```

See also:
sympy.geometry.line.Line3D.equation (page 2319)
property `direction_ratio`  
The direction ratio of a given line in 3D.

**Examples**

```python
>>> from sympy import Point3D, Line3D
>>> p1, p2 = Point3D(0, 0, 0), Point3D(5, 3, 1)
>>> l = Line3D(p1, p2)
>>> l.direction_ratio
[5, 3, 1]
```

See also:  
*sympy.geometry.line.Line3D.equation* (page 2319)

```python
class sympy.geometry.line.Line3D(p1, pt=None, direction_ratio=(), **kwargs)
```

An infinite 3D line in space.

A line is declared with two distinct points or a point and direction_ratio as defined using keyword `direction_ratio`.

**Parameters**

- `p1`: Point3D
- `pt`: Point3D
- `direction_ratio`: list

**Examples**

```python
>>> from sympy import Line3D, Point3D
>>> L = Line3D(Point3D(2, 3, 4), Point3D(3, 5, 1))
>>> L
Line3D(Point3D(2, 3, 4), Point3D(3, 5, 1))
>>> L.points
(Point3D(2, 3, 4), Point3D(3, 5, 1))
```

See also:  
*sympy.geometry.point.Point3D* (page 2286), *sympy.geometry.line.Line* (page 2303), *sympy.geometry.line.Line2D* (page 2313)

```python
equation(x='x', y='y', z='z')
```

Return the equations that define the line in 3D.

**Parameters**

- `x`: str, optional
  - The name to use for the x-axis, default value is ‘x’.
- `y`: str, optional
  - The name to use for the y-axis, default value is ‘y’.
- `z`: str, optional
  - The name to use for the z-axis, default value is ‘z’.
Returns

**equation** : Tuple of simultaneous equations

Examples

```python
>>> from sympy import Point3D, Line3D, solve
>>> from sympy.abc import x, y, z
>>> p1, p2 = Point3D(1, 0, 0), Point3D(5, 3, 0)
>>> l1 = Line3D(p1, p2)
>>> eq = l1.equation(x, y, z); eq
(-3*x + 4*y + 3, z)
>>> solve(eq.subs(z, 0), (x, y, z))
{x: 4*y/3 + 1}
```

class sympy.geometry.line.Ray3D(p1, pt=None, direction_ratio=(), **kwargs)

A Ray is a semi-line in the space with a source point and a direction.

**Parameters**

- **p1** : Point3D
  - The source of the Ray
- **p2** : Point or a direction vector
  - **direction_ratio** : Determines the direction in which the Ray propagates.

Examples

```python
>>> from sympy import Point3D, Ray3D
>>> r = Ray3D(Point3D(2, 3, 4), Point3D(3, 5, 0))
>>> r
Ray3D(Point3D(2, 3, 4), Point3D(3, 5, 0))
>>> r.points
(Point3D(2, 3, 4), Point3D(3, 5, 0))
>>> r.source
Point3D(2, 3, 4)
>>> r.xdirection
oo
>>> r.ydirection
oo
>>> r.direction_ratio
[1, 2, -4]
```

See also:

- *sympy.geometry.point.Point3D* (page 2286), *Line3D* (page 2319)
Attributes

| source | xdirection | ydirection | zdirection |

**property xdirection**

The x direction of the ray.

Positive infinity if the ray points in the positive x direction, negative infinity if the ray points in the negative x direction, or 0 if the ray is vertical.

**Examples**

```python
>>> from sympy import Point3D, Ray3D
>>> p1, p2, p3 = Point3D(0, 0, 0), Point3D(1, 1, 1), Point3D(0, -1, 0)
>>> r1, r2 = Ray3D(p1, p2), Ray3D(p1, p3)
>>> r1.xdirection
oo
>>> r2.xdirection
0
```

**See also:**

*ydirection* (page 2321)

**property ydirection**

The y direction of the ray.

Positive infinity if the ray points in the positive y direction, negative infinity if the ray points in the negative y direction, or 0 if the ray is horizontal.

**Examples**

```python
>>> from sympy import Point3D, Ray3D
>>> p1, p2, p3 = Point3D(0, 0, 0), Point3D(-1, -1, -1), Point3D(-1, 0, 1)
>>> r1, r2 = Ray3D(p1, p2), Ray3D(p1, p3)
>>> r1.ydirection
-oo
>>> r2.ydirection
0
```

**See also:**

*xdirection* (page 2321)

**property zdirection**

The z direction of the ray.

Positive infinity if the ray points in the positive z direction, negative infinity if the ray points in the negative z direction, or 0 if the ray is horizontal.
Examples

```python
>>> from sympy import Point3D, Ray3D
>>> p1, p2, p3 = Point3D(0, 0, 0), Point3D(-1, -1, -1), Point3D(-1, 0, 1)
>>> r1, r2 = Ray3D(p1, p2), Ray3D(p1, p3)
>>> r1.ydirection
-oo
>>> r2.ydirection
0
>>> r2.zdirection
0
```

See also:

`xdirection` (page 2321)

```python
class sympy.geometry.line.Segment3D(p1, p2, **kwargs)
```

A line segment in a 3D space.

**Parameters**

- `p1`: Point3D
- `p2`: Point3D

**Examples**

```python
>>> from sympy import Point3D, Segment3D
>>> Segment3D((1, 0, 0), (1, 1, 1))  # tuples are interpreted as pts
Segment3D(Point3D(1, 0, 0), Point3D(1, 1, 1))
>>> s = Segment3D(Point3D(4, 3, 9), Point3D(1, 1, 7)); s
Segment3D(Point3D(4, 3, 9), Point3D(1, 1, 7))
>>> s.points
(Point3D(4, 3, 9), Point3D(1, 1, 7))
>>> s.length
sqrt(17)
>>> s.midpoint
Point3D(5/2, 2, 8)
```

See also:

Curves

class sympy.geometry.curve.Curve(function, limits)
A curve in space.
A curve is defined by parametric functions for the coordinates, a parameter and the lower and upper bounds for the parameter value.

Parameters

function : list of functions
limits : 3-tuple
Function parameter and lower and upper bounds.

Raises
ValueError
When functions are specified incorrectly. When limits are specified incorrectly.

Examples

```python
>>> from sympy import Curve, sin, cos, interpolate
>>> from sympy.abc import t, a
>>> C = Curve((sin(t), cos(t)), (t, 0, 2))
>>> C.functions
(sin(t), cos(t))
>>> C.limits
(t, 0, 2)
>>> C.parameter
(t, 0, 2)
>>> C = Curve((t, interpolate([1, 4, 9, 16], t)), (t, 0, 1)); C
Curve((t, t**2), (t, 0, 1))
>>> C.subs(t, 4)
Point2D(4, 16)
>>> C.arbitrary_point(a)
Point2D(a, a**2)
```

See also:
sympy.core.function.Function (page 1096), sympy.polys.polyfuncts.interpolate (page 2502)

Attributes

functions parameter limits

property ambient_dimension
The dimension of the curve.
Returns

int:

the dimension of curve.

Examples

```python
>>> from sympy.abc import t
>>> from sympy import Curve
>>> C = Curve((t, t**2), (t, 0, 2))
>>> C.ambient_dimension
2
```

arbitrary_point(parameter='t')

A parameterized point on the curve.

Parameters

- **parameter**: str or Symbol, optional

  Default value is ‘t’. The Curve’s parameter is selected with None or self.parameter otherwise the provided symbol is used.

Returns

Point:

Returns a point in parametric form.

Raises

- **ValueError**

  When parameter already appears in the functions.

Examples

```python
>>> from sympy import Curve, Symbol
>>> from sympy.abc import s
>>> C = Curve([2*s, s**2], (s, 0, 2))
>>> C.arbitrary_point()
Point2D(2*t, t**2)
>>> C.arbitrary_point(C.parameter)
Point2D(2*s, s**2)
>>> C.arbitrary_point(None)
Point2D(2*s, s**2)
>>> C.arbitrary_point(Symbol('a'))
Point2D(2*a, a**2)
```

See also:

* sympy.geometry.point.Point (page 2277)

property free_symbols

Return a set of symbols other than the bound symbols used to parametrically define the Curve.

Returns

set:
Set of all non-parameterized symbols.

**Examples**

```python
>>> from sympy.abc import t, a
>>> from sympy import Curve
>>> Curve((t, t**2), (t, 0, 2)).free_symbols
set()
>>> Curve((t, t**2), (t, a, 2)).free_symbols
{a}
```

**property functions**

The functions specifying the curve.

**Returns**

- `functions`: list of parameterized coordinate functions.

**Examples**

```python
>>> from sympy.abc import t
>>> from sympy import Curve
>>> C = Curve((t, t**2), (t, 0, 2))
>>> C.functions
(t, t**2)
```

**See also:**

- `parameter` (page 2326)

**property length**

The curve length.

**Examples**

```python
>>> from sympy import Curve
>>> from sympy.abc import t
>>> Curve((t, t), (t, 0, 1)).length
sqrt(2)
```

**property limits**

The limits for the curve.

**Returns**

- `limits`: tuple

  Contains parameter and lower and upper limits.
**Examples**

```python
>>> from sympy.abc import t
>>> from sympy import Curve
>>> C = Curve([t, t**3], (t, -2, 2))
>>> C.limits
(t, -2, 2)
```

**See also:**

`plot_interval` (page 2326)

**property parameter**

The curve function variable.

**Returns**

Symbol:

returns a bound symbol.

**Examples**

```python
>>> from sympy.abc import t
>>> from sympy import Curve
>>> C = Curve([t, t**2], (t, 0, 2))
>>> C.parameter
```

**See also:**

`functions` (page 2325)

`plot_interval` (parameter='t')

The plot interval for the default geometric plot of the curve.

**Parameters**

- **parameter**: str or Symbol, optional
  - Default value is 't'; otherwise the provided symbol is used.

**Returns**

List:

the plot interval as below:

[parameter, lower_bound, upper_bound]

**Examples**

```python
>>> from sympy import Curve, sin
>>> from sympy.abc import x, s
>>> Curve((x, sin(x)), (x, 1, 2)).plot_interval()
[t, 1, 2]
>>> Curve((x, sin(x)), (x, 1, 2)).plot_interval(s)
[s, 1, 2]
```
See also:

**limits** *(page 2325)*

Returns limits of the parameter interval

**rotate** *(angle=0, pt=None)*

This function is used to rotate a curve along given point pt at given angle(in radian).

**Parameters**

- **angle** :
  
  the angle at which the curve will be rotated(in radian) in counter-clockwise direction. default value of angle is 0.

- **pt** : Point
  
  the point along which the curve will be rotated. If no point given, the curve will be rotated around origin.

**Returns**

- **Curve** :
  
  returns a curve rotated at given angle along given point.

**Examples**

```python
>>> from sympy import Curve, pi
>>> from sympy.abc import x
>>> Curve((x, x), (x, 0, 1)).rotate(pi/2)
Curve((-x, x), (x, 0, 1))
```

**scale** *(x=1, y=1, pt=None)*

Override GeometryEntity.scale since Curve is not made up of Points.

**Returns**

- **Curve** :
  
  returns scaled curve.

**Examples**

```python
>>> from sympy import Curve
>>> from sympy.abc import x
>>> Curve((x, x), (x, 0, 1)).scale(2)
Curve((2*x, x), (x, 0, 1))
```

**translate** *(x=0, y=0)*

Translate the Curve by (x, y).

**Returns**

- **Curve** :
  
  returns a translated curve.
Examples

```python
>>> from sympy import Curve
>>> from sympy.abc import x
>>> Curve((x, x), (x, 0, 1)).translate(1, 2)
Curve((x + 1, x + 2), (x, 0, 1))
```

Ellipses

class sympy.geometry.ellipse.Ellipse(center=None, hradius=None, vradius=None, eccentricity=None, **kwargs)

An elliptical GeometryEntity.

Parameters

**center** : Point, optional
Default value is Point(0, 0)

**hradius** : number or SymPy expression, optional

**vradius** : number or SymPy expression, optional

**eccentricity** : number or SymPy expression, optional

Two of **hradius**, **vradius** and **eccentricity** must be supplied to create an Ellipse. The third is derived from the two supplied.

Raises

**GeometryError**

When **hradius**, **vradius** and **eccentricity** are incorrectly supplied as parameters.

**TypeError**

When **center** is not a Point.

Notes

Constructed from a center and two radii, the first being the horizontal radius (along the x-axis) and the second being the vertical radius (along the y-axis).

When symbolic value for **hradius** and **vradius** are used, any calculation that refers to the foci or the major or minor axis will assume that the ellipse has its major radius on the x-axis. If this is not true then a manual rotation is necessary.
Examples

```python
>>> from sympy import Ellipse, Point, Rational
>>> e1 = Ellipse(Point(0, 0), 5, 1)
>>> e1.hradius, e1.vradius
(5, 1)
>>> e2 = Ellipse(Point(3, 1), hradius=3, eccentricity=Rational(4, 5))
>>> e2
Ellipse(Point2D(3, 1), 3, 9/5)
```

See also:

Circle (page 2344)

Attributes

<table>
<thead>
<tr>
<th>Attribute</th>

</tr>
<tr>
<td>periapsis</td>
</tr>
<tr>
<td>apoapsis</td>
</tr>
<tr>
<td>focus_distance</td>
</tr>
<tr>
<td>foci</td>
</tr>
</tbody>
</table>

property apoapsis

The apoapsis of the ellipse.

The greatest distance between the focus and the contour.

Returns

apoapsis : number

Examples

```python
>>> from sympy import Point, Ellipse
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, 1)
>>> e1.apoapsis
2*sqrt(2) + 3
```

See also:

periapsis (page 2338)

Returns shortest distance between foci and contour

arbitrary_point (parameter='t')

A parameterized point on the ellipse.
Parameters

**parameter** : str, optional
Default value is ‘t’.

Returns

**arbitrary_point** : Point

Raises

**ValueError**
When *parameter* already appears in the functions.

Examples

```python
>>> from sympy import Point, Ellipse
>>> e1 = Ellipse(Point(0, 0), 3, 2)
>>> e1.arbitrary_point()
Point2D(3*cos(t), 2*sin(t))
```

See also:

`sympy.geometry.point.Point` (page 2277)

**property area**
The area of the ellipse.

Returns

**area** : number

Examples

```python
>>> from sympy import Point, Ellipse
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, 1)
>>> e1.area
3*pi
```

**auxiliary_circle()**
Returns a Circle whose diameter is the major axis of the ellipse.

Examples

```python
>>> from sympy import Ellipse, Point, symbols
>>> c = Point(1, 2)
>>> Ellipse(c, 8, 7).auxiliary_circle()
Circle(Point2D(1, 2), 8)
>>> a, b = symbols('a b')
>>> Ellipse(c, a, b).auxiliary_circle()
Circle(Point2D(1, 2), Max(a, b))
```
property bounds
Return a tuple (xmin, ymin, xmax, ymax) representing the bounding rectangle for the geometric figure.

property center
The center of the ellipse.

    Returns
center : number

Examples

>>> from sympy import Point, Ellipse
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, 1)
>>> e1.center
Point2D(0, 0)

See also:
sympy.geometry.point.Point (page 2277)

property circumference
The circumference of the ellipse.

Examples

>>> from sympy import Point, Ellipse
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, 1)
>>> e1.circumference
12*elliptic_e(8/9)

director_circle()
Returns a Circle consisting of all points where two perpendicular tangent lines to the ellipse cross each other.

    Returns
circle

    A director circle returned as a geometric object.

Examples

>>> from sympy import Ellipse, Point, symbols
>>> c = Point(3,8)
>>> Ellipse(c, 7, 9).director_circle()
Circle(Point2D(3, 8), sqrt(130))
>>> a, b = symbols('a b')
>>> Ellipse(c, a, b).director_circle()
Circle(Point2D(3, 8), sqrt(a**2 + b**2))
property eccentricity

The eccentricity of the ellipse.

Returns

eccentricity : number

Examples

```python
>>> from sympy import Point, Ellipse, sqrt
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, sqrt(2))
>>> e1.eccentricity
sqrt(7)/3
```

eencloses_point(p)

Return True if p is enclosed by (is inside of) self.

Parameters

p : Point

Returns

encloses_point : True, False or None

Notes

Being on the border of self is considered False.

Examples

```python
>>> from sympy import Ellipse, S
>>> from sympy.abc import t
>>> e = Ellipse((0, 0), 3, 2)
>>> e.encloses_point((0, 0))
True
>>> e.encloses_point(e.arbitrary_point(t).subs(t, S.Half))
False
>>> e.encloses_point((4, 0))
False
```

See also:

sympy.geometry.point.Point (page 2277)

equation(x='x', y='y', _slope=None)

Returns the equation of an ellipse aligned with the x and y axes; when slope is given, the equation returned corresponds to an ellipse with a major axis having that slope.

Parameters

x : str, optional
Label for the x-axis. Default value is ‘x’.

\[ y : \text{str, optional} \]
Label for the y-axis. Default value is ‘y’.

\[ _\text{slope} : \text{Expr, optional} \]
The slope of the major axis. Ignored when ‘None’.

**Returns**

**equation** : SymPy expression

**Examples**

```python
>>> from sympy import Point, Ellipse, pi
>>> from sympy.abc import x, y
>>> e1 = Ellipse(Point(1, 0), 3, 2)
>>> eq1 = e1.equation(x, y); eq1
ey**2/4 + (x/3 - 1/3)**2 - 1
>>> eq2 = e1.equation(x, y, _slope=1); eq2
(-x + y + 1)**2/8 + (x + y - 1)**2/18 - 1
```

A point on \( e1 \) satisfies eq1. Let’s use one on the x-axis:

```python
>>> p1 = e1.center + Point(e1.major, 0)
>>> assert eq1.subs(x, p1.x).subs(y, p1.y) == 0
```

When rotated the same as the rotated ellipse, about the center point of the ellipse, it will satisfy the rotated ellipse’s equation, too:

```python
>>> r1 = p1.rotate(pi/4, e1.center)
>>> assert eq2.subs(x, r1.x).subs(y, r1.y) == 0
```

**See also:**

*arbitrary_point* (page 2329)
Returns parameterized point on ellipse

**References**

[R518], [R519]

\[ \text{evolute}(x='x', y='y') \]
The equation of evolute of the ellipse.

**Parameters**

\[ x : \text{str, optional} \]
Label for the x-axis. Default value is ‘x’.

\[ y : \text{str, optional} \]
Label for the y-axis. Default value is ‘y’.

**Returns**

**equation** : SymPy expression
Examples

```python
>>> from sympy import Point, Ellipse
>>> e1 = Ellipse(Point(1, 0), 3, 2)
>>> e1.evolute()
2**(2/3)*y**(2/3) + (3*x - 3)**(2/3) - 5**(2/3)
```

**property foci**

The foci of the ellipse.

**Raises**

*ValueError*

When the major and minor axis cannot be determined.

**Notes**

The foci can only be calculated if the major/minor axes are known.

Examples

```python
>>> from sympy import Point, Ellipse
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, 1)
>>> e1.foci
(Point2D(-2*sqrt(2), 0), Point2D(2*sqrt(2), 0))
```

See also:

*sympy.geometry.point.Point* (page 2277)

**focus_distance** (page 2334)

Returns the distance between focus and center

**property focus_distance**

The focal distance of the ellipse.

The distance between the center and one focus.

**Returns**

*focus_distance* : number

Examples

```python
>>> from sympy import Point, Ellipse
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, 1)
>>> e1.focus_distance
2*sqrt(2)
```

See also:

*foci* (page 2334)
property hradius

The horizontal radius of the ellipse.

Returns
hradius: number

Examples

```python
>>> from sympy import Point, Ellipse
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, 1)
>>> e1.hradius
3
```

See also:

vradius (page 2344), major (page 2336), minor (page 2337)

intersection(o)

The intersection of this ellipse and another geometrical entity o.

Parameters
o: GeometryEntity

Returns
intersection: list of GeometryEntity objects

Notes

Currently supports intersections with Point, Line, Segment, Ray, Circle and Ellipse types.

Examples

```python
>>> from sympy import Ellipse, Point, Line
>>> e = Ellipse(Point(0, 0), 5, 7)
>>> e.intersection(Point(0, 0))
[]
>>> e.intersection(Point(5, 0))
[Point2D(5, 0)]
>>> e.intersection(Line(Point(0,0), Point(0, 1)))
[Point2D(0, -7), Point2D(0, 7)]
>>> e.intersection(Line(Point(5,0), Point(5, 1)))
[Point2D(5, 0)]
>>> e.intersection(Line(Point(6,0), Point(6, 1)))
[]
>>> e = Ellipse(Point(-1, 0), 4, 3)
>>> e.intersection(Ellipse(Point(1, 0), 4, 3))
[Point2D(0, -3*sqrt(15)/4), Point2D(0, 3*sqrt(15)/4)]
>>> e.intersection(Ellipse(Point(5, 0), 4, 3))
[Point2D(2, -3*sqrt(7)/4), Point2D(2, 3*sqrt(7)/4)]
```

(continues on next page)
See also:  

`sympy.geometry.entity.GeometryEntity` (page 2269)

```
>>> e.intersection(Ellipse(Point(100500, 0), 4, 3))
[]
>>> e.intersection(Ellipse(Point(0, 0), 3, 4))
[Point2D(3, 0), Point2D(-363/175, -48*sqrt(111)/175), Point2D(-363/175, 48*sqrt(111)/175)]
>>> e.intersection(Ellipse(Point(-1, 0), 3, 4))
[Point2D(-17/5, -12/5), Point2D(-17/5, 12/5), Point2D(7/5, -12/5), Point2D(7/5, -12/5)]
```

```python

See also:

`sympy.geometry.entity.GeometryEntity` (page 2269)

```python
is_tangent(o)
```

Is o tangent to the ellipse?

**Parameters**

- o : GeometryEntity
  
  An Ellipse, LinearEntity or Polygon

**Returns**

- is_tangent: boolean
  
  True if o is tangent to the ellipse, False otherwise.

**Raises**

- `NotImplementedError`
  
  When the wrong type of argument is supplied.

**Examples**

```python
>>> from sympy import Point, Ellipse, Line
>>> p0, p1, p2 = Point(0, 0), Point(3, 0), Point(3, 3)
>>> e1 = Ellipse(p0, 3, 2)
>>> l1 = Line(p1, p2)
>>> e1.is_tangent(l1)
True
```

See also:

`tangent_lines` (page 2343)

**property major**

Longer axis of the ellipse (if it can be determined) else hradius.

**Returns**

- major: number or expression
Examples

```python
>>> from sympy import Point, Ellipse, Symbol
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, 1)
>>> e1.major
3

>>> a = Symbol('a')
>>> b = Symbol('b')
>>> Ellipse(p1, a, b).major
a
>>> Ellipse(p1, b, a).major
b

>>> m = Symbol('m')
>>> M = m + 1
>>> Ellipse(p1, m, M).major
m + 1
```

See also:

`hradius` (page 2334), `vradius` (page 2344), `minor` (page 2337)

**property minor**
Shorter axis of the ellipse (if it can be determined) else vradius.

**Returns**

`minor`: number or expression

Examples

```python
>>> from sympy import Point, Ellipse, Symbol
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, 1)
>>> e1.minor
1

>>> a = Symbol('a')
>>> b = Symbol('b')
>>> Ellipse(p1, a, b).minor
b
>>> Ellipse(p1, b, a).minor
a

>>> m = Symbol('m')
>>> M = m + 1
>>> Ellipse(p1, m, M).minor
m
```

See also:

`hradius` (page 2334), `vradius` (page 2344), `major` (page 2336)
normal_lines\(p, \text{prec=None}\)

Normal lines between \(p\) and the ellipse.

**Parameters**

\(p\) : Point

**Returns**

normal_lines : list with 1, 2 or 4 Lines

**Examples**

```python
>>> from sympy import Point, Ellipse
>>> e = Ellipse((0, 0), 2, 3)
>>> c = e.center
>>> e.normal_lines(c + Point(1, 0))
[Line2D(Point2D(0, 0), Point2D(1, 0))]
```

Off-axis points require the solution of a quartic equation. This often leads to very large expressions that may be of little practical use. An approximate solution of \(\text{prec}\) digits can be obtained by passing in the desired value:

```python
>>> e.normal_lines((3, 3), prec=2)
[Line2D(Point2D(-0.81, -2.7), Point2D(0.19, -1.2)), Line2D(Point2D(1.5, -2.0), Point2D(2.5, -2.7))]
```

Whereas the above solution has an operation count of 12, the exact solution has an operation count of 2020.

**property periapsis**

The periapsis of the ellipse.

The shortest distance between the focus and the contour.

**Returns**

periapsis : number

**Examples**

```python
>>> from sympy import Point, Ellipse
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, 1)
>>> e1.periapsis
3 - 2*sqrt(2)
```

**See also:**

apoapsis (page 2329)

Returns greatest distance between focus and contour
plot_interval\((parameter='t')\)

The plot interval for the default geometric plot of the Ellipse.

**Parameters**

- **parameter**: str, optional
  Default value is ‘t’.

**Returns**

- **plot_interval**: list
  [parameter, lower_bound, upper_bound]

**Examples**

```python
>>> from sympy import Point, Ellipse
>>> e1 = Ellipse(Point(0, 0), 3, 2)
>>> e1.plot_interval()
[t, -pi, pi]
```

polar_second_moment_of_area()

Returns the polar second moment of area of an Ellipse

It is a constituent of the second moment of area, linked through the perpendicular axis theorem. While the planar second moment of area describes an object’s resistance to deflection (bending) when subjected to a force applied to a plane parallel to the central axis, the polar second moment of area describes an object’s resistance to deflection when subjected to a moment applied in a plane perpendicular to the object’s central axis (i.e. parallel to the cross-section)

**Examples**

```python
>>> from sympy import symbols, Circle, Ellipse
>>> c = Circle((5, 5), 4)
>>> c.polar_second_moment_of_area()
128*pi
>>> a, b = symbols('a, b')
>>> e = Ellipse((0, 0), a, b)
>>> e.polar_second_moment_of_area()
pi*a**3*b/4 + pi*a*b**3/4
```

**References**

[R520]

random_point\((seed=None)\)

A random point on the ellipse.

**Returns**

- **point**: Point
Examples

```python
>>> from sympy import Point, Ellipse
>>> e1 = Ellipse(Point(0, 0), 3, 2)
>>> e1.random_point()  # gives some random point
Point2D(...)
>>> p1 = e1.random_point(seed=0); p1.n(2)
Point2D(2.1, 1.4)
```

Notes

When creating a random point, one may simply replace the parameter with a random number. When doing so, however, the random number should be made a Rational or else the point may not test as being in the ellipse:

```python
>>> from sympy.abc import t
>>> from sympy import Rational
>>> arb = e1.arbitrary_point(t); arb
Point2D(3*cos(t), 2*sin(t))
>>> arb.subs(t, .1) in e1
False
>>> arb.subs(t, Rational(.1)) in e1
True
>>> arb.subs(t, Rational('.1')) in e1
True
```

See also:

* `sympy.geometry.point.Point` (page 2277)

`arbitrary_point` (page 2329)

Returns parameterized point on ellipse

`reflect(line)`

Override GeometryEntity.reflect since the radius is not a GeometryEntity.

Examples

```python
>>> from sympy import Circle, Line
>>> Circle((0, 1), 1).reflect(Line((0, 0), (1, 1)))
Circle(Point2D(1, 0), -1)
>>> from sympy import Ellipse, Line, Point
>>> Ellipse(Point(3, 4), 1, 3).reflect(Line(Point(0, -4), Point(5, -4)))
Traceback (most recent call last):
...
NotImplementedError:
General Ellipse is not supported but the equation of the reflected
Ellipse is given by the zeros of: f(x, y) = (9*x/41 + 40*y/41 +
37/41)**2 + (40*x/123 - 3*y/41 - 364/123)**2 - 1
```
Notes

Until the general ellipse (with no axis parallel to the x-axis) is supported a NotImplemented error is raised and the equation whose zeros define the rotated ellipse is given.

rotate(angle=0, pt=None)
Rotate angle radians counterclockwise about Point pt.
Note: since the general ellipse is not supported, only rotations that are integer multiples of pi/2 are allowed.

Examples

```python
>>> from sympy import Ellipse, pi
>>> Ellipse((1, 0), 2, 1).rotate(pi/2)
Ellipse(Point2D(0, 1), 1, 2)
>>> Ellipse((1, 0), 2, 1).rotate(pi)
Ellipse(Point2D(-1, 0), 2, 1)
```

scale(x=1, y=1, pt=None)
Override GeometryEntity.scale since it is the major and minor axes which must be scaled and they are not GeometryEntities.

Examples

```python
>>> from sympy import Ellipse
>>> Ellipse((0, 0), 2, 1).scale(2, 4)
Circle(Point2D(0, 0), 4)
>>> Ellipse((0, 0), 2, 1).scale(2)
Ellipse(Point2D(0, 0), 4, 1)
```

second_moment_of_area(point=None)
Returns the second moment and product moment area of an ellipse.

Parameters

point : Point, two-tuple of sympifiable objects, or None(default=None)
point is the point about which second moment of area is to be found. If “point=None” it will be calculated about the axis passing through the centroid of the ellipse.

Returns

$I_{xx}, I_{yy}, I_{xy}$ : number or SymPy expression
$I_{xx}, I_{yy}$ are second moment of area of an ellipse. $I_{xy}$ is product moment of area of an ellipse.
Examples

```python
>>> from sympy import Point, Ellipse
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, 1)
>>> e1.second_moment_of_area()
(3*pi/4, 27*pi/4, 0)
```

References

[R521]

`section_modulus(point=None)`

Returns a tuple with the section modulus of an ellipse

Section modulus is a geometric property of an ellipse defined as the ratio of second moment of area to the distance of the extreme end of the ellipse from the centroidal axis.

Parameters

- **point**: Point, two-tuple of sympifyable objects, or None (default=None)

  point is the point at which section modulus is to be found. If “point=None” section modulus will be calculated for the point farthest from the centroidal axis of the ellipse.

Returns

- **S_x, S_y**: numbers or SymPy expressions

  S_x is the section modulus with respect to the x-axis S_y is the section modulus with respect to the y-axis A negative sign indicates that the section modulus is determined for a point below the centroidal axis.

Examples

```python
>>> from sympy import Symbol, Ellipse, Circle, Point2D
>>> d = Symbol('d', positive=True)
>>> c = Circle((0, 0), d/2)
>>> c.section_modulus()
(pi*d**3/32, pi*d**3/32)
>>> e = Ellipse(Point2D(0, 0), 2, 4)
>>> e.section_modulus()
(8*pi, 4*pi)
>>> e.section_modulus((2, 2))
(16*pi, 4*pi)
```
References

[R522]

**property semilatus_rectum**

Calculates the semi-latus rectum of the Ellipse.

Semi-latus rectum is defined as one half of the chord through a focus parallel to the conic section directrix of a conic section.

**Returns**

`semilatus_rectum`: number

**Examples**

```python
>>> from sympy import Point, Ellipse
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, 1)
>>> e1.semilatus_rectum
1/3
```

See also:

- **apoapsis** (page 2329)
  Returns greatest distance between focus and contour
- **periapsis** (page 2338)
  The shortest distance between the focus and the contour

References

[R523], [R524]

**tangent_lines**(*p*)

Tangent lines between *p* and the ellipse.

If *p* is on the ellipse, returns the tangent line through point *p*. Otherwise, returns the tangent line(s) from *p* to the ellipse, or None if no tangent line is possible (e.g., *p* inside ellipse).

**Parameters**

- *p*: Point

**Returns**

- `tangent_lines`: list with 1 or 2 Lines

**Raises**

- `NotImplementedError`

  Can only find tangent lines for a point, *p*, on the ellipse.
Examples

```python
>>> from sympy import Point, Ellipse
>>> e1 = Ellipse(Point(0, 0), 3, 2)
>>> e1.tangent_lines(Point(3, 0))
[Line2D(Point2D(3, 0), Point2D(3, -12))]
```

See also:

* `sympy.geometry.point.Point` (page 2277), `sympy.geometry.line.Line` (page 2303)

property vradius

The vertical radius of the ellipse.

Returns

vradius : number

Examples

```python
>>> from sympy import Point, Ellipse
>>> p1 = Point(0, 0)
>>> e1 = Ellipse(p1, 3, 1)
>>> e1.vradius
1
```

See also:

* `hradius` (page 2334), `major` (page 2336), `minor` (page 2337)

class sympy.geometry.ellipse.Circle(*args, **kwargs)

A circle in space.

Constructed simply from a center and a radius, from three non-collinear points, or the equation of a circle.

Parameters

- center : Point
- radius : number or SymPy expression
- points : sequence of three Points
- equation : equation of a circle

 Raises

- GeometryError

When the given equation is not that of a circle. When trying to construct circle from incorrect parameters.
Examples

```python
>>> from sympy import Point, Circle, Eq
>>> from sympy.abc import x, y, a, b

A circle constructed from a center and radius:

```python
>>> c1 = Circle(Point(0, 0), 5)
```  
```python
>>> c1.hradius, c1.vradius, c1.radius
(5, 5, 5)
```

A circle constructed from three points:

```python
>>> c2 = Circle(Point(0, 0), Point(1, 1), Point(1, 0))
>>> c2.hradius, c2.vradius, c2.radius, c2.center
(sqrt(2)/2, sqrt(2)/2, sqrt(2)/2, Point2D(1/2, 1/2))
```

A circle can be constructed from an equation in the form \(a * x^2 + b * y^2 + g * x + h * y + c = 0\), too:

```python
>>> Circle(x**2 + y**2 - 25)
Circle(Point2D(0, 0), 5)
```

If the variables corresponding to \(x\) and \(y\) are named something else, their name or symbol can be supplied:

```python
>>> Circle(Eq(a**2 + b**2, 25), x='a', y=b)
Circle(Point2D(0, 0), 5)
```

See also:

Ellipse (page 2328), sympy.geometry.point.Point (page 2277)

Attributes

- radius (synonymous with hradius, vradius, major and minor)
- circumference
- equation

property circumference

The circumference of the circle.

Returns

- circumference : number or SymPy expression
Examples

```python
>>> from sympy import Point, Circle
>>> c1 = Circle(Point(3, 4), 6)
>>> c1.circumference
12*pi
```

equation(x='x', y='y')

The equation of the circle.

**Parameters**

- `x`: str or Symbol, optional
  - Default value is 'x'.
- `y`: str or Symbol, optional
  - Default value is 'y'.

**Returns**

- `equation`: SymPy expression

Examples

```python
>>> from sympy import Point, Circle
>>> c1 = Circle(Point(0, 0), 5)
>>> c1.equation()
\(x^2 + y^2 - 25\)
```

intersection(o)

The intersection of this circle with another geometrical entity.

**Parameters**

- `o`: GeometryEntity

**Returns**

- `intersection`: list of GeometryEntities

Examples

```python
>>> from sympy import Point, Circle, Line, Ray
>>> p1, p2, p3 = Point(0, 0), Point(5, 5), Point(6, 0)
>>> p4 = Point(5, 0)
>>> c1 = Circle(p1, 5)
>>> c1.intersection(p2)
[]
>>> c1.intersection(p4)
[Point2D(5, 0)]
>>> c1.intersection(Ray(p1, p2))
[Point2D(5*sqrt(2)/2, 5*sqrt(2)/2)]
>>> c1.intersection(Line(p2, p3))
[]
```
property radius

The radius of the circle.

Returns
radius : number or SymPy expression

Examples

```python
>>> from sympy import Point, Circle
>>> c1 = Circle(Point(3, 4), 6)
>>> c1.radius
6
```

See also:

Ellipse.major (page 2336), Ellipse.minor (page 2337), Ellipse.hradius (page 2334), Ellipse.vradius (page 2344)

reflect(line)

Override GeometryEntity.reflect since the radius is not a GeometryEntity.

Examples

```python
>>> from sympy import Circle, Line
>>> Circle((0, 1), 1).reflect(Line((0, 0), (1, 1)))
Circle(Point2D(1, 0), -1)
```

scale(x=1, y=1, pt=None)

Override GeometryEntity.scale since the radius is not a GeometryEntity.

Examples

```python
>>> from sympy import Circle
>>> Circle((0, 0), 1).scale(2, 2)
Circle(Point2D(0, 0), 2)
>>> Circle((0, 0), 1).scale(2, 4)
Ellipse(Point2D(0, 0), 2, 4)
```

property vradius

This Ellipse property is an alias for the Circle’s radius.

Whereas hradius, major and minor can use Ellipse’s conventions, the vradius does not exist for a circle. It is always a positive value in order that the Circle, like Polygons, will have an area that can be positive or negative as determined by the sign of the hradius.
Examples

```python
>>> from sympy import Point, Circle
>>> c1 = Circle(Point(3, 4), 6)
>>> c1.vradius
6
```

Polygons

```python
class sympy.geometry.polygon.Polygon(*args, n=0, **kwargs)
A two-dimensional polygon.
A simple polygon in space. Can be constructed from a sequence of points or from a
center, radius, number of sides and rotation angle.

Parameters
vertices
A sequence of points.
n : int, optional
If > 0, an n-sided RegularPolygon is created. Default value is 0.

Raises
GeometryError
If all parameters are not Points.

Notes
Polygons are treated as closed paths rather than 2D areas so some calculations can be
be negative or positive (e.g., area) based on the orientation of the points.
Any consecutive identical points are reduced to a single point and any points collinear
and between two points will be removed unless they are needed to define an explicit
intersection (see examples).
A Triangle, Segment or Point will be returned when there are 3 or fewer points provided.

Examples

```python
>>> from sympy import Polygon, pi
>>> p1, p2, p3, p4, p5 = [(0, 0), (1, 0), (5, 1), (0, 1), (3, 0)]
>>> Polygon(p1, p2, p3, p4, p5)
Polygon(Point2D(0, 0), Point2D(1, 0), Point2D(5, 1), Point2D(0, 1))
```

The area of a polygon is calculated as positive when vertices are traversed in a ccw
direction. When the sides of a polygon cross the area will have positive and negative
contributions. The following defines a Z shape where the bottom right connects back to the top left.

```python
>>> Polygon((0, 2), (2, 2), (0, 0), (2, 0)).area
0
```

When the keyword $n$ is used to define the number of sides of the Polygon then a RegularPolygon is created and the other arguments are interpreted as center, radius and rotation. The unrotated RegularPolygon will always have a vertex at Point($r$, 0) where $r$ is the radius of the circle that circumscribes the RegularPolygon. Its method spin can be used to increment that angle.

```python
>>> p = Polygon((0,0), 1, n=3)
>>> p
RegularPolygon(Point2D(0, 0), 1, 3, 0)
>>> p.vertices[0]
Point2D(1, 0)
>>> p.args[0]
Point2D(0, 0)
>>> p.spin(pi/2)
>>> p.vertices[0]
Point2D(0, 1)
```

See also:
sympy.geometry.point.Point (page 2277), sympy.geometry.line.Segment (page 2308), Triangle (page 2368)

Attributes

- **area**
- **angles**
- **perimeter**
- **vertices**
- **centroid**
- **sides**

**property angles**

The internal angle at each vertex.

Returns

- **angles** : dict
  
  A dictionary where each key is a vertex and each value is the internal angle at that vertex. The vertices are represented as Points.
Examples

```python
>>> from sympy import Point, Polygon
>>> p1, p2, p3, p4 = map(Point, [(0, 0), (1, 0), (5, 1), (0, 1)])
>>> poly = Polygon(p1, p2, p3, p4)
>>> poly.angles[p1]
pi/2
>>> poly.angles[p2]
acos(-4*sqrt(17)/17)
```

See also:

- `sympy.geometry.point.Point` (page 2277), `sympy.geometry.line.LinearEntity.angle_between` (page 2291)

`arbitrary_point`(parameter='t')

A parameterized point on the polygon.

The parameter, varying from 0 to 1, assigns points to the position on the perimeter that is that fraction of the total perimeter. So the point evaluated at t=1/2 would return the point from the first vertex that is 1/2 way around the polygon.

**Parameters**

- `parameter`: str, optional
  - Default value is ‘t’.

**Returns**

- `arbitrary_point`: Point

**Raises**

- `ValueError`
  - When `parameter` already appears in the Polygon’s definition.

Examples

```python
>>> from sympy import Polygon, Symbol
>>> t = Symbol('t', real=True)
>>> tri = Polygon((0, 0), (1, 0), (1, 1))
>>> p = tri.arbitrary_point('t')
>>> perimeter = tri.perimeter
>>> s1, s2 = [s.length for s in tri.sides[:2]]
>>> p.subs(t, (s1 + s2/2)/perimeter)
Point2D(1, 1/2)
```

See also:

- `sympy.geometry.point.Point` (page 2277)

**property area**

The area of the polygon.
Notes

The area calculation can be positive or negative based on the orientation of the points. If any side of the polygon crosses any other side, there will be areas having opposite signs.

Examples

```python
>>> from sympy import Point, Polygon
>>> p1, p2, p3, p4 = map(Point, [(0, 0), (1, 0), (5, 1), (0, 1)])
>>> poly = Polygon(p1, p2, p3, p4)
>>> poly.area
3
```

In the Z shaped polygon (with the lower right connecting back to the upper left) the areas cancel out:

```python
>>> Z = Polygon((0, 1), (1, 1), (0, 0), (1, 0))
>>> Z.area
0
```

In the M shaped polygon, areas do not cancel because no side crosses any other (though there is a point of contact).

```python
>>> M = Polygon((0, 0), (0, 1), (2, 0), (3, 1), (3, 0))
>>> M.area
-3/2
```

See also:
- `sympy.geometry.ellipse.Ellipse.area` (page 2330)

`bisectors` *(prec=None)*

Returns angle bisectors of a polygon. If prec is given then approximate the point defining the ray to that precision.

The distance between the points defining the bisector ray is 1.

Examples

```python
>>> from sympy import Polygon, Point
>>> p = Polygon(Point(0, 0), Point(2, 0), Point(1, 1), Point(0, 3))
>>> p.bisectors(2)
{Point2D(0, 0): Ray2D(Point2D(0, 0), Point2D(0.71, 0.71)),
 Point2D(0, 3): Ray2D(Point2D(0, 3), Point2D(0.23, 2.0)),
 Point2D(1, 1): Ray2D(Point2D(1, 1), Point2D(0.19, 0.42)),
 Point2D(2, 0): Ray2D(Point2D(2, 0), Point2D(1.1, 0.38))}
```

`property bounds`

Return a tuple (xmin, ymin, xmax, ymax) representing the bounding rectangle for the geometric figure.
property centroid

The centroid of the polygon.

Returns

centroid : Point

Examples

```python
>>> from sympy import Point, Polygon
>>> p1, p2, p3, p4 = map(Point, [(0, 0), (1, 0), (5, 1), (0, 1)])
>>> poly = Polygon(p1, p2, p3, p4)
>>> poly.centroid
Point2D(31/18, 11/18)
```

See also:

sympy.geometry.point.Point (page 2277), sympy.geometry.util.centroid (page 2275)

cut_section(line)

Returns a tuple of two polygon segments that lie above and below the intersecting line respectively.

Parameters

- line: Line object of geometry module

  line which cuts the Polygon. The part of the Polygon that lies above and below this line is returned.

Returns

- upper_polygon, lower_polygon: Polygon objects or None

  upper_polygon is the polygon that lies above the given line. lower_polygon is the polygon that lies below the given line. upper_polygon and lower polygon are None when no polygon exists above the line or below the line.

Raises

- ValueError: When the line does not intersect the polygon

Examples

```python
>>> from sympy import Polygon, Line
>>> a, b = 20, 10
>>> p1, p2, p3, p4 = [(0, b), (0, 0), (a, 0), (a, b)]
>>> rectangle = Polygon(p1, p2, p3, p4)
>>> t = rectangle.cut_section(Line((0, 5), slope=0))
>>> t
(Polygon(Point2D(0, 10), Point2D(0, 5), Point2D(20, 5), Point2D(20, 0)),
 Polygon(Point2D(0, 5), Point2D(0, 0), Point2D(20, 0), Point2D(20, 5)))
>>> upper_segment, lower_segment = t
>>> upper_segment.area
100
```

(continues on next page)
upper_segment.centroid
Point2D(10, 15/2)

lower_segment.centroid
Point2D(10, 5/2)

References

[R525]
distance(o)

Returns the shortest distance between self and o.
If o is a point, then self does not need to be convex. If o is another polygon self and o must be convex.

Examples

from sympy import Point, Polygon, RegularPolygon
>>> p1, p2 = map(Point, [(0, 0), (7, 5)])
>>> poly = Polygon(*RegularPolygon(p1, 1, 3).vertices)
>>> poly.distance(p2)
sqrt(61)

encloses_point(p)

Return True if p is enclosed by (is inside of) self.

Parameters
p : Point

Returns
encloses_point : True, False or None

Notes

Being on the border of self is considered False.

Examples

from sympy import Polygon, Point
>>> p = Polygon((0, 0), (4, 0), (4, 4))
>>> p.encloses_point(Point(2, 1))
True
>>> p.encloses_point(Point(2, 2))
False
>>> p.encloses_point(Point(5, 5))
False
See also:

```
sympy.geometry.point.Point  (page 2277),  sympy.geometry.ellipse.Ellipse. encloses_point  (page 2332)
```

References

[R526]

first_moment_of_area(point=None)

Returns the first moment of area of a two-dimensional polygon with respect to a certain point of interest.

First moment of area is a measure of the distribution of the area of a polygon in relation to an axis. The first moment of area of the entire polygon about its own centroid is always zero. Therefore, here it is calculated for an area, above or below a certain point of interest, that makes up a smaller portion of the polygon. This area is bounded by the point of interest and the extreme end (top or bottom) of the polygon. The first moment for this area is then determined about the centroidal axis of the initial polygon.

Parameters

point: Point, two-tuple of sympifyable objects, or None (default=None)

point is the point above or below which the area of interest lies If point=None then the centroid acts as the point of interest.

Returns

Q_x, Q_y: number or SymPy expressions

Q_x is the first moment of area about the x-axis Q_y is the first moment of area about the y-axis A negative sign indicates that the section modulus is determined for a section below (or left of) the centroidal axis

Examples

```python
>>> from sympy import Point, Polygon
>>> a, b = 50, 10
>>> p1, p2, p3, p4 = [(0, b), (0, 0), (a, 0), (a, b)]
>>> p = Polygon(p1, p2, p3, p4)
>>> p.first_moment_of_area()
(625, 3125)
>>> p.first_moment_of_area(point=Point(30, 7))
(525, 3000)
```
**References**

[R527], [R528]

**intersection(o)**

The intersection of polygon and geometry entity.

The intersection may be empty and can contain individual Points and complete Line Segments.

**Parameters**

other: GeometryEntity

**Returns**

Intersection: list

The list of Segments and Points

**Examples**

```python
>>> from sympy import Point, Polygon, Line
>>> p1, p2, p3, p4 = map(Point, [(0, 0), (1, 0), (5, 1), (0, 1)])
>>> poly1 = Polygon(p1, p2, p3, p4)
>>> p5, p6, p7 = map(Point, [(3, 2), (1, -1), (0, 2)])
>>> poly2 = Polygon(p5, p6, p7)
>>> poly1.intersection(poly2)
[Point2D(1/3, 1), Point2D(2/3, 0), Point2D(9/5, 1/5), Point2D(7/3, 1)]
>>> poly1.intersection(Line(p1, p2))
[Segment2D(Point2D(0, 0), Point2D(1, 0))]
>>> poly1.intersection(p1)
[Point2D(0, 0)]
```

**See also:**

`sympy.geometry.point.Point` (page 2277), `sympy.geometry.line.Segment` (page 2308)

**is_convex()**

Is the polygon convex?

A polygon is convex if all its interior angles are less than 180 degrees and there are no intersections between sides.

**Returns**

is_convex: boolean

True if this polygon is convex, False otherwise.
Examples

```python
>>> from sympy import Point, Polygon
>>> p1, p2, p3, p4 = map(Point, [(0, 0), (1, 0), (5, 1), (0, 1)])
>>> poly = Polygon(p1, p2, p3, p4)
>>> poly.is_convex()
True
```

See also:

`sympy.geometry.util.convex_hull` (page 2273)

property `perimeter`

The perimeter of the polygon.

   Returns
   perimeter : number or Basic instance

Examples

```python
>>> from sympy import Point, Polygon
>>> p1, p2, p3, p4 = map(Point, [(0, 0), (1, 0), (5, 1), (0, 1)])
>>> poly = Polygon(p1, p2, p3, p4)
>>> poly.perimeter
sqrt(17) + 7
```

See also:

`sympy.geometry.line.Segment.length` (page 2310)

`plot_interval`(parameter='t')

The plot interval for the default geometric plot of the polygon.

   Parameters
   parameter : str, optional
     Default value is ‘t’.
   Returns
   plot_interval : list (plot interval)
     [parameter, lower_bound, upper_bound]

Examples

```python
>>> from sympy import Polygon
>>> p = Polygon((0, 0), (1, 0), (1, 1))
>>> p.plot_interval()
[t, 0, 1]
```

`polar_second_moment_of_area()`

Returns the polar modulus of a two-dimensional polygon
It is a constituent of the second moment of area, linked through the perpendicular axis theorem. While the planar second moment of area describes an object’s resistance to deflection (bending) when subjected to a force applied to a plane parallel to the central axis, the polar second moment of area describes an object’s resistance to deflection when subjected to a moment applied in a plane perpendicular to the object’s central axis (i.e. parallel to the cross-section)

Examples

```python
>>> from sympy import Polygon, symbols
>>> a, b = symbols('a, b')
>>> rectangle = Polygon((0, 0), (a, 0), (a, b), (0, b))
>>> rectangle.polar_second_moment_of_area()
a**3*b/12 + a*b**3/12
```

References

[R529]

**second_moment_of_area**(point=None)

Returns the second moment and product moment of area of a two dimensional polygon.

Parameters

- **point**: Point, two-tuple of sympifiable objects, or None(default=None)
  point is the point about which second moment of area is to be found. If “point=None” it will be calculated about the axis passing through the centroid of the polygon.

Returns

- I_xx, I_yy, I_xy : number or SymPy expression

  I_xx, I_yy are second moment of area of a two dimensional polygon. I_xy is product moment of area of a two dimensional polygon.

Examples

```python
>>> from sympy import Polygon, symbols
>>> a, b = symbols('a, b')
>>> p1, p2, p3, p4, p5 = [(0, 0), (a, 0), (a, b), (0, b), (a/3, b/3)]
>>> rectangle = Polygon(p1, p2, p3, p4)
>>> rectangle.second_moment_of_area()
(a*b**3/12, a**3*b/12, 0)
>>> rectangle.second_moment_of_area(p5)
(a*b**3/9, a**3*b/9, a**2*b**2/36)
```
References

[R530]

section_modulus(point=None)

Returns a tuple with the section modulus of a two-dimensional polygon.

Section modulus is a geometric property of a polygon defined as the ratio of second moment of area to the distance of the extreme end of the polygon from the centroidal axis.

Parameters

point : Point, two-tuple of sympifiable objects, or None (default=None)

point is the point at which section modulus is to be found. If "point=None" it will be calculated for the point farthest from the centroidal axis of the polygon.

Returns

S_x, S_y: numbers or SymPy expressions

S_x is the section modulus with respect to the x-axis S_y is the section modulus with respect to the y-axis A negative sign indicates that the section modulus is determined for a point below the centroidal axis.

Examples

```python
>>> from sympy import symbols, Polygon, Point
>>> a, b = symbols('a, b', positive=True)
>>> rectangle = Polygon((0, 0), (a, 0), (a, b), (0, b))
>>> rectangle.section_modulus()
(a*b**2/6, a**2*b/6)
>>> rectangle.section_modulus(Point(a/4, b/4))
(-a*b**2/3, -a**2*b/3)
```

References

[R531]

property sides

The directed line segments that form the sides of the polygon.

Returns

sides : list of sides

Each side is a directed Segment.
Examples

```python
>>> from sympy import Point, Polygon
>>> p1, p2, p3, p4 = map(Point, [(0, 0), (1, 0), (5, 1), (0, 1)])
>>> poly = Polygon(p1, p2, p3, p4)
>>> poly.sides
[Segment2D(Point2D(0, 0), Point2D(1, 0)),
 Segment2D(Point2D(1, 0), Point2D(5, 1)),
 Segment2D(Point2D(5, 1), Point2D(0, 1)), Segment2D(Point2D(0, 1),
 →Point2D(0, 0))]
```

See also:

- `sympy.geometry.point.Point` (page 2277), `sympy.geometry.line.Segment` (page 2308)

**property vertices**

The vertices of the polygon.

**Returns**

- `vertices` : list of Points

**Notes**

When iterating over the vertices, it is more efficient to index `self` rather than to request the vertices and index them. Only use the vertices when you want to process all of them at once. This is even more important with RegularPolygons that calculate each vertex.

Examples

```python
>>> from sympy import Point, Polygon
>>> p1, p2, p3, p4 = map(Point, [(0, 0), (1, 0), (5, 1), (0, 1)])
>>> poly = Polygon(p1, p2, p3, p4)
>>> poly.vertices
[Point2D(0, 0), Point2D(1, 0), Point2D(5, 1), Point2D(0, 1)]
>>> poly.vertices[0]
Point2D(0, 0)
```

See also:

- `sympy.geometry.point.Point` (page 2277)

**class** `sympy.geometry.polygon.RegularPolygon(c, r, n, rot=0, **kwargs)`

A regular polygon.

Such a polygon has all internal angles equal and all sides the same length.

**Parameters**

- `center` : Point
- `radius` : number or Basic instance
  The distance from the center to a vertex
- `n` : int
The number of sides

**Raises**  
**GeometryError**

If the `center` is not a Point, or the `radius` is not a number or Basic instance, or the number of sides, `n`, is less than three.

**Notes**

A RegularPolygon can be instantiated with Polygon with the kwarg `n`.

Regular polygons are instantiated with a center, radius, number of sides and a rotation angle. Whereas the arguments of a Polygon are vertices, the vertices of the Regular-Polygon must be obtained with the vertices method.

**Examples**

```python
>>> from sympy import RegularPolygon, Point
>>> r = RegularPolygon(Point(0, 0), 5, 3)
>>> r
RegularPolygon(Point2D(0, 0), 5, 3, 0)
>>> r.vertices[0]
Point2D(5, 0)
```

**See also:**

* sympy.geometry.point.Point (page 2277), Polygon (page 2348) *

**Attributes**

<table>
<thead>
<tr>
<th>vertices</th>
<th>center</th>
<th>radius</th>
<th>rotation</th>
<th>apothem</th>
<th>interior_angle</th>
<th>exterior_angle</th>
<th>circumcircle</th>
<th>incircle</th>
<th>angles</th>
</tr>
</thead>
</table>

**property angles**

Returns a dictionary with keys, the vertices of the Polygon, and values, the interior angle at each vertex.
Examples

```python
>>> from sympy import RegularPolygon, Point
>>> r = RegularPolygon(Point(0, 0), 5, 3)
>>> r.angles
{Point2D(-5/2, -5*sqrt(3)/2): pi/3,
 Point2D(-5/2, 5*sqrt(3)/2): pi/3,
 Point2D(5, 0): pi/3}
```

**property apothem**

The inradius of the RegularPolygon.

The apothem/inradius is the radius of the inscribed circle.

**Returns**

| apothem : number or instance of Basic

Examples

```python
>>> from sympy import Symbol
>>> from sympy import RegularPolygon, Point
>>> radius = Symbol('r')
>>> rp = RegularPolygon(Point(0, 0), radius, 4)
>>> rp.apothem
sqrt(2)*r/2
```

See also:

- `sympy.geometry.line.Segment.length` (page 2310), `sympy.geometry.ellipse.Circle.radius` (page 2346)

**property area**

Returns the area.

Examples

```python
>>> from sympy import RegularPolygon
>>> square = RegularPolygon((0, 0), 1, 4)
>>> square.area
2
>>> _ == square.length**2
True
```

**property args**

Returns the center point, the radius, the number of sides, and the orientation angle.
Examples

```python
>>> from sympy import RegularPolygon, Point
>>> r = RegularPolygon(Point(0, 0), 5, 3)
>>> r.args
(Point2D(0, 0), 5, 3, 0)
```

property `center`

The center of the `RegularPolygon`

This is also the center of the circumscribing circle.

Returns

```
center : Point
```

Examples

```python
>>> from sympy import RegularPolygon, Point
>>> rp = RegularPolygon(Point(0, 0), 5, 4)
>>> rp.center
Point2D(0, 0)
```

See also:

`sympy.geometry.point.Point` (page 2277), `sympy.geometry.ellipse.Ellipse.center` (page 2331)

property `centroid`

The center of the `RegularPolygon`

This is also the center of the circumscribing circle.

Returns

```
center : Point
```

Examples

```python
>>> from sympy import RegularPolygon, Point
>>> rp = RegularPolygon(Point(0, 0), 5, 4)
>>> rp.center
Point2D(0, 0)
```

See also:

`sympy.geometry.point.Point` (page 2277), `sympy.geometry.ellipse.Ellipse.center` (page 2331)

property `circumcenter`

Alias for `center`.

Examples

```python
>>> from sympy import RegularPolygon, Point
>>> rp = RegularPolygon(Point(0, 0), 5, 4)
>>> rp.circumcenter
Point2D(0, 0)
```

**property circumcircle**

The circumcircle of the RegularPolygon.

Returns
- **circumcircle**: Circle

**Examples**

```python
>>> from sympy import RegularPolygon, Point
>>> rp = RegularPolygon(Point(0, 0), 4, 8)
>>> rp.circumcircle
Circle(Point2D(0, 0), 4)
```

See also:
- `circumcenter` (page 2362), `sympy.geometry.ellipse.Circle` (page 2344)

**property circumradius**

Alias for radius.

**Examples**

```python
>>> from sympy import Symbol

>>> from sympy import RegularPolygon, Point

>>> radius = Symbol('r')

>>> rp = RegularPolygon(Point(0, 0), radius, 4)
>>> rp.circumradius
r
```

**encloses_point(p)**

Return True if p is enclosed by (is inside of) self.

Parameters
- **p**: Point

Returns
- **encloses_point**: True, False or None
Notes

Being on the border of self is considered False.
The general Polygon.encloses_point method is called only if a point is not within or beyond the incircle or circumcircle, respectively.

Examples

```python
>>> from sympy import RegularPolygon, S, Point, Symbol
>>> p = RegularPolygon((0, 0), 3, 4)
>>> p.encloses_point(Point(0, 0))
True
>>> r, R = p.inradius, p.circumradius
>>> p.encloses_point(Point((r + R)/2, 0))
True
>>> p.encloses_point(Point(R/2, R/2 + (R - r)/10))
False
>>> t = Symbol('t', real=True)
>>> p.encloses_point(p.arbitrary_point().subs(t, S.Half))
False
>>> p.encloses_point(Point(5, 5))
False
```

See also:

* [sympy.geometry.ellipse.Ellipse.encloses_point](page2332)

**property exterior_angle**

Measure of the exterior angles.

**Returns**

* `exterior_angle` : number

Examples

```python
>>> from sympy import RegularPolygon, Point
>>> rp = RegularPolygon(Point(0, 0), 4, 8)
>>> rp.exterior_angle
pi/4
```

See also:

* [sympy.geometry.line.LinearEntity.angle_between](page2291)

**property incircle**

The incircle of the RegularPolygon.

**Returns**

* `incircle` : Circle
Examples

```python
>>> from sympy import RegularPolygon, Point
>>> rp = RegularPolygon(Point(0, 0), 4, 7)
>>> rp.incircle
Circle(Point2D(0, 0), 4*cos(pi/7))
```

See also:

`inradius` (page 2365), `sympy.geometry.ellipse.Circle` (page 2344)

property inradius

Alias for apothem.

Examples

```python
>>> from sympy import Symbol
>>> from sympy import RegularPolygon, Point
>>> radius = Symbol('r')
>>> rp = RegularPolygon(Point(0, 0), radius, 4)
>>> rp.inradius
sqrt(2)*r/2
```

property interior_angle

Measure of the interior angles.

Returns

- `interior_angle` : number

Examples

```python
>>> from sympy import RegularPolygon, Point
>>> rp = RegularPolygon(Point(0, 0), 4, 8)
>>> rp.interior_angle
3*pi/4
```

See also:

`sympy.geometry.line.LinearEntity.angle_between` (page 2291)

property length

Returns the length of the sides.

The half-length of the side and the apothem form two legs of a right triangle whose hypotenuse is the radius of the regular polygon.
Examples

```python
>>> from sympy import RegularPolygon
>>> from sympy import sqrt
>>> s = square_in_unit_circle = RegularPolygon((0, 0), 1, 4)
>>> s.length
sqrt(2)
>>> sqrt((_/2)**2 + s.apothem**2) == s.radius
True
```

property `radius`

Radius of the RegularPolygon

This is also the radius of the circumscribing circle.

Returns

`radius` : number or instance of Basic

Examples

```python
>>> from sympy import Symbol
>>> from sympy import RegularPolygon, Point
>>> radius = Symbol('r')
>>> rp = RegularPolygon(Point(0, 0), radius, 4)
>>> rp.radius
r
```

See also:

`sympy.geometry.line.Segment.length` (page 2310), `sympy.geometry.ellipse.Circle.radius` (page 2346)

`reflect(line)`

Override GeometryEntity.reflect since this is not made of only points.

Examples

```python
>>> from sympy import RegularPolygon, Line
```

```python
>>> RegularPolygon((0, 0), 1, 4).reflect(Line((0, 1), slope=-2))
RegularPolygon(Point2D(4/5, 2/5), -1, 4, atan(4/3))
```

`rotate(angle, pt=None)`

Override GeometryEntity.rotate to first rotate the RegularPolygon about its center.

```python
>>> from sympy import Point, RegularPolygon, pi
>>> t = RegularPolygon(Point(1, 0), 1, 3)
>>> t.vertices[0] # vertex on x-axis
Point2D(2, 0)
>>> t.rotate(pi/2).vertices[0] # vertex on y axis now
Point2D(0, 2)
```
See also:

rotation (page 2367)

spin (page 2367)
  Rotates a RegularPolygon in place

property rotation
  CCW angle by which the RegularPolygon is rotated

    Returns
    rotation : number or instance of Basic

Examples

```python
>>> from sympy import pi
>>> from sympy import RegularPolygon, Point
>>> RegularPolygon(Point(0, 0), 3, 4, pi/4).rotation
pi/4
```

Numerical rotation angles are made canonical:

```python
>>> RegularPolygon(Point(0, 0), 3, 4, a).rotation
a
>>> RegularPolygon(Point(0, 0), 3, 4, pi).rotation
0
```

scale(x=1, y=1, pt=None)

Override GeometryEntity.scale since it is the radius that must be scaled (if x == y) or else a new Polygon must be returned.

```python
>>> from sympy import RegularPolygon
```

Symmetric scaling returns a RegularPolygon:

```python
>>> RegularPolygon((0, 0), 1, 4).scale(2, 2)
RegularPolygon(Point2D(0, 0), 2, 4, 0)
```

Asymmetric scaling returns a kite as a Polygon:

```python
>>> RegularPolygon((0, 0), 1, 4).scale(2, 1)
Polygon(Point2D(2, 0), Point2D(0, 1), Point2D(-2, 0), Point2D(0, -1))
```

spin(angle)

Increment in place the virtual Polygon’s rotation by ccw angle.

See also: rotate method which moves the center.

```python
>>> from sympy import Polygon, Point, pi
>>> r = Polygon(Point(0,0), 1, n=3)
>>> r.vertices[0]
Point2D(1, 0)
>>> r.spin(pi/6)
```
See also:
rotation (page 2367)
rotate (page 2366)
Creates a copy of the RegularPolygon rotated about a Point

property vertices
The vertices of the RegularPolygon.

Returns
vertices : list
Each vertex is a Point.

Examples

```python
>>> from sympy import RegularPolygon, Point
>>> rp = RegularPolygon(Point(0, 0), 5, 4)
>>> rp.vertices
[Point2D(5, 0), Point2D(0, 5), Point2D(-5, 0), Point2D(0, -5)]
```

See also:
sympy.geometry.point.Point (page 2277)

class sympy.geometry.polygon.Triangle(*args, **kwargs)
A polygon with three vertices and three sides.

Parameters
points : sequence of Points

keyword: asa, sas, or sss to specify sides/angles of the triangle

Raises
GeometryError
If the number of vertices is not equal to three, or one of the vertices
is not a Point, or a valid keyword is not given.

Examples

```python
>>> from sympy import Triangle, Point
>>> Triangle(Point(0, 0), Point(4, 0), Point(4, 3))
Triangle(Point2D(0, 0), Point2D(4, 0), Point2D(4, 3))
```

Keywords sss, sas, or asa can be used to give the desired side lengths (in order) and
interior angles (in degrees) that define the triangle:
```
>>> Triangle(sss=(3, 4, 5))
Triangle(Point2D(0, 0), Point2D(3, 0), Point2D(3, 4))
>>> Triangle(asa=(30, 1, 30))
Triangle(Point2D(0, 0), Point2D(1, 0), Point2D(1/2, sqrt(3)/6))
>>> Triangle(sas=(1, 45, 2))
Triangle(Point2D(0, 0), Point2D(2, 0), Point2D(sqrt(2)/2, sqrt(2)/2))
```

See also:

`sympy.geometry.point.Point` (page 2277), `Polygon` (page 2348)

**Attributes**

- **vertices**
- **altitudes**
- **orthocenter**
- **circumcenter**
- **circumradius**
- **circumcircle**
- **inradius**
- **incircle**
- **exradii**
- **medians**
- **medial**
- **nine_point_circle**

**property altitudes**

The altitudes of the triangle.

An altitude of a triangle is a segment through a vertex, perpendicular to the opposite side, with length being the height of the vertex measured from the line containing the side.

**Returns**

**altitudes** : dict

The dictionary consists of keys which are vertices and values which are Segments.

**Examples**

```
>>> from sympy import Point, Triangle
>>> p1, p2, p3 = Point(0, 0), Point(1, 0), Point(0, 1)
>>> t = Triangle(p1, p2, p3)
>>> t.altitudes[p1]
Segment2D(Point2D(0, 0), Point2D(1/2, 1/2))
```

See also:

`sympy.geometry.point.Point` (page 2277), `sympy.geometry.line.Segment.length` (page 2310)
bisectors()

The angle bisectors of the triangle.
An angle bisector of a triangle is a straight line through a vertex which cuts the corresponding angle in half.

Returns

bisectors : dict

Each key is a vertex (Point) and each value is the corresponding bisector (Segment).

Examples

```python
>>> from sympy import Point, Triangle, Segment
>>> p1, p2, p3 = Point(0, 0), Point(1, 0), Point(0, 1)
>>> t = Triangle(p1, p2, p3)
>>> from sympy import sqrt
>>> t.bisectors()[p2] == Segment(Point(1, 0), Point(0, sqrt(2) - 1))
True
```

See also:
sympy.geometry.point.Point (page 2277), sympy.geometry.line.Segment (page 2308)

property circumcenter

The circumcenter of the triangle
The circumcenter is the center of the circumcircle.

Returns

circumcenter : Point

Examples

```python
>>> from sympy import Point, Triangle
>>> p1, p2, p3 = Point(0, 0), Point(1, 0), Point(0, 1)
>>> t = Triangle(p1, p2, p3)
>>> t.circumcenter
Point2D(1/2, 1/2)
```

See also:
sympy.geometry.point.Point (page 2277)

property circumcircle

The circle which passes through the three vertices of the triangle.

Returns

circumcircle : Circle
Examples

```python
>>> from sympy import Point, Triangle
>>> p1, p2, p3 = Point(0, 0), Point(1, 0), Point(0, 1)
>>> t = Triangle(p1, p2, p3)
>>> t.circumcircle
Circle(Point2D(1/2, 1/2), sqrt(2)/2)
```

See also:
`sympy.geometry.ellipse.Circle` (page 2344)

property circumradius
The radius of the circumcircle of the triangle.

Returns
circumradius : number of Basic instance

Examples

```python
>>> from sympy import Symbol
>>> from sympy import Point, Triangle
>>> a = Symbol('a')
>>> p1, p2, p3 = Point(0, 0), Point(1, 0), Point(0, a)
>>> t = Triangle(p1, p2, p3)
>>> t.circumradius
sqrt(a**2/4 + 1/4)
```

See also:
`sympy.geometry.ellipse.Circle.radius` (page 2346)

property eulerline
The Euler line of the triangle.

The line which passes through circumcenter, centroid and orthocenter.

Returns
eulerline : Line (or Point for equilateral triangles in which case all
centers coincide)

Examples

```python
>>> from sympy import Point, Triangle
>>> p1, p2, p3 = Point(0, 0), Point(1, 0), Point(0, 1)
>>> t = Triangle(p1, p2, p3)
>>> t.eulerline
Line2D(Point2D(0, 0), Point2D(1/2, 1/2))
```

property excenters
Excenters of the triangle.

An excenter is the center of a circle that is tangent to a side of the triangle and the
extensions of the other two sides.
Returns

**excenters** : dict

**Examples**

The excenters are keyed to the side of the triangle to which their corresponding excircle is tangent: The center is keyed, e.g. the excenter of a circle touching side 0 is:

```python
>>> from sympy import Point, Triangle
>>> p1, p2, p3 = Point(0, 0), Point(6, 0), Point(0, 2)
>>> t = Triangle(p1, p2, p3)
>>> t.excenters[t.sides[0]]
Point2D(12*sqrt(10), 2/3 + sqrt(10)/3)
```

**See also:**

*sympy.geometry.polygon.Triangle.exradii* (page 2372)

**References**

[R532]

**property exradii**

The radius of excircles of a triangle.

An excircle of the triangle is a circle lying outside the triangle, tangent to one of its sides and tangent to the extensions of the other two.

Returns

**exradii** : dict

**Examples**

The exradius touches the side of the triangle to which it is keyed, e.g. the exradius touching side 2 is:

```python
>>> from sympy import Point, Triangle
>>> p1, p2, p3 = Point(0, 0), Point(6, 0), Point(0, 2)
>>> t = Triangle(p1, p2, p3)
>>> t.exradii[t.sides[2]]
-2 + sqrt(10)
```

**See also:**

*sympy.geometry.polygon.Triangle.inradius* (page 2373)
property incenter

The center of the incircle.
The incircle is the circle which lies inside the triangle and touches all three sides.

Returns

incenter : Point

Examples

```python
>>> from sympy import Point, Triangle
>>> p1, p2, p3 = Point(0, 0), Point(1, 0), Point(0, 1)
>>> t = Triangle(p1, p2, p3)
>>> t.incenter
Point2D(1 - sqrt(2)/2, 1 - sqrt(2)/2)
```

See also:

* incircle (page 2373), sympy.geometry.point.Point (page 2277)

property incircle

The incircle of the triangle.
The incircle is the circle which lies inside the triangle and touches all three sides.

Returns

incircle : Circle

Examples

```python
>>> from sympy import Point, Triangle
>>> p1, p2, p3 = Point(0, 0), Point(2, 0), Point(0, 2)
>>> t = Triangle(p1, p2, p3)
>>> t.incircle
Circle(Point2D(2 - sqrt(2), 2 - sqrt(2)), 2 - sqrt(2))
```

See also:

* sympy.geometry.ellipse.Circle (page 2344)

property inradius

The radius of the incircle.

Returns

inradius : number of Basic instance
Examples

```python
>>> from sympy import Point, Triangle
>>> p1, p2, p3 = Point(0, 0), Point(4, 0), Point(0, 3)
>>> t = Triangle(p1, p2, p3)
>>> t.inradius
1
```

See also:

`incircle` (page 2373), `sympy.geometry.ellipse.Circle.radius` (page 2346)

**is_equilateral()**

Are all the sides the same length?

**Returns**

`is_equilateral` : boolean

Examples

```python
>>> from sympy import Triangle, Point
>>> t1 = Triangle(Point(0, 0), Point(4, 0), Point(4, 3))
>>> t1.is_equilateral()
False

>>> from sympy import sqrt
>>> t2 = Triangle(Point(0, 0), Point(10, 0), Point(5, 5*sqrt(3)))
>>> t2.is_equilateral()
True
```

See also:

`sympy.geometry.entity.GeometryEntity.is_similar` (page 2270), `RegularPolygon` (page 2359), `is_isosceles` (page 2374), `is_right` (page 2374), `is_scalene` (page 2375)

**is_isosceles()**

Are two or more of the sides the same length?

**Returns**

`is_isosceles` : boolean

Examples

```python
>>> from sympy import Triangle, Point
>>> t1 = Triangle(Point(0, 0), Point(4, 0), Point(2, 4))
>>> t1.is_isosceles()
True
```

See also:

`is_equilateral` (page 2374), `is_right` (page 2374), `is_scalene` (page 2375)
is_right()
Is the triangle right-angled.

Returns
is_right : boolean

Examples

```python
>>> from sympy import Triangle, Point
>>> t1 = Triangle(Point(0, 0), Point(4, 0), Point(4, 3))
>>> t1.is_right()
True
```

See also:

* sympy.geometry.line.LinearEntity.is_perpendicular (page 2296),
  * is_equilateral (page 2374), is_isosceles (page 2374), is_scalene (page 2375)

is_scalene()
Are all the sides of the triangle of different lengths?

Returns
is_scalene : boolean

Examples

```python
>>> from sympy import Triangle, Point
>>> t1 = Triangle(Point(0, 0), Point(4, 0), Point(1, 4))
>>> t1.is_scalene()
True
```

See also:

* is_equilateral (page 2374), is_isosceles (page 2374), is_right (page 2374)

is_similar(t2)
Is another triangle similar to this one.
Two triangles are similar if one can be uniformly scaled to the other.

Parameters
other : Triangle

Returns
is_similar : boolean
Examples

```python
from sympy import Triangle, Point

>>> t1 = Triangle(Point(0, 0), Point(4, 0), Point(4, 3))
>>> t2 = Triangle(Point(0, 0), Point(-4, 0), Point(-4, -3))
>>> t1.is_similar(t2)
True

>>> t2 = Triangle(Point(0, 0), Point(-4, 0), Point(-4, -4))
>>> t1.is_similar(t2)
False
```

See also:

sympy.geometry.entity.GeometryEntity.is_similar (page 2270)

property medial

The medial triangle of the triangle.

The triangle which is formed from the midpoints of the three sides.

Returns

medial : Triangle

Examples

```python
from sympy import Point, Triangle

>>> p1, p2, p3 = Point(0, 0), Point(1, 0), Point(0, 1)
>>> t = Triangle(p1, p2, p3)
>>> t.medial
Triangle(Point2D(1/2, 0), Point2D(1/2, 1/2), Point2D(0, 1/2))
```

See also:

sympy.geometry.line.Segment.midpoint (page 2310)

property medians

The medians of the triangle.

A median of a triangle is a straight line through a vertex and the midpoint of the opposite side, and divides the triangle into two equal areas.

Returns

medians : dict

Each key is a vertex (Point) and each value is the median (Segment) at that point.
Examples

```python
>>> from sympy import Point, Triangle
>>> p1, p2, p3 = Point(0, 0), Point(1, 0), Point(0, 1)
>>> t = Triangle(p1, p2, p3)
>>> t.medians[p1]
Segment2D(Point2D(0, 0), Point2D(1/2, 1/2))
```

See also:
- `sympy.geometry.point.Point.midpoint` (page 2282), `sympy.geometry.line.Segment.midpoint` (page 2310)

**property nine_point_circle**

The nine-point circle of the triangle.

Nine-point circle is the circumcircle of the medial triangle, which passes through the feet of altitudes and the middle points of segments connecting the vertices and the orthocenter.

Returns

```
nine_point_circle : Circle
```

Examples

```python
>>> from sympy import Point, Triangle
>>> p1, p2, p3 = Point(0, 0), Point(1, 0), Point(0, 1)
>>> t = Triangle(p1, p2, p3)
>>> t.nine_point_circle
Circle(Point2D(1/4, 1/4), sqrt(2)/4)
```

See also:
- `sympy.geometry.line.Segment.midpoint` (page 2310), `sympy.geometry.polygon.Triangle.medial` (page 2376), `sympy.geometry.polygon.Triangle.orthocenter` (page 2377)

**property orthocenter**

The orthocenter of the triangle.

The orthocenter is the intersection of the altitudes of a triangle. It may lie inside, outside or on the triangle.

Returns

```
orthocenter : Point
```
Examples

```python
>>> from sympy import Point, Triangle
>>> p1, p2, p3 = Point(0, 0), Point(1, 0), Point(0, 1)
>>> t = Triangle(p1, p2, p3)
>>> t.orthocenter
Point2D(0, 0)
```

See also:

`sympy.geometry.point.Point` (page 2277)

**property vertices**

The triangle’s vertices

Returns

vertices : tuple

Each element in the tuple is a Point

Examples

```python
>>> from sympy import Triangle, Point
>>> t = Triangle(Point(0, 0), Point(4, 0), Point(4, 3))
>>> t.vertices
(Point2D(0, 0), Point2D(4, 0), Point2D(4, 3))
```

See also:

`sympy.geometry.point.Point` (page 2277)

Plane

```python
class sympy.geometry.plane.Plane(p1, a=None, b=None, **kwargs)
```

A plane is a flat, two-dimensional surface. A plane is the two-dimensional analogue of a point (zero-dimensions), a line (one-dimension) and a solid (three-dimensions). A plane can generally be constructed by two types of inputs. They are three non-collinear points and a point and the plane’s normal vector.

Examples

```python
>>> from sympy import Plane, Point3D
>>> Plane(Point3D(1, 1, 1), Point3D(2, 3, 4), Point3D(2, 2, 2))
>>> Plane(Point3D(1, 1, 1), (-1, 2, -1))
>>> Plane((1, 1, 1), (2, 3, 4), (2, 2, 2))
>>> Plane(Point3D(1, 1, 1), (-1, 2, -1))
>>> Plane(Point3D(1, 1, 1), normal_vector=(1, 4, 7))
>>> Plane(Point3D(1, 1, 1), (1, 4, 7))
```
Attributes

 angle_between(o)
 Angle between the plane and other geometric entity.

 Parameters
  LinearEntity3D, Plane.

 Returns
  angle : angle in radians

 Notes
 This method accepts only 3D entities as it's parameter, but if you want to calculate
 the angle between a 2D entity and a plane you should first convert to a 3D entity by
 projecting onto a desired plane and then proceed to calculate the angle.

 Examples

 >>> from sympy import Point3D, Line3D, Plane
 >>> a = Plane(Point3D(1, 2, 2), normal_vector=(1, 2, 3))
 >>> b = Line3D(Point3D(1, 3, 4), Point3D(2, 2, 2))
 >>> a.angle_between(b)
 -asin(sqrt(21)/6)

 arbitrary_point(u=None, v=None)
 Returns an arbitrary point on the Plane. If given two parameters, the point ranges
 over the entire plane. If given 1 or no parameters, returns a point with one param-
 eter which, when varying from 0 to 2*pi, moves the point in a circle of radius 1 about
 p1 of the Plane.

 Returns
  Point3D

 Examples

 >>> from sympy import Plane, Ray
 >>> from sympy.abc import u, v, t, r
 >>> p = Plane((1, 1, 1), normal_vector=(1, 0, 0))
 >>> p.arbitrary_point(u, v)
 Point3D(1, u + 1, v + 1)
 >>> p.arbitrary_point(t)
 Point3D(1, cos(t) + 1, sin(t) + 1)

 While arbitrary values of u and v can move the point anywhere in the plane, the
 single-parameter point can be used to construct a ray whose arbitrary point can be
 located at angle t and radius r from p.p1:
static are_concurrent(*planes)

Is a sequence of Planes concurrent?

Two or more Planes are concurrent if their intersections are a common line.

Parameters
planes: list

Returns
Boolean

Examples

```python
>>> from sympy import Plane, Point3D
>>> a = Plane(Point3D(5, 0, 0), normal_vector=(1, -1, 1))
>>> b = Plane(Point3D(0, -2, 0), normal_vector=(3, 1, 1))
>>> c = Plane(Point3D(0, -1, 0), normal_vector=(5, -1, 9))
>>> Plane.are_concurrent(a, b)
True
>>> Plane.are_concurrent(a, b, c)
False
```

distance(o)

Distance between the plane and another geometric entity.

Parameters
Point3D, LinearEntity3D, Plane.

Returns
distance

Notes

This method accepts only 3D entities as it’s parameter; but if you want to calculate the distance between a 2D entity and a plane you should first convert to a 3D entity by projecting onto a desired plane and then proceed to calculate the distance.

Examples

```python
>>> from sympy import Point3D, Line3D, Plane
>>> a = Plane(Point3D(1, 1, 1), normal_vector=(1, 1, 1))
>>> b = Point3D(1, 2, 3)
>>> a.distance(b)
sqrt(3)
>>> c = Line3D(Point3D(2, 3, 1), Point3D(1, 2, 2))
>>> a.distance(c)
0
```
equals(o)
Returns True if self and o are the same mathematical entities.

Examples

```python
>>> from sympy import Plane, Point3D
>>> a = Plane(Point3D(1, 2, 3), normal_vector=(1, 1, 1))
>>> b = Plane(Point3D(1, 2, 3), normal_vector=(2, 2, 2))
>>> c = Plane(Point3D(1, 2, 3), normal_vector=(-1, 4, 6))
>>> a.equals(a)
True
>>> a.equals(b)
True
>>> a.equals(c)
False
```

equation(x=None, y=None, z=None)
The equation of the Plane.

Examples

```python
>>> from sympy import Point3D, Plane
>>> a = Plane(Point3D(1, 1, 2), Point3D(2, 4, 7), Point3D(3, 5, 1))
>>> a.equation()
-23*x + 11*y - 2*z + 16
>>> a = Plane(Point3D(1, 4, 2), normal_vector=(6, 6, 6))
>>> a.equation()
6*x + 6*y + 6*z - 42
```

intersection(o)
The intersection with other geometrical entity.

Parameters
Plane, Point3D, LinearEntity, LinearEntity3D

Returns
List

Examples

```python
>>> from sympy import Point3D, Line3D, Plane
>>> a = Plane(Point3D(1, 2, 3), normal_vector=(1, 1, 1))
>>> b = Point3D(1, 2, 3)
>>> a.intersection(b)
[Point3D(1, 2, 3)]
>>> c = Line3D(Point3D(1, 4, 7), Point3D(2, 2, 2))
>>> a.intersection(c)
[Point3D(2, 2, 2)]
>>> d = Plane(Point3D(6, 0, 0), normal_vector=(2, -5, 3))
```
is_coplanar(o)
Returns True if o is coplanar with self, else False.

Examples

```python
>>> from sympy import Plane
>>> o = (0, 0, 0)
>>> p = Plane(o, (1, 1, 1))
>>> p2 = Plane(o, (2, 2, 2))
>>> p == p2
False
>>> p.is_coplanar(p2)
True
```

is_parallel(l)
Is the given geometric entity parallel to the plane?

Parameters
LinearEntity3D or Plane

Returns
Boolean

Examples

```python
>>> from sympy import Plane, Point3D
>>> a = Plane(Point3D(1,4,6), normal_vector=(2, 4, 6))
>>> b = Plane(Point3D(3,1,3), normal_vector=(4, 8, 12))
>>> a.is_parallel(b)
True
```

is_perpendicular(l)
Is the given geometric entity perpendicular to the given plane?

Parameters
LinearEntity3D or Plane

Returns
Boolean
Examples

```python
>>> from sympy import Plane, Point3D
>>> a = Plane(Point3D(1, 4, 6), normal_vector=(2, 4, 6))
>>> b = Plane(Point3D(2, 2, 2), normal_vector=(-1, 2, -1))
>>> a.is_perpendicular(b)
True
```

property normal_vector
Normal vector of the given plane.

Examples

```python
>>> from sympy import Plane, Point3D
>>> a = Plane(Point3D(1, 1, 1), Point3D(2, 3, 4), Point3D(2, 2, 2))
>>> a.normal_vector
(-1, 2, -1)
>>> a = Plane(Point3D(1, 1, 1), normal_vector=(1, 4, 7))
>>> a.normal_vector
(1, 4, 7)
```

property p1
The only defining point of the plane. Others can be obtained from the arbitrary_point method.

Examples

```python
>>> from sympy import Plane, Point3D
>>> a = Plane(Point3D(1, 1, 1), Point3D(2, 3, 4), Point3D(2, 2, 2))
>>> a.p1
Point3D(1, 1, 1)
```

See also:
sympy.geometry.point.Point3D (page 2286)

parallel_plane(pt)
Plane parallel to the given plane and passing through the point pt.

Parameters
pt: Point3D

Returns
Plane
SymPy Documentation, Release 1.12.1

Examples

```python
>>> from sympy import Plane, Point3D
>>> a = Plane(Point3D(1, 4, 6), normal_vector=(2, 4, 6))
>>> a.parallel_plane(Point3D(2, 3, 5))
Plane(Point3D(2, 3, 5), (2, 4, 6))
```

**parameter_value**(other, u=None, v=None)

Return the parameter(s) corresponding to the given point.

Examples

```python
>>> from sympy import pi, Plane
>>> from sympy import pi
>>> from sympy import t, u, v

>>> p = Plane((2, 0, 0), (0, 0, 1), (0, 1, 0))
By default, the parameter value returned defines a point that is a distance of 1 from
the Plane’s p1 value and in line with the given point:

```python
>>> on_circle = p.arbitrary_point(t).subs(t, pi/4)
>>> on_circle.distance(p.p1)
1
>>> p.parameter_value(on_circle, t)
{t: pi/4}
```

Moving the point twice as far from p1 does not change the parameter value:

```python
>>> off_circle = p.p1 + (on_circle - p.p1)*2
>>> off_circle.distance(p.p1)
2
>>> p.parameter_value(off_circle, t)
{t: pi/4}
```

If the 2-value parameter is desired, supply the two parameter symbols and a replacement
dictionary will be returned:

```python
>>> p.parameter_value(on_circle, u, v)
{u: sqrt(10)/10, v: sqrt(10)/30}
>>> p.parameter_value(off_circle, u, v)
{u: sqrt(10)/5, v: sqrt(10)/15}
```

**perpendicular_line**(pt)

A line perpendicular to the given plane.

Parameters

- **pt**: Point3D

Returns

Line3D
Examples

```python
>>> from sympy import Plane, Point3D
>>> a = Plane(Point3D(1, 4, 6), normal_vector=(2, 4, 6))
>>> a.perpendicular_line(Point3D(9, 8, 7))
Line3D(Point3D(9, 8, 7), Point3D(11, 12, 13))
```

perpendicular_plane(*pts)
Return a perpendicular passing through the given points. If the direction ratio between the points is the same as the Plane's normal vector then, to select from the infinite number of possible planes, a third point will be chosen on the z-axis (or the y-axis if the normal vector is already parallel to the z-axis). If less than two points are given they will be supplied as follows: if no point is given then p1 will be self.p1; if a second point is not given it will be a point through p1 on a line parallel to the z-axis (if the normal is not already the z-axis, otherwise on the line parallel to the y-axis).

Parameters
pts: 0, 1 or 2 Point3D

Returns
Plane

Examples

```python
>>> from sympy import Plane, Point3D
>>> a, b = Point3D(0, 0, 0), Point3D(0, 1, 0)
>>> Z = (0, 0, 1)
>>> p = Plane(a, normal_vector=Z)
>>> p.perpendicular_plane(a, b)
Plane(Point3D(0, 0, 0), (1, 0, 0))
```

projection(pt)
Project the given point onto the plane along the plane normal.

Parameters
Point or Point3D

Returns
Point3D

Examples

```python
>>> from sympy import Plane, Point3D
>>> A = Plane(Point3D(1, 1, 2), normal_vector=(1, 1, 1))
```

The projection is along the normal vector direction, not the z axis, so (1, 1) does not project to (1, 1, 2) on the plane A:

```python
>>> b = Point3D(1, 1)
>>> A.projection(b)
Point3D(5/3, 5/3, 2/3)
```
But the point (1, 1, 2) projects to (1, 1) on the XY-plane:

```python
>>> XY = Plane((0, 0, 0), (0, 0, 1))
>>> XY.projection((1, 1, 2))
Point3D(1, 1, 0)
```

**project_line(line)**

Project the given line onto the plane through the normal plane containing the line.

**Parameters**

- **LinearEntity or LinearEntity3D**

**Returns**

- Point3D, Line3D, Ray3D or Segment3D

**Notes**

For the interaction between 2D and 3D lines (segments, rays), you should convert the line to 3D by using this method. For example for finding the intersection between a 2D and a 3D line, convert the 2D line to a 3D line by projecting it on a required plane and then proceed to find the intersection between those lines.

**Examples**

```python
>>> from sympy import Plane, Line, Line3D, Point3D
>>> a = Plane(Point3D(1, 1, 1), normal_vector=(1, 1, 1))
>>> b = Line(Point3D(1, 1), Point3D(2, 2))
>>> a.project_line(b)
Line3D(Point3D(4/3, 4/3, 1/3), Point3D(5/3, 5/3, -1/3))
>>> c = Line3D(Point3D(1, 1, 1), Point3D(2, 2, 2))
>>> a.project_line(c)
Point3D(1, 1, 1)
```

**random_point(seed=None)**

Returns a random point on the Plane.

**Returns**

- Point3D
Examples

```python
>>> from sympy import Plane
>>> p = Plane((1, 0, 0), normal_vector=(0, 1, 0))
>>> r = p.random_point(seed=42)  # seed value is optional
>>> r.n(3)
Point3D(2.29, 0, -1.35)
```

The random point can be moved to lie on the circle of radius 1 centered on p1:

```python
>>> c = p.p1 + (r - p.p1).unit
>>> c.distance(p.p1).equals(1)
True
```

Holonomic

The holonomic (page 2387) module is intended to deal with holonomic functions along with various operations on them like addition, multiplication, composition, integration and differentiation. The module also implements various kinds of conversions such as converting holonomic functions to a different form and the other way around.

Contents

About Holonomic Functions

This text aims to explain holonomic functions. We assume you have a basic idea of Differential equations and Abstract algebra.

Definition

Holonomic function is a very general type of special function that includes lots of simple known functions as its special cases. In fact the more known hypergeometric function and Meijer G-function are also a special case of it.

A function is called holonomic if it’s a solution to an ordinary differential equation having polynomial coefficients only. Since the general solution of a differential equation consists of a family of functions rather than a single function, holonomic functions are usually defined by a set of initial conditions along with the differential equation.

Let $K$ be a field of characteristic 0. For example, $K$ can be QQ or RR. A function $f(x)$ will be holonomic if there exists polynomials $p_0, p_1, p_2, ... p_r \in K[x]$ such that

$$p_0 \cdot f(x) + p_1 \cdot f^{(1)}(x) + p_2 \cdot f^{(2)}(x) + ... + p_r \cdot f^{(r)}(x) = 0$$

This differential equation can also be written as $L \cdot f(x) = 0$ where

$$L = p_0 + p_1 \cdot D + p_2 \cdot D^2 + ... p_r \cdot D^r$$

Here $D$ is the Differential Operator and $L$ is called the annihilator of the function.
A unique holonomic function can be defined from the annihilator and a set of initial conditions. For instance:

\[
\begin{align*}
  f(x) &= \exp(x) : L = D - 1, \ f(0) = 1 \\
  f(x) &= \sin(x) : L = D^2 + 1, \ f(0) = 0, \ f'(0) = 1
\end{align*}
\]

Other fundamental functions such as \( \cos(x) \), \( \log(x) \), bessel functions etc. are also holonomic. The family of holonomic functions is closed under addition, multiplication, integration, composition. This means if two functions are given are holonomic, then the function resulting on applying these operation on them will also be holonomic.

Representation of holonomic functions in SymPy

Class \texttt{DifferentialOperator} (page 2390) is used to represent the annihilator but we create differential operators easily using the function \texttt{DifferentialOperators()} (page 2390). Class \texttt{HolonomicFunction} (page 2388) represents a holonomic function.

Let’s explain this with an example:

Take \( \sin(x) \) for instance, the differential equation satisfied by it is \( y''(x) + y(x) = 0 \). By definition we conclude it is a holonomic function. The general solution of this ODE is \( C_1 \cdot \sin(x) + C_2 \cdot \cos(x) \) but to get \( \sin(x) \) we need to provide initial conditions i.e. \( y(0) = 0, \ y'(0) = 1 \).

To represent the same in this module one needs to provide the differential equation in the form of annihilator. Basically a differential operator is an operator on functions that differentiates them. So \( D^n \cdot y(x) = y^{(n)}(x) \) where \( y^{(n)}(x) \) denotes \( n \) times differentiation of \( y(x) \) with respect to \( x \).

So the differential equation can also be written as \( D^2 \cdot y(x) + y(x) = 0 \) or \( (D^2 + 1) \cdot y(x) = 0 \). The part left of \( y(x) \) is the annihilator i.e. \( D^2 + 1 \).

So this is how one will represent \( \sin(x) \) as a Holonomic Function:

```python
>>> from sympy.holonomic import DifferentialOperators, HolonomicFunction
>>> from sympy.abc import x
>>> R, D = DifferentialOperators(ZZ.old_poly_ring(x), 'D')
>>> HolonomicFunction(D**2 + 1, x, 0, [0, 1])
HolonomicFunction((1) + (1)*D**2, x, 0, [0, 1])
```

The polynomial coefficients will be members of the ring \( \mathbb{Z}[x] \) in the example. The \( D \) operator returned by the function \texttt{DifferentialOperators()} (page 2390) can be used to create annihilators just like SymPy expressions. We currently use the older implementations of rings in SymPy for priority mechanism.

class sympy.holonomic.holonomic.HolonomicFunction(annihilator, x, x0=0, y0=None)

A Holonomic Function is a solution to a linear homogeneous ordinary differential equation with polynomial coefficients. This differential equation can also be represented by an annihilator i.e. a Differential Operator \( L \) such that \( Lf = 0 \). For uniqueness of these functions, initial conditions can also be provided along with the annihilator.
Explanation

Holonomic functions have closure properties and thus forms a ring. Given two Holonomic Functions f and g, their sum, product, integral and derivative is also a Holonomic Function.

For ordinary points initial condition should be a vector of values of the derivatives i.e. \([y(x_0), y'(x_0), y''(x_0)]\).

For regular singular points initial conditions can also be provided in this format:

\(s_0 : [C_0, C_1, ...], s_1 : [C_0, C_1, ...], ...\) where \(s_0, s_1, ...
\) are the roots of indicial equation and vectors \([C_0, C_1, ...], [C_0, C_1, ...], ...\) are the corresponding initial terms of the associated power series. See Examples below.

Examples

```python
>>> from sympy.holonomic.holonomic import HolonomicFunction,
    DifferentialOperators
>>> from sympy import QQ
>>> from sympy import symbols, S
>>> x = symbols('x')
>>> R, Dx = DifferentialOperators(QQ.old_poly_ring(x), 'Dx')
>>> p = HolonomicFunction(Dx - 1, x, 0, [1])  # e^x
>>> q = HolonomicFunction(Dx**2 + 1, x, 0, [0, 1])  # sin(x)

>>> p + q  # annihilator of e^x + sin(x)
HolonomicFunction((-1) + (1)*Dx + (-1)*Dx**2 + (1)*Dx**3, x, 0, [1, 2, 1])

>>> p * q  # annihilator of e^x * sin(x)
HolonomicFunction((2) + (-2)*Dx + (1)*Dx**2, x, 0, [0, 1])
```

An example of initial conditions for regular singular points, the indicial equation has only one root 1/2.

```python
>>> HolonomicFunction(-S(1)/2 + x*Dx, x, 0, {S(1)/2: [1]})
HolonomicFunction((-1/2) + (x)*Dx, x, 0, [1/2: [1]])
```

To plot a Holonomic Function, one can use `.evalf()` for numerical computation. Here's an example on \(\sin(x) * 2/x\) using numpy and matplotlib.

```python
>>> import sympy.holonomic
>>> from sympy import var, sin
>>> import matplotlib.pyplot as plt
>>> import numpy as np
>>> var("x")
>>> r = np.linspace(1, 5, 100)
>>> y = sympy.holonomic.expr_to_holonomic(sin(x)**2/x, x0=1).evalf(r)
```

(continues on next page)
class sympy.holonomic.holonomic.DifferentialOperator(list_of_poly, parent)

Differential Operators are elements of Weyl Algebra. The Operators are defined by a list of polynomials in the base ring and the parent ring of the Operator i.e. the algebra it belongs to.

Explanation

Takes a list of polynomials for each power of \(Dx\) and the parent ring which must be an instance of DifferentialOperatorAlgebra.

A Differential Operator can be created easily using the operator \(Dx\). See examples below.

Examples

```python
>>> from sympy.holonomic.holonomic import DifferentialOperator,
    DifferentialOperators
>>> from sympy import ZZ
>>> from sympy import symbols
>>> x = symbols('x')
>>> R, Dx = DifferentialOperators(ZZ.old_poly_ring(x), 'Dx')

>>> DifferentialOperator([0, 1, x**2], R)
(1)*Dx + (x**2)*Dx**2

>>> (x**2*Dx*x + 1 - Dx**2)**2
(2*x**2 + 2*x + 1) + (4*x**3 + 2*x**2 - 4)*Dx + (x**4 - 6*x - 2)*Dx**2 + (-2*x**2)*Dx**3 + (1)*Dx**4
```

See also:

DifferentialOperatorAlgebra (page 2391)

is_singular\((x0)\)

Checks if the differential equation is singular at \(x0\).

sympy.holonomic.holonomic.DifferentialOperators\((base, generator)\)

This function is used to create annihilators using \(Dx\).

Parameters

base:

Base polynomial ring for the algebra. The base polynomial ring is the ring of polynomials in \(x\) that will appear as coefficients in the operators.

generator:

Generator of the algebra which can be either a noncommutative Symbol or a string. e.g. “Dx” or “D”.

---

2390 Chapter 5. API Reference
Explanation

Returns an Algebra of Differential Operators also called Weyl Algebra and the operator for differentiation i.e. the $Dx$ operator.

Examples

```python
>>> from sympy import ZZ
>>> from sympy.abc import x
>>> from sympy.holonomic.holonomic import DifferentialOperators
>>> R, Dx = DifferentialOperators(ZZ.old_poly_ring(x), 'Dx')
>>> R
Univariate Differential Operator Algebra in intermediate Dx over the
← base ring ZZ[x]
```

```python
>>> Dx*x
(1) + (x)*Dx
```

class sympy.holonomic.holonomic.DifferentialOperatorAlgebra(base, generator)

An Ore Algebra is a set of noncommutative polynomials in the intermediate $Dx$ and coefficients in a base polynomial ring $A$. It follows the commutation rule:

$$Dxa = \sigma(a)Dx + \delta(a)$$

for $a \in A$.

Where $\sigma : A \Rightarrow A$ is an endomorphism and $\delta : A \rightarrow A$ is a skew-derivation i.e. $\delta(ab) = \delta(a)b + \sigma(a)\delta(b)$.

If one takes the sigma as identity map and delta as the standard derivation then it becomes the algebra of Differential Operators also called a Weyl Algebra i.e. an algebra whose elements are Differential Operators.

This class represents a Weyl Algebra and serves as the parent ring for Differential Operators.

Examples

```python
>>> from sympy import ZZ
>>> from sympy import symbols
>>> from sympy.holonomic.holonomic import DifferentialOperators
>>> x = symbols('x')
>>> R, Dx = DifferentialOperators(ZZ.old_poly_ring(x), 'Dx')
>>> R
Univariate Differential Operator Algebra in intermediate Dx over the
←base ring ZZ[x]
```

See also:

DifferentialOperator (page 2390)
Operations on holonomic functions

Addition and Multiplication

Two holonomic functions can be added or multiplied with the result also a holonomic function.

```python
>>> from sympy.holonomic.holonomic import HolonomicFunction, 
    DifferentialOperators
>>> from sympy.polys.domains import QQ
>>> from sympy import symbols
>>> x = symbols('x')
>>> R, Dx = DifferentialOperators(QQ.old_poly_ring(x),'Dx')

```

p and q here are holonomic representation of $e^x$ and $\sin(x)$ respectively.

```python
>>> p = HolonomicFunction(Dx - 1, x, 0, [1])
>>> q = HolonomicFunction(Dx**2 + 1, x, 0, [0, 1])

```

Holonomic representation of $e^x + \sin(x)$

```python
>>> p + q
HolonomicFunction((-1) + (1)*Dx + (-1)*Dx**2 + (1)*Dx**3, x, 0, [1, \text{\ldots, 2, 1}])

```

Holonomic representation of $e^x \cdot \sin(x)$

```python
>>> p * q
HolonomicFunction((2) + (-2)*Dx + (1)*Dx**2, x, 0, [0, 1])

```

Integration and Differentiation

HolonomicFunction.integrate(\text{\textit{limits, initcond=False}})

Integrates the given holonomic function.

Examples

```python
>>> from sympy.holonomic.holonomic import HolonomicFunction, 
    DifferentialOperators
>>> from sympy import QQ
>>> from sympy import symbols
>>> x = symbols('x')
>>> R, Dx = DifferentialOperators(QQ.old_poly_ring(x),'Dx')

```

```python
>>> HolonomicFunction(Dx - 1, x, 0, [1]).integrate((x, 0, x)) # e^x - 1
HolonomicFunction((-1)*Dx + (1)*Dx**2, x, 0, [0, 1])

```

```python
>>> HolonomicFunction(Dx**2 + 1, x, 0, [1, 0]).integrate((x, 0, x))
HolonomicFunction((1)*Dx + (1)*Dx**3, x, 0, [0, 1, 0])

```

HolonomicFunction.diff(*\text{\textit{args, \textendash\textendash kwargs}})

Differentiation of the given Holonomic function.
Examples

```python
>>> from sympy.holonomic.holonomic import HolonomicFunction,
    DifferentialOperators
>>> from sympy import ZZ
>>> from sympy import symbols
>>> x = symbols('x')
>>> R, Dx = DifferentialOperators(ZZ.old_poly_ring(x), 'Dx')
>>> HolonomicFunction(Dx**2 + 1, x, 0, [0, 1]).diff().to_expr()
    cos(x)
>>> HolonomicFunction(Dx - 2, x, 0, [1]).diff().to_expr()
    2*exp(2*x)
```

See also:
`integrate` (page 2392)

Composition with polynomials

`HolonomicFunction.composition(expr, *args, **kwargs)`

Returns function after composition of a holonomic function with an algebraic function. The method cannot compute initial conditions for the result by itself, so they can be also be provided.

Examples

```python
>>> from sympy.holonomic.holonomic import HolonomicFunction,
    DifferentialOperators
>>> from sympy import QQ
>>> from sympy import symbols
>>> x = symbols('x')
>>> R, Dx = DifferentialOperators(QQ.old_poly_ring(x), 'Dx')
>>> HolonomicFunction(Dx - 1, x).composition(x**2, 0, [1])  # e^(x**2)
    HolonomicFunction((-2*x) + (1)*Dx, x, 0, [1])
>>> HolonomicFunction((4*x**3) + (-1)*Dx + (x)*Dx**2, x, 1, [1, 0])
```

See also:
`from_hyper` (page 2397)

Convert to holonomic sequence

`HolonomicFunction.to_sequence(lb=True)`

Finds recurrence relation for the coefficients in the series expansion of the function about \(x_0\), where \(x_0\) is the point at which the initial condition is stored.
**Explanation**

If the point \(x_0\) is ordinary, solution of the form \([R; n_0]\) is returned. Where \(R\) is the recurrence relation and \(n_0\) is the smallest \(n\) for which the recurrence holds true.

If the point \(x_0\) is regular singular, a list of solutions in the format \((R; p; n_0)\) is returned, i.e. \([R; p; n_0, \ldots]\). Each tuple in this vector represents a recurrence relation \(R\) associated with a root of the indicial equation \(p\). Conditions of a different format can also be provided in this case, see the docstring of HolonomicFunction class.

If it’s not possible to numerically compute an initial condition, it is returned as a symbol \(C_j\), denoting the coefficient of \((x - x_0)^j\) in the power series about \(x_0\).

**Examples**

```python
>>> from sympy.holonomic.holonomic import HolonomicFunction, ...
    DifferentialOperators
>>> from sympy import QQ
>>> from sympy import symbols, S
>>> x = symbols('x')
>>> R, Dx = DifferentialOperators(QQ.old_poly_ring(x), 'Dx')
>>> HolonomicFunction(Dx - 1, x, 0, [1]).to_sequence()
[(HolonomicSequence((-1) + (n + 1)Sn, n), u(0) = 1, 0)]
>>> HolonomicFunction((1 + x)*Dx**2 + Dx, x, 0, [0, 1]).to_sequence()
[(HolonomicSequence((n**2) + (n**2 + n)Sn, n), u(0) = 0, u(1) = 1, u(2) = -1/2, 2)]
>>> HolonomicFunction(-S(1)/2 + x*Dx, x, 0, {S(1)/2: [1]}).to_sequence()
[(HolonomicSequence((n), n), u(0) = 1, 1/2, 1)]
```

See also:

*HolonomicFunction.series* (page 2394)

**References**

[R537], [R538]

**Series expansion**

*HolonomicFunction.series*(\(n=6, coefficient=False, order=True, _recur=None\))

Finds the power series expansion of given holonomic function about \(x_0\).
Explanation

A list of series might be returned if \( x_0 \) is a regular point with multiple roots of the indicial equation.

Examples

```python
>>> from sympy.holonomic.holonomic import HolonomicFunction,
    DifferentialOperators
>>> from sympy import QQ
>>> from sympy import symbols
>>> x = symbols('x')
>>> R, Dx = DifferentialOperators(QQ.old_poly_ring(x), 'Dx')
>>> HolonomicFunction(Dx - 1, x, 0, [1]).series()  # e^x
1 + x + x**2/2 + x**3/6 + x**4/24 + x**5/120 + O(x**6)
>>> HolonomicFunction(Dx**2 + 1, x, 0, [0, 1]).series(n=8)  # sin(x)
x - x**3/6 + x**5/120 - x**7/5040 + O(x**8)
```

See also:

*HolonomicFunction.to_sequence* (page 2393)

Numerical evaluation

`HolonomicFunction.evalf(points, method='RK4', h=0.05, derivatives=False)`

Finds numerical value of a holonomic function using numerical methods. (RK4 by default). A set of points (real or complex) must be provided which will be the path for the numerical integration.

Explanation

The path should be given as a list \([x_1, x_2, \ldots, x_n]\). The numerical values will be computed at each point in this order \( x_1 \to x_2 \to x_3 \cdots \to x_n \).

Returns values of the function at \( x_1, x_2, \ldots, x_n \) in a list.

Examples

```python
>>> from sympy.holonomic.holonomic import HolonomicFunction,
    DifferentialOperators
>>> from sympy import QQ
>>> from sympy import symbols
>>> x = symbols('x')
>>> R, Dx = DifferentialOperators(QQ.old_poly_ring(x), 'Dx')
>>> r = [0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1]
```

A straight line on the real axis from (0 to 1)

Runge-Kutta 4th order on \( e^x \) from 0.1 to 1. Exact solution at 1 is 2.71828182845905

5.8. Topics 2395
Euler's method for the same

```python
>>> HolonomicFunction(Dx - 1, x, 0, [1]).evalf(r, method='Euler')
[1.1, 1.21, 1.331, 1.4641, 1.61051, 1.771561, 1.9487171, 2.14358881, 2.357947691, 2.5937424601]
```

One can also observe that the value obtained using Runge-Kutta 4th order is much more accurate than Euler's method.

### Convert to a linear combination of hypergeometric functions

HolonomicFunction.to_hyper(as_list=False, _recur=None)

Returns a hypergeometric function (or linear combination of them) representing the given holonomic function.

**Explanation**

Returns an answer of the form: $a_1 x^{b_1} \cdot \text{hyper}() + a_2 x^{b_2} \cdot \text{hyper}()$...

This is very useful as one can now use hyperexpand to find the symbolic expressions/functions.

**Examples**

```python
>>> from sympy.holonomic.holonomic import HolonomicFunction,

>>> from sympy import ZZ
>>> from sympy import symbols
>>> x = symbols('x')
>>> R, Dx = DifferentialOperators(ZZ.old_poly_ring(x),'Dx')
>>> # sin(x)
>>> HolonomicFunction(Dx**2 + 1, x, 0, [0, 1]).to_hyper()
x*hyper(), (3/2,), -x**2/4)
>>> # exp(x)
>>> HolonomicFunction(Dx - 1, x, 0, [1]).to_hyper()
hyper(), (), x)
```

**See also:**

from_hyper (page 2397), from_meijerg (page 2398)
Convert to a linear combination of Meijer G-functions

HolonomicFunction.to_meijerg()

Returns a linear combination of Meijer G-functions.

Examples

```python
>>> from sympy.holonomic import expr_to_holonomic
>>> from sympy import sin, cos, hyperexpand, log, symbols
>>> x = symbols('x')
>>> hyperexpand(expr_to_holonomic(cos(x) + sin(x)).to_meijerg())
sin(x) + cos(x)
>>> hyperexpand(expr_to_holonomic(log(x)).to_meijerg()).simplify()
log(x)
```

See also:

to_hyper (page 2396)

Convert to expressions

HolonomicFunction.to_expr()

Converts a Holonomic Function back to elementary functions.

Examples

```python
>>> from sympy.holonomic.holonomic import HolonomicFunction,

DifferentialOperators
>>> from sympy import ZZ
>>> from sympy import symbols, S
>>> x = symbols('x')
>>> R, Dx = DifferentialOperators(ZZ.old_poly_ring(x), 'Dx')
>>> HolonomicFunction(x**2*Dx**2 + x*Dx + (x**2 - 1), x, 0, [0, S(1)/2]).

.to_expr()
besselj(1, x)
>>> HolonomicFunction((1 + x)*Dx**3 + Dx**2, x, 0, [1, 1, 1]).to_expr()
x*log(x + 1) + log(x + 1) + 1
```

Converting other representations to holonomic

Converting hypergeometric functions

sympy.holonomic.holonomic.from_hyper(func, x0=0, evalf=False)

Converts a hypergeometric function to holonomic. func is the Hypergeometric Function and x0 is the point at which initial conditions are required.
Examples

```python
>>> from sympy.holonomic.holonomic import from_hyper
>>> from sympy import symbols, hyper, S
>>> x = symbols('x')
>>> from_hyper(hyper([], [S(3)/2], x**2/4))
HolonomicFunction((-x) + (2)*Dx + (x)*Dx**2, x, 1, [sinh(1), -sinh(1) + \cosh(1)])
```

Converting Meijer G-functions

```python
sympy.holonomic.holonomic.from_meijerg(func, x0=0, evaf=False, initcond=True, domain=QQ)
```

Converts a Meijer G-function to Holonomic. func is the G-Function and x0 is the point at which initial conditions are required.

Examples

```python
>>> from sympy.holonomic.holonomic import from_meijerg
>>> from sympy import symbols, meijerg, S
>>> x = symbols('x')
>>> from_meijerg(meijerg([[], []], ([S(1)/2], [0]), x**2/4))
HolonomicFunction((1) + (1)*Dx**2, x, 0, [0, 1/sqrt(pi)])
```

Converting symbolic expressions

```python
sympy.holonomic.holonomic.expr_to_holonomic(func, x=None, x0=0, y0=None, lenics=None, domain=None, initcond=True)
```

Converts a function or an expression to a holonomic function.

**Parameters**

- **func:**
  - The expression to be converted.
- **x:**
  - variable for the function.
- **x0:**
  - point at which initial condition must be computed.
- **y0:**
  - One can optionally provide initial condition if the method is not able to do it automatically.
- **lenics:**
  - Number of terms in the initial condition. By default it is equal to the order of the annihilator.
domain:
Ground domain for the polynomials in x appearing as coefficients in the annihilator.

initcond:
Set it false if you do not want the initial conditions to be computed.

Examples

```python
>>> from sympy.holonomic.holonomic import expr_to_holonomic
>>> from sympy import sin, exp, symbols
>>> x = symbols('x')
>>> expr_to_holonomic(sin(x))
HolonomicFunction((1) + (1)*Dx**2, x, 0, [0, 1])
>>> expr_to_holonomic(exp(x))
HolonomicFunction((-1) + (1)*Dx, x, 0, [1])
```

See also:
- `sympy.integrals.meijerint._rewrite1` (page 631),
- `_convert_poly_rat_alg` (page 2400),
- `_create_table` (page 2400)

Uses and Current limitations

Integration

One can perform integrations using holonomic functions by following these steps:
1. Convert the integrand to a holonomic function.
2. Now integrate the holonomic representation of the function.
3. Convert the integral back to expressions.

Examples

```python
>>> from sympy import x, a
>>> from sympy import sin
>>> from sympy.holonomic.holonomic import expr_to_holonomic
>>> expr_to_holonomic(1/(x**2+a), x).integrate(x).to_expr()
atan(x/sqrt(a))/sqrt(a)
>>> expr_to_holonomic(sin(x)/x).integrate(x).to_expr()
Si(x)
```

As you can see in the first example we converted the function to holonomic, integrated the result and then converted back to symbolic expression.
Limitations

1. Converting to expressions is not always possible. The holonomic function should have a hypergeometric series at $x_0$.

2. Implementation of converting to holonomic sequence currently doesn’t support Frobenius method when the solutions need to have log terms. This happens when at least one pair of the roots of the indicial equation differ by an integer and frobenius method yields linearly dependent series solutions. Since we use this while converting to expressions, sometimes `to_expr()` (page 2397) fails.

3. There doesn’t seem to be a way for computing indefinite integrals, so `integrate()` (page 2392) basically computes $\int_{x_0}^x f(x)dx$ if no limits are given, where $x_0$ is the point at which initial conditions for the integrand are stored. Sometimes this gives an additional constant in the result. For instance:

\[
\begin{align*}
\text{>>> expr_to_holonomic(sin(x)).integrate(x).to_expr()} &= 1 - \cos(x) \\
\text{>>> sin(x).integrate(x) &= -\cos(x)}
\end{align*}
\]

The indefinite integral of $\sin(x)$ is $-\cos(x)$. But the output is $-\cos(x) + 1$ which is $\int_{x_0}^x \sin(x)dx$. Although both are considered correct but $-\cos(x)$ is simpler.

Internal API

```
sympy.holonomic.holonomic._create_table(table, domain=QQ)
    Creates the look-up table. For a similar implementation see meijerint._create_lookup_table.
	sympy.holonomic.holonomic._convert_poly_rat_alg(func, x, x0=0, y0=None, lenics=None, domain=QQ, initcond=True)
    Converts polynomials, rationals and algebraic functions to holonomic.
```

Lie Algebra

```
class sympy.liealgebras.root_system.RootSystem(cartantype)
    Represent the root system of a simple Lie algebra

    Every simple Lie algebra has a unique root system. To find the root system, we first consider the Cartan subalgebra of g, which is the maximal abelian subalgebra, and consider the adjoint action of g on this subalgebra. There is a root system associated with this action. Now, a root system over a vector space V is a set of finite vectors Phi (called roots), which satisfy:
    1. The roots span V
    2. The only scalar multiples of x in Phi are x and -x
    3. For every x in Phi, the set Phi is closed under reflection through the hyperplane perpendicular to x.
    4. If x and y are roots in Phi, then the projection of y onto the line through x is a half-integral multiple of x.
```

Now, there is a subset of \( \Phi \), which we will call \( \Delta \), such that:
1. \( \Delta \) is a basis of \( V \).
2. Each root \( x \) in \( \Phi \) can be written \( x = \sum k_y y \) for \( y \) in \( \Delta \).

The elements of \( \Delta \) are called the simple roots. Therefore, we see that the simple roots span the root space of a given simple Lie algebra.

add_as_roots\((\text{root}_1, \text{root}_2)\)
Add two roots together if and only if their sum is also a root.

It takes as input two vectors which should be roots. It then computes their sum and checks if it is in the list of all possible roots. If it is, it returns the sum. Otherwise it returns a string saying that the sum is not a root.

Examples

```python
>>> from sympy.liealgebras.root_system import RootSystem
>>> c = RootSystem("A3")
>>> c.add_as_roots([1, 0, -1, 0], [0, 0, 1, -1])
[1, 0, 0, -1]
>>> c.add_as_roots([1, -1, 0, 0], [0, 0, -1, 1])
'The sum of these two roots is not a root'
```

add_simple_roots\((\text{root}_1, \text{root}_2)\)
Add two simple roots together.

The function takes as input two integers, \( \text{root}_1 \) and \( \text{root}_2 \). It then uses these integers as keys in the dictionary of simple roots, and gets the corresponding simple roots, and then adds them together.

Examples

```python
>>> from sympy.liealgebras.root_system import RootSystem
>>> c = RootSystem("A3")
>>> newroot = c.add_simple_roots(1, 2)
>>> newroot
[1, 0, -1, 0]
```

all_roots()
Generate all the roots of a given root system.

The result is a dictionary where the keys are integer numbers. It generates the roots by getting the dictionary of all positive roots from the bases classes, and then taking each root, and multiplying it by -1 and adding it to the dictionary. In this way all the negative roots are generated.

cartan_matrix()
Cartan matrix of Lie algebra associated with this root system.
Examples

```python
>>> from sympy.liealgebras.root_system import RootSystem
>>> c = RootSystem("A3")
>>> c.cartan_matrix()
Matrix([[2, -1, 0],
       [-1, 2, -1],
       [0, -1, 2]])
```

dynkin_diagram()

Dynkin diagram of the Lie algebra associated with this root system

Examples

```python
>>> from sympy.liealgebras.root_system import RootSystem
>>> c = RootSystem("A3")
>>> print(c.dynkin_diagram())
0---0---0
1 2 3
```

root_space()

Return the span of the simple roots

The root space is the vector space spanned by the simple roots, i.e. it is a vector space with a distinguished basis, the simple roots. This method returns a string that represents the root space as the span of the simple roots, \( \alpha[1], \ldots, \alpha[n] \).

Examples

```python
>>> from sympy.liealgebras.root_system import RootSystem
>>> c = RootSystem("A3")
>>> c.root_space()
```

simple_roots()

Generate the simple roots of the Lie algebra

The rank of the Lie algebra determines the number of simple roots that it has. This method obtains the rank of the Lie algebra, and then uses the simple_root method from the Lie algebra classes to generate all the simple roots.
Examples

```python
>>> from sympy.liealgebras.root_system import RootSystem
>>> c = RootSystem("A3")
>>> roots = c.simple_roots()
>>> roots
{1: [1, -1, 0, 0], 2: [0, 1, -1, 0], 3: [0, 0, 1, -1]}
```

class sympy.liealgebras.type_a.TypeA(n)
This class contains the information about the A series of simple Lie algebras.

basic_root(i,j)
This is a method just to generate roots with a 1 in the i\text{th} position and a -1 in the j\text{th} position.

basis()
Returns the number of independent generators of A_n

cartan_matrix()
Returns the Cartan matrix for A_n. The Cartan matrix for a Lie algebra is generated by assigning an ordering to the simple roots, (alpha[1], ..., alpha[l]). Then the ij\text{th} entry of the Cartan matrix is (\langle alpha[i], alpha[j]\rangle).

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType('A4')
>>> c.cartan_matrix()
Matrix(
    [ 2, -1, 0, 0],
    [-1, 2, -1, 0],
    [ 0, -1, 2, -1],
    [ 0, 0, -1, 2])
```

dimension()
Dimension of the vector space V underlying the Lie algebra

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("A4")
>>> c.dimension()
5
```

highest_root()
Returns the highest weight root for A_n

lie_algebra()
Returns the Lie algebra associated with A_n
positive_roots()

This method generates all the positive roots of $A_n$. This is half of all the roots of $A_n$; by multiplying all the positive roots by -1 we get the negative roots.

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("A3")
>>> c.positive_roots()
{1: [1, -1, 0, 0], 2: [1, 0, -1, 0], 3: [1, 0, 0, -1], 4: [0, 1, -1, -1], 5: [0, 1, 0, -1], 6: [0, 0, 1, -1]}
```

roots()

Returns the total number of roots for $A_n$

simple_root($i$)

Every lie algebra has a unique root system. Given a root system $Q$, there is a subset of the roots such that an element of $Q$ is called a simple root if it cannot be written as the sum of two elements in $Q$. If we let $D$ denote the set of simple roots, then it is clear that every element of $Q$ can be written as a linear combination of elements of $D$ with all coefficients non-negative.

In $A_n$ the $i$th simple root is the root which has a 1 in the $i$th position, a -1 in the $(i+1)$th position, and zeroes elsewhere.

This method returns the $i$th simple root for the $A$ series.

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("A4")
>>> c.simple_root(1)
[1, -1, 0, 0, 0]
```

class sympy.liealgebras.type_b.TypeB($n$)

basic_root($i$, $j$)

This is a method just to generate roots with a 1 in the $i$th position and a -1 in the $j$th position.

basis()

Returns the number of independent generators of $B_n$

cartan_matrix()

Returns the Cartan matrix for $B_n$. The Cartan matrix matrix for a Lie algebra is generated by assigning an ordering to the simple roots, $(\alpha[1], \ldots, \alpha[l])$. Then the $ij$th entry of the Cartan matrix is $(\langle \alpha[i], \alpha[j] \rangle)$.
Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType('B4')
>>> c.cartan_matrix()
Matrix([[ 2, -1, 0, 0],
       [-1, 2, -1, 0],
       [ 0, -1, 2, -2],
       [ 0, 0, -1, 2]])
```

dimension()

Dimension of the vector space V underlying the Lie algebra

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("B3")
>>> c.dimension()
3
```

lie_algebra()

Returns the Lie algebra associated with B_n

positive_roots()

This method generates all the positive roots of A_n. This is half of all of the roots of B_n; by multiplying all the positive roots by -1 we get the negative roots.

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("A3")
>>> c.positive_roots()
{1: [1, -1, 0, 0], 2: [1, 0, -1, 0], 3: [1, 0, 0, -1], 4: [0, 1, -1, 0], 5: [0, 1, 0, -1], 6: [0, 0, 1, -1]}
```

roots()

Returns the total number of roots for B_n

simple_root(i)

Every lie algebra has a unique root system. Given a root system Q, there is a subset of the roots such that an element of Q is called a simple root if it cannot be written as the sum of two elements in Q. If we let D denote the set of simple roots, then it is clear that every element of Q can be written as a linear combination of elements of D with all coefficients non-negative.

In B_n the first n-1 simple roots are the same as the roots in A_(n-1) (a 1 in the ith position, a -1 in the (i+1)th position, and zeroes elsewhere). The n-th simple root is the root with a 1 in the n-th position and zeroes elsewhere.

This method returns the ith simple root for the B series.
Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("B3")
>>> c.simple_root(2)
[0, 1, -1]
```

class `sympy.liealgebras.type_c.TypeC(n)`

**basic_root(i, j)**
Generate roots with 1 in ith position and a -1 in jth position

**basis()**
Returns the number of independent generators of C_n

**cartan_matrix()**
The Cartan matrix for C_n

The Cartan matrix matrix for a Lie algebra is generated by assigning an ordering to the simple roots, (alpha[1], ..., alpha[l]). Then the ijth entry of the Cartan matrix is (alpha[i], alpha[j]).

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType('C4')
>>> c.cartan_matrix()
Matrix([[2, -1, 0, 0],
[-1, 2, -1, 0],
[0, -1, 2, -1],
[0, 0, -2, 2]])
```

**dimension()**
Dimension of the vector space V underlying the Lie algebra

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType('C3')
>>> c.dimension()
3
```

**lie_algebra()**
Returns the Lie algebra associated with C_n

**positive_roots()**
Generates all the positive roots of A_n

This is half of all the roots of C_n; by multiplying all the positive roots by -1 we get the negative roots.
Examples

```python
from sympy.liealgebras.cartan_type import CartanType
c = CartanType("A3")
c.positive_roots()
{1: [1, -1, 0, 0], 2: [1, 0, -1, 0], 3: [1, 0, 0, -1], 4: [0, 1, -1, 0], 5: [0, 1, 0, -1], 6: [0, 0, 1, -1]}
```

`roots()`

Returns the total number of roots for C_n

`simple_root(i)`

The ith simple root for the C series

Every lie algebra has a unique root system. Given a root system Q, there is a subset of the roots such that an element of Q is called a simple root if it cannot be written as the sum of two elements in Q. If we let D denote the set of simple roots, then it is clear that every element of Q can be written as a linear combination of elements of D with all coefficients non-negative.

In C_n, the first n-1 simple roots are the same as the roots in A_(n-1) (a 1 in the ith position, a -1 in the (i+1)th position, and zeroes elsewhere). The nth simple root is the root in which there is a 2 in the nth position and zeroes elsewhere.

Examples

```python
from sympy.liealgebras.cartan_type import CartanType
c = CartanType("C3")
c.simple_root(2)
[0, 1, -1]
```

class sympy.liealgebras.type_d.TypeD(n)

`basic_root(i, j)`

This is a method just to generate roots with a 1 in the ith position and a -1 in the jth position.

`basis()`

Returns the number of independent generators of D_n

`cartan_matrix()`

Returns the Cartan matrix for D_n. The Cartan matrix matrix for a Lie algebra is generated by assigning an ordering to the simple roots, (alpha[1], ..., alpha[l]). Then the ijth entry of the Cartan matrix is (<alpha[i],alpha[j]>).
Examples

```python
>>> from sympy.liealgebraskartan_type import CartanType
>>> c = CartanType('D4')
>>> c.cartan_matrix()
Matrix([[2, -1, 0, 0], [-1, 2, -1, -1], [0, -1, 2, 0], [0, -1, 0, 2]])
```

dimension()
Dimension of the vector space $V$ underlying the Lie algebra

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType('D4')
>>> c.dimension()
4
```

lie_algebra()
Returns the Lie algebra associated with $D_n$

positive_roots()
This method generates all the positive roots of $A_n$. This is half of all the roots of $D_n$ by multiplying all the positive roots by -1 we get the negative roots.

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType('A3')
>>> c.positive_roots()
{1: [1, -1, 0, 0], 2: [1, 0, -1, 0], 3: [1, 0, 0, -1], 4: [0, 1, -1, 0], 5: [0, 1, 0, -1], 6: [0, 0, 1, -1]}
```

roots()
Returns the total number of roots for $D_n$

simple_root(i)
Every Lie algebra has a unique root system. Given a root system $Q$, there is a subset of the roots such that an element of $Q$ is called a simple root if it cannot be written as the sum of two elements in $Q$. If we let $D$ denote the set of simple roots, then it is clear that every element of $Q$ can be written as a linear combination of elements of $D$ with all coefficients non-negative.

In $D_n$, the first $n-1$ simple roots are the same as the roots in $A_{(n-1)}$ (a 1 in the $i$th position, a -1 in the $(i+1)$th position, and zeroes elsewhere). The $n$th simple root is the root in which there is 1 in the $n$th and $(n-1)$th positions, and zeroes elsewhere.

This method returns the $i$th simple root for the $D$ series.
Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("D4")
>>> c.simple_root(2)
[0, 1, -1, 0]
```

class sympy.liealgebras.type_e.TypeE(n)

- **basic_root(i,j)**
  This is a method just to generate roots with a -1 in the ith position and a 1 in the jth position.

- **basis()**
  Returns the number of independent generators of E_n

- **cartan_matrix()**
  Returns the Cartan matrix for G_2 The Cartan matrix matrix for a Lie algebra is generated by assigning an ordering to the simple roots, (alpha[1], ...., alpha[l]). Then the ijth entry of the Cartan matrix is (<alpha[i],alpha[j]>).

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType('A4')
>>> c.cartan_matrix()
Matrix([[2, -1, 0, 0],
[-1, 2, -1, 0],
[0, -1, 2, -1],
[0, 0, -1, 2]])
```

- **dimension()**
  Dimension of the vector space V underlying the Lie algebra

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("E6")
>>> c.dimension()
8
```

- **positive_roots()**
  This method generates all the positive roots of A_n. This is half of all of the roots of E_n; by multiplying all the positive roots by -1 we get the negative roots.
Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("A3")
>>> c.positive_roots()
{1: [1, -1, 0, 0], 2: [1, 0, -1, 0], 3: [1, 0, 0, -1], 4: [0, 1, -1, 0],
  5: [0, 1, 0, -1], 6: [0, 0, 1, -1]}
```

`roots()`

Returns the total number of roots of E_n

`simplified_root(i)`

Every lie algebra has a unique root system. Given a root system Q, there is a subset of the roots such that an element of Q is called a simple root if it cannot be written as the sum of two elements in Q. If we let D denote the set of simple roots, then it is clear that every element of Q can be written as a linear combination of elements of D with all coefficients non-negative.

This method returns the ith simple root for E_n.

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("E6")
>>> c.simple_root(2)
[1, 1, 0, 0, 0, 0, 0, 0]
```

class sympy.liealgebras.type_f.TypeF(n)

`basic_root(i, j)`

Generate roots with 1 in ith position and -1 in jth position

`basis()`

Returns the number of independent generators of F_4

`cartan_matrix()`

The Cartan matrix for F_4

The Cartan matrix matrix for a Lie algebra is generated by assigning an ordering to the simple roots, (alpha[1], ..., alpha[l]). Then the ijth entry of the Cartan matrix is (<alpha[i], alpha[j]>).

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("A4")
>>> c.cartan_matrix()
Matrix([[2, -1, 0, 0], [-1, 2, -1, 0], [-1, 2, -1, 0], [2, -1, 0, 0]])
```
dimension()
Dimension of the vector space V underlying the Lie algebra

Examples

```python
c = CartanType("F4")
c.dimension()
```

positive_roots()
Generate all the positive roots of A_n
This is half of all the roots of F_4; by multiplying all the positive roots by -1 we get the negative roots.

Examples

```python
c = CartanType("A3")
c.positive_roots()
```

roots()
Returns the total number of roots for F_4

simple_root(i)
The ith simple root of F_4
Every lie algebra has a unique root system. Given a root system Q, there is a subset of the roots such that an element of Q is called a simple root if it cannot be written as the sum of two elements in Q. If we let D denote the set of simple roots, then it is clear that every element of Q can be written as a linear combination of elements of D with all coefficients non-negative.

Examples

```python
c = CartanType("F4")
c.simple_root(3)
```

class sympy.liealgebras.type_g.TypeG(n)
basis()  
Returns the number of independent generators of G_2

cartan_matrix()  
The Cartan matrix for G_2  
The Cartan matrix matrix for a Lie algebra is generated by assigning an ordering to the simple roots, (alpha[1], ..., alpha[l]). Then the i,jth entry of the Cartan matrix is (<alpha[i],alpha[j]>).

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("G2")
>>> c.cartan_matrix()
Matrix([[2, -1],
       [-3, 2]])
```

dimension()  
Dimension of the vector space V underlying the Lie algebra

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("G2")
>>> c.dimension()
3
```

positive_roots()  
Generate all the positive roots of A_n  
This is half of all of the roots of A_n; by multiplying all the positive roots by -1 we get the negative roots.

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("A3")
>>> c.positive_roots()
{1: [1, -1, 0, 0], 2: [1, 0, -1, 0], 3: [1, 0, 0, -1], 4: [0, 1, -1, 0], 5: [0, 1, 0, -1], 6: [0, 0, 1, -1]}
```

roots()  
Returns the total number of roots of G_2
simple_root(i)
The ith simple root of G_2

Every lie algebra has a unique root system. Given a root system Q, there is a subset of the roots such that an element of Q is called a simple root if it cannot be written as the sum of two elements in Q. If we let D denote the set of simple roots, then it is clear that every element of Q can be written as a linear combination of elements of D with all coefficients non-negative.

Examples

```python
>>> from sympy.liealgebras.cartan_type import CartanType
>>> c = CartanType("G2")
>>> c.simple_root(1)
[0, 1, -1]
```

class sympy.liealgebras.weyl_group.WeylGroup(cartantype)

For each semisimple Lie group, we have a Weyl group. It is a subgroup of the isometry group of the root system. Specifically, it’s the subgroup that is generated by reflections through the hyperplanes orthogonal to the roots. Therefore, Weyl groups are reflection groups, and so a Weyl group is a finite Coxeter group.

coxeter_diagram()

This method returns the Coxeter diagram corresponding to a Weyl group. The Coxeter diagram can be obtained from a Lie algebra’s Dynkin diagram by deleting all arrows; the Coxeter diagram is the undirected graph. The vertices of the Coxeter diagram represent the generating reflections of the Weyl group, s_i. An edge is drawn between s_i and s_j if the order m(i, j) of s_i s_j is greater than two. If there is one edge, the order m(i, j) is 3. If there are two edges, the order m(i, j) is 4, and if there are three edges, the order m(i, j) is 6.

Examples

```python
>>> from sympy.liealgebras.weyl_group import WeylGroup
>>> c = WeylGroup("B3")
>>> print(c.coxeter_diagram())
0---0===0
1 2 3
```

delete_doubles(reflections)

This is a helper method for determining the order of an element in the Weyl group of G2. It takes a Weyl element and if repeated simple reflections in it, it deletes them.

element_order(weylelt)

This method returns the order of a given Weyl group element, which should be specified by the user in the form of products of the generating reflections, i.e. of the form r1*r2 etc.

For types A-F, this method current works by taking the matrix form of the specified element, and then finding what power of the matrix is the identity. It then returns this power.
Examples

```python
>>> from sympy.liealgebras.weyl_group import WeylGroup
>>> b = WeylGroup("B4")
>>> b.element_order('r1*r4*r2')
4
```

generators()

This method creates the generating reflections of the Weyl group for a given Lie algebra. For a Lie algebra of rank n, there are n different generating reflections. This function returns them as a list.

```python
>>> from sympy.liealgebras.weyl_group import WeylGroup
>>> c = WeylGroup("F4")
>>> c.generators()
['r1', 'r2', 'r3', 'r4']
```

group_name()

This method returns some general information about the Weyl group for a given Lie algebra. It returns the name of the group and the elements it acts on, if relevant.

```python
>>> from sympy.liealgebras.weyl_group import WeylGroup
>>> c = WeylGroup("D4")
>>> c.group_order()
192.0
```

matrix_form(weylelt)

This method takes input from the user in the form of products of the generating reflections, and returns the matrix corresponding to the element of the Weyl group. Since each element of the Weyl group is a reflection of some type, there is a corresponding matrix representation. This method uses the standard representation for all the generating reflections.

```python
>>> from sympy.liealgebras.weyl_group import WeylGroup
>>> c = WeylGroup("D4")
>>> c.group_order()
192.0
```
Examples

>>> from sympy.liealgebras.weyl_group import WeylGroup
>>> f = WeylGroup("F4")
>>> f.matrix_form('r2*r3')
Matrix([1, 0, 0, 0],
     [0, 1, 0, 0],
     [0, 0, 0, -1],
     [0, 0, 1, 0])

class sympy.liealgebras.cartan_type.CartanType_generator
    Constructor for actually creating things

class sympy.liealgebras.cartan_type.Standard_Cartan(series, n)
    Concrete base class for Cartan types such as A4, etc

    rank()
        Returns the rank of the Lie algebra

    series()
        Returns the type of the Lie algebra

sympy.liealgebras.dynkin_diagram.DynkinDiagram(t)
    Display the Dynkin diagram of a given Lie algebra

    Works by generating the CartanType for the input, t, and then returning the Dynkin
diagram method from the individual classes.

Examples

>>> from sympy.liealgebras.dynkin_diagram import DynkinDiagram
>>> print(DynkinDiagram("A3"))
0---0---0
1 2 3

>>> print(DynkinDiagram("B4"))
0---0---0=>=0
1 2 3 4

sympy.liealgebras.cartan_matrix.CartanMatrix(ct)
    Access the Cartan matrix of a specific Lie algebra
Examples

```python
>>> from sympy.liealgebras.cartan_matrix import CartanMatrix
>>> CartanMatrix("A2")
Matrix([[2, -1],
[1, 2]])
```

```python
>>> CartanMatrix([['C', 3]])
Matrix([[2, -1, 0],
[-1, 2, -1],
[0, -2, 2]])
```

This method works by returning the Cartan matrix which corresponds to Cartan type t.

**Polynomial Manipulation**

Computations with polynomials are at the core of computer algebra and having a fast and robust polynomials manipulation module is a key for building a powerful symbolic manipulation system. SymPy has a dedicated module `sympy.polys` (page 2435) for computing in polynomial algebras over various coefficient domains.

There is a vast number of methods implemented, ranging from simple tools like polynomial division, to advanced concepts including Gröbner bases and multivariate factorization over algebraic number domains.

**Contents**

**Basic functionality of the module**

**Introduction**

This tutorial tries to give an overview of the functionality concerning polynomials within SymPy. All code examples assume:

```python
>>> from sympy import *
>>> x, y, z = symbols('x,y,z')
>>> init_printing(use_unicode=False, wrap_line=False)
```

**Basic concepts**

**Polynomials**

Given a family \((x_i)\) of symbols, or other suitable objects, including numbers, expressions derived from them by repeated addition, subtraction and multiplication are called *polynomial expressions in the generators* \(x_i\).

By the distributive law it is possible to perform multiplications before additions and subtractions. The products of generators thus obtained are called *monomials*. They are usually
written in the form \( x_1^{\nu_1}x_2^{\nu_2} \cdots x_n^{\nu_n} \) where the exponents \( \nu_i \) are nonnegative integers. It is often convenient to write this briefly as \( x^{\nu} \) where \( x = (x_1, x_2, \ldots, x_n) \) denotes the family of generators and \( \nu = (\nu_1, \nu_2, \ldots, \nu_n) \) is the family of exponents.

When all monomials having the same exponents are combined, the polynomial expression becomes a sum of products \( c_\nu x^{\nu} \), called the terms of the polynomial, where the coefficients \( c_\nu \) are integers. If some of the \( x_i \) are manifest numbers, they are incorporated in the coefficients and not regarded as generators. Such coefficients are typically rational, real or complex numbers. Some symbolic numbers, e.g., \( \pi \), can be either coefficients or generators.

A polynomial expression that is a sum of terms with different monomials is uniquely determined by its family of coefficients \( \{c_\nu\} \). Such an expression is customarily called a polynomial, though, more properly, that name does stand for the coefficient family once the generators are given. SymPy implements polynomials by default as dictionaries with monomials as keys and coefficients as values. Another implementation consists of nested lists of coefficients.

The set of all polynomials with integer coefficients in the generators \( x_i \) is a ring, i.e., the sums, differences and products of its elements are again polynomials in the same generators. This ring is denoted \( \mathbb{Z}[x_1, x_2, \ldots, x_n] \), or \( \mathbb{Z}[(x_i)] \), and called the ring of polynomials in the \( x_i \) with integer coefficients.

More generally, the coefficients of a polynomial can be elements of any commutative ring \( A \), and the corresponding polynomial ring is then denoted \( A[x_1, x_2, \ldots, x_n] \). The ring \( A \) can also be a polynomial ring. In SymPy, the coefficient ring is called the domain of the polynomial ring, and it can be given as a keyword parameter. By default, it is determined by the coefficients of the polynomial arguments.

Polynomial expressions can be transformed into polynomials by the method `sympy.core.expr.Expr.as_poly` (page 1007):

```python
>>> e = (x + y)*(y - 2*z)
>>> e.as_poly()
Poly(x*y - 2*x*z + y**2 - 2*y*z, x, y, z, domain='ZZ')
```

If a polynomial expression contains numbers that are not integers, they are regarded as coefficients and the coefficient ring is extended accordingly. In particular, division by integers leads to rational coefficients:

```python
>>> e = (3*x/2 + y)*(z - 1)
>>> e.as_poly()
Poly(3/2*x*z - 3/2*x + y*z - y, x, y, z, domain='QQ')
```

Symbolic numbers are considered generators unless they are explicitly excluded, in which case they are adjoined to the coefficient ring:

```python
>>> e = (x + 2*pi)*y
>>> e.as_poly()
Poly(x*y + 2*y*pi, x, y, pi, domain='ZZ')
>>> e.as_poly(x, y)
Poly(x*y + 2*pi*y, x, y, domain='ZZ[pi]')
```

Alternatively, the coefficient domain can be specified by means of a keyword argument:

```python
>>> e = (x + 2*pi)*y
>>> e.as_poly(domain=ZZ[pi])
Poly(x*y + 2*pi*y, x, y, domain='ZZ[pi]')
```
Note that the ring \( \mathbb{Z}[\pi][x, y] \) of polynomials in \( x \) and \( y \) with coefficients in \( \mathbb{Z}[\pi] \) is mathematically equivalent to \( \mathbb{Z}[\pi, x, y] \), only their implementations differ.

If an expression contains functions of the generators, other than their positive integer powers, these are interpreted as new generators:

```python
>>> e = x*sin(y) - y
>>> e.as_poly()
Poly(x*(sin(y)) - y, x, y, sin(y), domain='ZZ')
```

Since \( y \) and \( \sin(y) \) are algebraically independent they can both appear as generators in a polynomial. However, polynomial expressions must not contain negative powers of generators:

```python
>>> e = x - 1/x
>>> e.as_poly()
Poly(x - (1/x), x, 1/x, domain='ZZ')
```

It is important to realize that the generators \( x \) and \( 1/x = x^{-1} \) are treated as algebraically independent variables. In particular, their product is not equal to 1. Hence generators in denominators should be avoided even if they raise no error in the current implementation. This behavior is undesirable and may change in the future. Similar problems emerge with rational powers of generators. So, for example, \( x \) and \( \sqrt{x} = x^{1/2} \) are not recognized as algebraically dependent.

If there are algebraic numbers in an expression, it is possible to adjoin them to the coefficient ring by setting the keyword `extension`:

```python
>>> e = x + sqrt(2)
>>> e.as_poly()
Poly(x + (sqrt(2)), x, sqrt(2), domain='ZZ')
>>> e.as_poly(extension=True)
Poly(x + sqrt(2), x, domain='QQ<sqrt(2)>')
```

With the default setting `extension=False`, both \( x \) and \( \sqrt{2} \) are incorrectly considered algebraically independent variables. With coefficients in the extension field \( \mathbb{Q}(\sqrt{2}) \) the square root is treated properly as an algebraic number. Setting `extension=True` whenever algebraic numbers are involved is definitely recommended even though it is not forced in the current implementation.

### Divisibility

The fourth rational operation, division, or inverted multiplication, is not generally possible in rings. If \( a \) and \( b \) are two elements of a ring \( A \), then there may exist a third element \( q \) in \( A \) such that \( a = bq \). In fact, there may exist several such elements.

If also \( a = bq' \) for some \( q' \) in \( A \), then \( b(q - q') = 0 \). Hence either \( b \) or \( q - q' \) is zero, or they are both zero divisors, nonzero elements whose product is zero.
Integral domains

Commutative rings with no zero divisors are called integral domains. Most of the commonly encountered rings, the ring of integers, fields, and polynomial rings over integral domains are integral domains.

Assume now that \( A \) is an integral domain, and consider the set \( P \) of its nonzero elements, which is closed under multiplication. If \( a \) and \( b \) are in \( P \), and there exists an element \( q \) in \( P \) such that \( a = bq \), then \( q \) is unique and called the quotient, \( a/b \), of \( a \) by \( b \). Moreover, it is said that

- \( a \) is divisible by \( b \),
- \( b \) is a divisor of \( a \),
- \( a \) is a multiple of \( b \),
- \( b \) is a factor of \( a \).

An element \( a \) of \( P \) is a divisor of 1 if and only if it is invertible in \( A \), with the inverse \( a^{-1} = 1/a \). Such elements are called units. The units of the ring of integers are 1 and \(-1\). The invertible elements in a polynomial ring over a field are the nonzero constant polynomials.

If two elements of \( P \), \( a \) and \( b \), are divisible by each other, then the quotient \( a/b \) is invertible with inverse \( b/a \), or equivalently, \( b = ua \) where \( u \) is a unit. Such elements are said to be associated with, or associates of, each other. The associates of an integer \( n \) are \( n \) and \(-n\). In a polynomial ring over a field the associates of a polynomial are its constant multiples.

Each element of \( P \) is divisible by its associates and the units. An element is irreducible if it has no other divisors and is not a unit. The irreducible elements in the ring of integers are the prime numbers \( p \) and their opposites \(-p\). In a field, every nonzero element is invertible and there are no irreducible elements.

Factorial domains

In the ring of integers, each nonzero element can be represented as a product of irreducible elements and optionally a unit \( \pm 1 \). Moreover, any two such products have the same number of irreducible factors which are associated with each other in a suitable order. Integral domains having this property are called factorial, or unique factorization domains. In addition to the ring of integers, all polynomial rings over a field are factorial, and so are more generally polynomial rings over any factorial domain. Fields are trivially factorial since there are only units. The irreducible elements of a factorial domain are usually called primes.

A family of integers has only a finite number of common divisors and the greatest of them is divisible by all of them. More generally, given a family of nonzero elements \((a_i)\) in an integral domain, a common divisor \( d \) of the elements is called a greatest common divisor, abbreviated \( gcd \), of the family if it is a multiple of all common divisors. A greatest common divisor, if it exists, is not unique in general; all of its associates have the same property. It is denoted by \( d = gcd(a_1, \ldots, a_n) \) if there is no danger of confusion. A least common multiple, or \( lcm \), of a family \((a_i)\) is defined analogously as a common multiple \( m \) that divides all common multiples. It is denoted by \( m = lcm(a_1, \ldots, a_n) \).

In a factorial domain, greatest common divisors always exists. They can be found, at least in principle, by factoring each element of a family into a product of prime powers and an optional unit, and, for each prime, taking the least power that appears in the factorizations. The product of these prime powers is then a greatest common divisor. A least common multiple
can be obtained from the same factorizations as the product of the greatest powers for each prime.

**Euclidean domains**

A practical algorithm for computing a greatest common divisor can be implemented in *Euclidean domains*. They are integral domains that can be endowed with a function $w$ assigning a nonnegative integer to each nonzero element of the domain and having the following property:

if $a$ and $b$ are nonzero, there are $q$ and $r$ that satisfy the *division identity*

$$a = qb + r$$

such that either $r = 0$ or $w(r) < w(b)$.

The ring of integers and all univariate polynomial rings over fields are Euclidean domains with $w(a) = |a|$ resp. $w(a) = \deg(a)$.

The division identity for integers is implemented in Python as the built-in function `divmod` that can also be applied to SymPy Integers:

```python
>>> divmod(Integer(53), Integer(7))
(7, 4)
```

For polynomials the division identity is given in SymPy by the function `div()` (page 2437):

```python
>>> f = 5*x**2 + 10*x + 3
>>> g = 2*x + 2

>>> q, r = div(f, g, domain='QQ')

>>> q
5*x - 5
--- + -
2 2

>>> r
-2

>>> (q*g + r).expand()
2
5*x + 10*x + 3
```

The division identity can be used to determine the divisibility of elements in a Euclidean domain. If $r = 0$ in the division identity, then $a$ is divisible by $b$. Conversely, if $a = cb$ for some element $c$, then $(c - q)b = r$. It follows that $c = q$ and $r = 0$ if $w$ has the additional property:

if $a$ and $b$ are nonzero, then $w(ab) \geq w(b)$.

This is satisfied by the functions given above. (And it is always possible to redefine $w(a)$ by taking the minimum of the values $w(xa)$ for $x \neq 0$.)

The principal application of the division identity is the efficient computation of a greatest common divisor by means of the *Euclidean algorithm*. It applies to two elements of a Euclidean domain. A gcd of several elements can be obtained by iteration.

The function for computing the greatest common divisor of integers in SymPy is currently `igcd()` (page 1045):
For univariate polynomials over a field the function has its common name \texttt{gcd()} (page 2442), and the returned polynomial is monic:

\begin{verbatim}
>>> f = 4*x**2 - 1
>>> g = 8*x**3 + 1
>>> gcd(f, g, domain=QQ)
x + 1/2
\end{verbatim}

### Divisibility of polynomials

The ring $A = \mathbb{Z}[x]$ of univariate polynomials over the ring of integers is not Euclidean but it is still factorial. To see this, consider the divisibility in $A$.

Let $f$ and $g$ be two nonzero polynomials in $A$. If $f$ is divisible by $g$ in $A$, then it is also divisible in the ring $B = \mathbb{Q}[x]$ of polynomials with rational coefficients. Since $B$ is Euclidean, this can be determined by means of the division identity.

Assume, conversely, that $f = gh$ for some polynomial $h$ in $B$. Then $f$ is divisible by $g$ in $A$ if and only if the coefficients of $h$ are integers. To find out when this is true it is necessary to consider the divisibility of the coefficients.

For a polynomial $f$ in $A$, let $c$ be the greatest common divisor of its coefficients. Then $f$ is divisible by the constant polynomial $c$ in $A$, and the quotient $f/c = p$ is a polynomial whose coefficients are integers that have no common divisor apart from the units. Such polynomials are called 	extit{primitive}. A polynomial with rational coefficients can also be written as $f = cp$, where $c$ is a rational number and $p$ is a primitive polynomial. The constant $c$ is called the 	extit{content} of $f$, and $p$ is its 	extit{primitive part}. These components can be found by the method \texttt{sympy.core.expr.Expr.as_content_primitive} (page 1002):

\begin{verbatim}
>>> f = 6*x**2 - 3*x + 9
>>> c, p = f.as_content_primitive()
>>> c, p
(3, 2*x - x + 3)
>>> f = x**2/3 - x/2 + 1
>>> c, p = f.as_content_primitive()
>>> c, p
(1/6, 2*x - 3*x + 6)
\end{verbatim}

Let $f, f'$ be polynomials with contents $c, c'$ and primitive parts $p, p'$. Then $ff' = (cc')(pp')$ where the product $pp'$ is primitive by Gauss's lemma. It follows that

- the content of a product of polynomials is the product of their contents and the
- primitive part of the product is the product of the primitive parts.

Returning to the divisibility in the ring $\mathbb{Z}[x]$, assume that $f$ and $g$ are two polynomials with integer coefficients such that the division identity in $\mathbb{Q}[x]$ yields the equality $f = gh$ for some polynomial $h$ with rational coefficients. Then the content of $f$ is equal to the content of $g$.
multiplied by the content of \( h \). As \( h \) has integer coefficients if and only if its content is an integer, we get the following criterion:

\[
\begin{align*}
& f \text{ is divisible by } g \text{ in the ring } \mathbb{Z}[x] \text{ if and only if} \\
& \quad \text{i. } f \text{ is divisible by } g \text{ in } \mathbb{Q}[x], \text{ and} \\
& \quad \text{ii. the content of } f \text{ is divisible by the content of } g \text{ in } \mathbb{Z}.
\end{align*}
\]

If \( f = cp \) is irreducible in \( \mathbb{Z}[x] \), then either \( c \) or \( p \) must be a unit. If \( p \) is not a unit, it must be irreducible also in \( \mathbb{Q}[x] \). For if it is a product of two polynomials, it is also the product of their primitive parts, and one of them must be a unit. Hence there are two kinds of irreducible elements in \( \mathbb{Z}[x] \):

i. prime numbers of \( \mathbb{Z} \), and

ii. primitive polynomials that are irreducible in \( \mathbb{Q}[x] \).

It follows that each polynomial in \( \mathbb{Z}[x] \) is a product of irreducible elements. It suffices to factor its content and primitive part separately. These products are essentially unique; hence \( \mathbb{Z}[x] \) is also factorial.

Another important consequence is that a greatest common divisor of two polynomials in \( \mathbb{Z}[x] \) can be found efficiently by applying the Euclidean algorithm separately to their contents and primitive parts in the Euclidean domains \( \mathbb{Z} \) and \( \mathbb{Q}[x] \). This is also implemented in SymPy:

```
>>> f = 4*x**2 - 1
>>> g = 8*x**3 + 1
>>> gcd(f, g)
2*x + 1
>>> gcd(6*f, 3*g)
6*x + 3
```

Basic functionality

These functions provide different algorithms dealing with polynomials in the form of SymPy expression, like symbols, sums etc.

Division

The function `div()` (page 2437) provides division of polynomials with remainder. That is, for polynomials \( f \) and \( g \), it computes \( q \) and \( r \), such that \( f = g \cdot q + r \) and \( \text{deg}(r) < \text{deg}(q) \). For polynomials in one variables with coefficients in a field, say, the rational numbers, \( q \) and \( r \) are uniquely defined this way:

```
>>> f = 5*x**2 + 10*x + 3
>>> g = 2*x + 2

>>> q, r = div(f, g, domain='QQ')

>>> q
5*x + 5
- - + -
2 2

>>> r
-2
```

(continues on next page)
As you can see, \( q \) has a non-integer coefficient. If you want to do division only in the ring of polynomials with integer coefficients, you can specify an additional parameter:

\[
>>> q, r = \text{div}(f, g, \text{domain='ZZ'})
\]

\[
>>> q
0
\]

\[
>>> r
2
5^x + 10^x + 3
\]

But be warned, that this ring is no longer Euclidean and that the degree of the remainder doesn't need to be smaller than that of \( f \). Since 2 doesn't divide 5, \( 2x \) doesn't divide \( 5x^2 \), even if the degree is smaller. But:

\[
>>> g = 5^x + 1
\]

\[
>>> q, r = \text{div}(f, g, \text{domain='ZZ'})
\]

\[
>>> q
x
\]

\[
>>> r
9^x + 3
\]

\[
>>> (q*g + r).expand()
2
5^x + 10^x + 3
\]

This also works for polynomials with multiple variables:

\[
>>> f = x*y + y*z
\]

\[
>>> g = 3^x + 3^z
\]

\[
>>> q, r = \text{div}(f, g, \text{domain='QQ'})
\]

\[
>>> q
y
\]

\[
>>> r
3
\]

\[
>>> (q*g + r).expand()
2
5^x + 10^x + 3
\]

In the last examples, all of the three variables \( x \), \( y \) and \( z \) are assumed to be variables of the polynomials. But if you have some unrelated constant as coefficient, you can specify the variables explicitly:

\[
>>> a, b, c = \text{symbols('a,b,c')}
\]

\[
>>> f = a*x**2 + b*x + c
\]

\[
>>> g = 3^x + 2
\]

\[
>>> q, r = \text{div}(f, g, \text{domain='QQ'})
\]

\[
>>> q
a*x  2*a  b
---  -  --- +  -
\]
GCD and LCM

With division, there is also the computation of the greatest common divisor and the least common multiple.

When the polynomials have integer coefficients, the contents’ gcd is also considered:

```python
>>> f = (12*x + 12)*x
>>> g = 16*x**2
>>> gcd(f, g)
4*x
```

But if the polynomials have rational coefficients, then the returned polynomial is monic:

```python
>>> f = 3*x**2/2
>>> g = 9*x/4
>>> gcd(f, g)
x
```

It also works with multiple variables. In this case, the variables are ordered alphabetically, by default, which has influence on the leading coefficient:

```python
>>> f = x*y/2 + y**2
>>> g = 3*x + 6*y
>>> gcd(f, g)
x + 2*y
```

The lcm is connected with the gcd and one can be computed using the other:

```python
>>> f = x*y**2 + x**2*y
>>> g = x**2*y**2
>>> gcd(f, g)
x*y
>>> lcm(f, g)
3 2 2 3
>>> (f*g).expand()
4 3 3 4
>>> (gcd(f, g, x, y)*lcm(f, g, x, y)).expand()
4 3 3 4
>>> x*y + x*y
```
Square-free factorization

The square-free factorization of a univariate polynomial is the product of all factors (not necessarily irreducible) of degree 1, 2 etc.:

```python
>>> f = 2*x**2 + 5*x**3 + 4*x**4 + x**5

>>> sqf_list(f)
(1, [(x + 2, 1), (x + x, 2)])

>>> sqf(f)
(x + 2)**2*(x + x)/
```

Factorization

This function provides factorization of univariate and multivariate polynomials with rational coefficients:

```python
>>> factor(x**4/2 + 5*x**3/12 - x**2/3)
x*(2*x - 1)*(3*x + 4)
```

Groebner bases

Buchberger’s algorithm is implemented, supporting various monomial orders:

```python
>>> groebner([x**2 + 1, y**4*x + x**3], x, y, order='lex')
\GroebnerBasis\[x + 1, y - 1\], x, y, domain=ZZ, order=lex/
```

```python
>>> groebner([x**2 + 1, y**4*x + x**3, x*y*z**3], x, y, z, order='grevlex')
\GroebnerBasis\[y - 1, z, x + 1\], x, y, z, domain=ZZ, order=grevlex/
```
Solving Equations

We have (incomplete) methods to find the complex or even symbolic roots of polynomials and to solve some systems of polynomial equations:

```python
>>> from sympy import roots, solve_poly_system

>>> solve(x**3 + 2*x + 3, x)
[-1, -1/11*I, 1/11*I]

>>> p = Symbol('p')
>>> q = Symbol('q')

>>> solve(x**2 + p*x + q, x)
[-p/2 - sqrt(p**2 - 4*q)/2, -p/2 + sqrt(p**2 - 4*q)/2]

>>> solve_poly_system([y - x, x - 5], x, y)
[(5, 5)]

>>> solve_poly_system([y**2 - x**3 + 1, y*x], x, y)
[(0, -I), (0, I), (1, 0), (-1, 0), (1, 0), (-1, 0)]
```

Examples from Wester’s Article

Introduction

In this tutorial we present examples from Wester’s article concerning comparison and critique of mathematical abilities of several computer algebra systems (see [Wester1999]). All the examples are related to polynomial and algebraic computations and SymPy specific remarks were added to all of them.

Examples

All examples in this tutorial are computable, so one can just copy and paste them into a Python shell and do something useful with them. All computations were done using the following setup:

```python
>>> from sympy import *

>>> init_printing(use_unicode=True, wrap_line=False)
```
Simple univariate polynomial factorization

To obtain a factorization of a polynomial use \texttt{factor()} (page 2447) function. By default \texttt{factor()} (page 2447) returns the result in unevaluated form, so the content of the input polynomial is left unexpanded, as in the following example:

\begin{verbatim}
>>> factor(6*x - 10)
2·(3·x - 5)
\end{verbatim}

To achieve the same effect in a more systematic way use \texttt{primitive()} (page 2444) function, which returns the content and the primitive part of the input polynomial:

\begin{verbatim}
>>> primitive(6*x - 10)
(2, 3·x - 5)
\end{verbatim}

\textbf{Note:} The content and the primitive part can be computed only over a ring. To simplify coefficients of a polynomial over a field use \texttt{monic()} (page 2443).

Univariate GCD, resultant and factorization

Consider univariate polynomials \( f \), \( g \) and \( h \) over integers:

\begin{verbatim}
>>> f = 64*x**34 - 21*x**47 - 126*x**8 - 46*x**5 - 16*x**60 - 81
>>> g = 72*x**60 - 25*x**25 - 19*x**23 - 22*x**39 - 83*x**52 + 54*x**10 + 81
>>> h = 34*x**19 - 25*x**16 + 70*x**7 + 20*x**3 - 91*x - 86
\end{verbatim}

We can compute the greatest common divisor (GCD) of two polynomials using \texttt{gcd()} (page 2442) function:

\begin{verbatim}
>>> gcd(f, g)
1
\end{verbatim}

We see that \( f \) and \( g \) have no common factors. However, \( f*h \) and \( g*h \) have an obvious factor \( h \):

\begin{verbatim}
>>> gcd(expand(f*h), expand(g*h)) - h
0
\end{verbatim}

The same can be verified using the resultant of univariate polynomials:

\begin{verbatim}
>>> resultant(expand(f*h), expand(g*h))
0
\end{verbatim}

Factorization of large univariate polynomials (of degree 120 in this case) over integers is also possible:
Multivariate GCD and factorization

What can be done in univariate case, can be also done for multivariate polynomials. Consider the following polynomials $f$, $g$ and $h$ in $\mathbb{Z}[x,y,z]$:

\begin{verbatim}
>>> f = 24*x*y**19*z**8 - 47*x**17*y**5*z**8 + 6*x**15*y**9*z**2 - 3*x**22 + 5
>>> g = 34*x**5*y**8*z**13 + 20*x**7*y**7*z**7 + 12*x**9*y**16*z**4 + 80*y**14*z
>>> h = 11*x**12*y**7*z**13 - 23*x**2*y**8*z**10 + 47*x**17*y**5*z**8
\end{verbatim}

As previously, we can verify that $f$ and $g$ have no common factors:

\begin{verbatim}
>>> gcd(f, g)
1
\end{verbatim}

However, $f*h$ and $g*h$ have an obvious factor $h$:

\begin{verbatim}
>>> gcd(expand(f*h), expand(g*h)) - h
0
\end{verbatim}

Multivariate factorization of large polynomials is also possible:

\begin{verbatim}
>>> factor(expand(f*g))
7 ( 9 9 3 7 6 5 12 7 ) / 22 17 5 8
-16*x + 21*x - 64*x + 46*x + 81 / 72*x - 83*x - 22*x - 25*x - 19*x + 54*x + 81
\end{verbatim}

Support for symbols in exponents

Polynomial manipulation functions provided by `sympy.polys` (page 2435) are mostly used with integer exponents. However, it’s perfectly valid to compute with symbolic exponents, e.g.:

\begin{verbatim}
>>> n = var('n')
>>> gcd(x**n - x**(2*n), x**n)
2
\end{verbatim}

Results may depend on powers being expanded (which will depend on assumptions of the base):

\begin{verbatim}
>>> gcd(x**(n + 4), x**(n + 1) - 3*x**n)
\end{verbatim}
Testing if polynomials have common zeros

To test if two polynomials have a root in common we can use `resultant()` function. The theory says that the resultant of two polynomials vanishes if there is a common zero of those polynomials. For example:

```python
>>> x = var('x')
>>> resultant(3*x**4 + 3*x**3 + x**2 - x - 2, x**3 - 3*x**2 + x + 5)
0
```

We can visualize this fact by factoring the polynomials:

```python
>>> factor(3*x**4 + 3*x**3 + x**2 - x - 2)
(x + 1)*(3*x + x - 2)

>>> factor(x**3 - 3*x**2 + x + 5)
(x + 1)*(x - 4*x + 5)
```

In both cases we obtained the factor $x + 1$ which tells us that the common root is $x = -1$.

Normalizing simple rational functions

To remove common factors from the numerator and the denominator of a rational function the elegant way, use `cancel()` function. For example:

```python
>>> cancel((x**2 - 4)/(x**2 + 4*x + 4))
x - 2
─────
x + 2
```

Expanding expressions and factoring back

One can work easily with expressions in both expanded and factored forms. Consider a polynomial $f$ in expanded form. We differentiate it and factor the result back:

```python
>>> f = expand((x + 1)**20)
>>> g = diff(f, x)
>>> factor(g)
```
The same can be achieved in factored form:

```python
>>> diff((x + 1)**20, x)
19
20⋅(x + 1)
```

### Factoring in terms of cyclotomic polynomials

SymPy can very efficiently decompose polynomials of the form \(x^n \pm 1\) in terms of cyclotomic polynomials:

```python
>>> factor(x**15 - 1)
(x - 1) ⋅ (x + x + 1) ⋅ (x + x + x + x + 1) ⋅ (x - x + x - x + x - x + 1)
```

The original Wester’s example was \(x^{100} - 1\), but was truncated for readability purpose. Note that this is not a big struggle for `factor()` (page 2447) to decompose polynomials of degree 1000 or greater.

### Univariate factoring over Gaussian numbers

Consider a univariate polynomial \(f\) with integer coefficients:

```python
>>> f = 4*x**4 + 8*x**3 + 77*x**2 + 18*x + 153
```

We want to obtain a factorization of \(f\) over Gaussian numbers. To do this we use `factor()` (page 2447) as previously, but this time we set `gaussian` keyword to `True`:

```python
>>> factor(f, gaussian=True)
4 ⋅ (x - 3⋅i/2) ⋅ (x + 3⋅i/2) ⋅ (x + 1 - 4⋅i) ⋅ (x + 1 + 4⋅i)
```

As the result we got a splitting factorization of \(f\) with monic factors (this is a general rule when computing in a field with SymPy). The `gaussian` keyword is useful for improving code readability, however the same result can be computed using more general syntax:

```python
>>> factor(f, extension=I)
4 ⋅ (x - 3⋅i/2) ⋅ (x + 3⋅i/2) ⋅ (x + 1 - 4⋅i) ⋅ (x + 1 + 4⋅i)
```
Computing with automatic field extensions

Consider two univariate polynomials $f$ and $g$:

```python
>>> f = x**3 + (sqrt(2) - 2)*x**2 - (2*sqrt(2) + 3)*x - 3*sqrt(2)
>>> g = x**2 - 2
```

We would like to reduce degrees of the numerator and the denominator of a rational function $f/g$. To do this we employ `cancel()` (page 2451) function:

```python
>>> cancel(f/g)
3  2  2
x - 2·x + √2·x - 3·x - 2·√2·x - 3·√2
───────────────────────────────────────
2
x - 2
```

Unfortunately nothing interesting happened. This is because by default SymPy treats $\sqrt{2}$ as a generator, obtaining a bivariate polynomial for the numerator. To make `cancel()` (page 2451) recognize algebraic properties of $\sqrt{2}$, one needs to use extension keyword:

```python
>>> cancel(f/g, extension=True)
2
x - 2·x - 3
────────────
x - √2
```

Setting `extension=True` tells `cancel()` (page 2451) to find minimal algebraic number domain for the coefficients of $f/g$. The automatically inferred domain is $Q(\sqrt{2})$. If one doesn't want to rely on automatic inference, the same result can be obtained by setting the extension keyword with an explicit algebraic number:

```python
>>> cancel(f/g, extension=sqrt(2))
2
x - 2·x - 3
────────────
x - √2
```

Univariate factoring over various domains

Consider a univariate polynomial $f$ with integer coefficients:

```python
>>> f = x**4 - 3*x**2 + 1
```

With `sympy.polys` (page 2435) we can obtain factorizations of $f$ over different domains, which includes:

- rationals:

```python
>>> factor(f)
( 2
(x - x - 1)·(x + x - 1)
```

- finite fields:
Factoring polynomials into linear factors

Currently SymPy can factor polynomials into irreducibles over various domains, which can result in a splitting factorization (into linear factors). However, there is currently no systematic way to infer a splitting field (algebraic number field) automatically. In future the following syntax will be implemented:

```python
>>> factor(x**3 + x**2 - 7, split=True)
Traceback (most recent call last):
...     NotImplementedError: 'split' option is not implemented yet
```

Note this is different from extension=True, because the later only tells how expression parsing should be done, not what should be the domain of computation. One can simulate the split keyword for several classes of polynomials using `solve()` (page 882) function.

Advanced factoring over finite fields

Consider a univariate polynomial $f$ with integer coefficients:

```python
>>> f = x**11 + x + 1
We can factor $f$ over a large finite field $F_{65537}$:

```python
>>> factor(f, modulus=65537)
```

and expand the resulting factorization back:

```python
>>> expand(_)
11
x + x + 1
```

obtaining polynomial $f$. This was done using symmetric polynomial representation over finite fields. The same thing can be done using non-symmetric representation:

```python
>>> factor(f, modulus=65537, symmetric=False)
```
As with symmetric representation we can expand the factorization to get the input polynomial back. This time, however, we need to truncate coefficients of the expanded polynomial modulo 65537:

```python
>>> trunc(expand(_), 65537)
11
x  + x  + 1
```

**Working with expressions as polynomials**

Consider a multivariate polynomial \( f \) in \( \mathbb{Z}[x, y, z] \):

```python
>>> f = expand((x - 2*y**2 + 3*z**3)**20)
```

We want to compute factorization of \( f \). To do this we use `factor` as usually, however we note that the polynomial in consideration is already in expanded form, so we can tell the factorization routine to skip expanding \( f \):

```python
>>> factor(f, expand=False)
20
\( \begin{pmatrix} 2 & 3 \\ x - 2\cdot y + 3\cdot z \end{pmatrix} \)
```

The default in `sympy.polys` (page 2435) is to expand all expressions given as arguments to polynomial manipulation functions and `Poly` (page 2453) class. If we know that expanding is unnecessary, then by setting `expand=False` we can save quite a lot of time for complicated inputs. This can be really important when computing with expressions like:

```python
>>> g = expand((sin(x) - 2*cos(y)**2 + 3*tan(z)**3)**20)
>>> factor(g, expand=False)
20
\( \begin{pmatrix} 2 & 3 \\ -\sin(x) + 2\cdot \cos(y) - 3\cdot \tan(z) \end{pmatrix} \)
```

**Computing reduced Gröbner bases**

To compute a reduced Gröbner basis for a set of polynomials use the `groebner()` (page 2451) function. The function accepts various monomial orderings, e.g.: `lex`, `grlex`, and `grevlex`, or a user defined one, via `order` keyword. The `lex` ordering is the most interesting because it has elimination property, which means that if the system of polynomial equations to `groebner()` (page 2451) is zero-dimensional (has finite number of solutions) the last element of the basis is a univariate polynomial. Consider the following example:

```python
>>> f = expand((1 - c**2)**5 * (1 - s**2)**5 * (c**2 + s**2)**10)
>>> groebner([f, c**2 + s**2 - 1])
GroebnerBasis([c + s - 1, c - 5\cdot c + 10\cdot c - 10\cdot c + 5\cdot c - c ], s, order=lex)
```

5.8. Topics 2433
The result is an ordinary Python list, so we can easily apply a function to all its elements, for example we can factor those elements:

```python
>>> list(map(factor, _))
[[2, 2, 10, 5, 5], [c + s - 1, c ·(c - 1) ·(c + 1)]
```

From the above we can easily find all solutions of the system of polynomial equations. Or we can use `solve()` (page 882) to achieve this in a more systematic way:

```python
>>> solve([f, s**2 + c**2 - 1], c, s)
[(-1, 0), (0, -1), (0, 1), (1, 0)]
```

### Multivariate factoring over algebraic numbers

Computing with multivariate polynomials over various domains is as simple as in univariate case. For example consider the following factorization over \(\mathbb{Q}(\sqrt{-3})\):

```python
>>> factor(x**3 + y**3, extension=sqrt(-3))
(x + y)·(x + y·(1 + √3·i))·(x + y·(1 - √3·i))
```

**Note:** Currently multivariate polynomials over finite fields aren’t supported.

### Partial fraction decomposition

Consider a univariate rational function \(f\) with integer coefficients:

```python
>>> f = (x**2 + 2*x + 3)/(x**3 + 4*x**2 + 5*x + 2)
```

To decompose \(f\) into partial fractions use `apart()` (page 2522) function:

```python
>>> apart(f)
3/2 - 2/((x + 2)·(x + 1)) + 2/(x + 1)
```

To return from partial fractions to the rational function use a composition of `together()` (page 2521) and `cancel()` (page 2451):

```python
>>> cancel(together(_))
2/3 + 2·x + 3
```

### Chapter 5. API Reference
**Literature**

**Polynomials Manipulation Module Reference**

Polynomial manipulation algorithms and algebraic objects.

See *Polynomial Manipulation* (page 2416) for an index of documentation for the polys module and *Basic functionality of the module* (page 2416) for an introductory explanation.

**Basic polynomial manipulation functions**

```python
sympy.polys.polytools.poly(expr, *gens, **args)
```

Efficiently transform an expression into a polynomial.

**Examples**

```python
>>> from sympy import poly
>>> from sympy.abc import x

>>> poly(x*(x**2 + x - 1)**2)
Poly(x**5 + 2*x**4 - x**3 - 2*x**2 + x, x, domain='ZZ')
```

```python
sympy.polys.polytools.poly_from_expr(expr, *gens, **args)
```

Construct a polynomial from an expression.

```python
sympy.polys.polytools.parallel_poly_from_expr(exprs, *gens, **args)
```

Construct polynomials from expressions.

```python
sympy.polys.polytools.degree(f, gen=0)
```

Return the degree of f in the given variable.

The degree of 0 is negative infinity.

**Examples**

```python
>>> from sympy import degree
>>> from sympy.abc import x, y

>>> degree(x**2 + y*x + 1, gen=x)
2
>>> degree(x**2 + y*x + 1, gen=y)
1
>>> degree(0, x)
-inf
```

See also:

`sympy.polys.polytools.Poly.total_degree` (page 2497), `degree_list` (page 2435)

```python
sympy.polys.polytools.degree_list(f, *gens, **args)
```

Return a list of degrees of f in all variables.

---

5.8. Topics 2435
Examples

```python
>>> from sympy import degree_list
>>> from sympy.abc import x, y

>>> degree_list(x**2 + y*x + 1)
(2, 1)
```

`sympy.polys.polytools.LC(f, *gens, **args)`
Return the leading coefficient of \( f \).

Examples

```python
>>> from sympy import LC
>>> from sympy.abc import x, y

>>> LC(4*x**2 + 2*x*y**2 + x*y + 3*y)
4
```

`sympy.polys.polytools.LM(f, *gens, **args)`
Return the leading monomial of \( f \).

Examples

```python
>>> from sympy import LM
>>> from sympy.abc import x, y

>>> LM(4*x**2 + 2*x*y**2 + x*y + 3*y)
x**2
```

`sympy.polys.polytools.LT(f, *gens, **args)`
Return the leading term of \( f \).

Examples

```python
>>> from sympy import LT
>>> from sympy.abc import x, y

>>> LT(4*x**2 + 2*x*y**2 + x*y + 3*y)
4*x**2
```

`sympy.polys.polytools.pdiv(f, g, *gens, **args)`
Compute polynomial pseudo-division of \( f \) and \( g \).
Examples

```python
>>> from sympy import pdiv
>>> from sympy.abc import x

>>> pdiv(x**2 + 1, 2*x - 4)
(2*x + 4, 20)
```

sympy.polys.polytools.prem(f, g, *gens, **args)

Compute polynomial pseudo-remainder of f and g.

Examples

```python
>>> from sympy import prem
>>> from sympy.abc import x

>>> prem(x**2 + 1, 2*x - 4)
20
```

sympy.polys.polytools.pquo(f, g, *gens, **args)

Compute polynomial pseudo-quotient of f and g.

Examples

```python
>>> from sympy import pquo
>>> from sympy.abc import x

>>> pquo(x**2 + 1, 2*x - 4)
2*x + 4
>>> pquo(x**2 - 1, 2*x - 1)
2*x + 1
```

sympy.polys.polytools.pexquo(f, g, *gens, **args)

Compute polynomial exact pseudo-quotient of f and g.

Examples

```python
>>> from sympy import pexquo
>>> from sympy.abc import x

>>> pexquo(x**2 - 1, 2*x - 2)
2*x + 2
>>> pexquo(x**2 + 1, 2*x - 4)
Traceback (most recent call last):
...
ExactQuotientFailed: 2*x - 4 does not divide x**2 + 1
```
sympy.polys.polytools.div(f, g, *gens, **args)
Compute polynomial division of f and g.

Examples

```python
>>> from sympy import div, ZZ, QQ
>>> from sympy.abc import x

>>> div(x**2 + 1, 2*x - 4, domain=ZZ)
(0, x**2 + 1)
>>> div(x**2 + 1, 2*x - 4, domain=QQ)
(x/2 + 1, 5)
```

sympy.polys.polytools.rem(f, g, *gens, **args)
Compute polynomial remainder of f and g.

Examples

```python
>>> from sympy import rem, ZZ, QQ
>>> from sympy.abc import x

>>> rem(x**2 + 1, 2*x - 4, domain=ZZ)
x**2 + 1
>>> rem(x**2 + 1, 2*x - 4, domain=QQ)
5
```

sympy.polys.polytools.quo(f, g, *gens, **args)
Compute polynomial quotient of f and g.

Examples

```python
>>> from sympy import quo
>>> from sympy.abc import x

>>> quo(x**2 + 1, 2*x - 4)
x/2 + 1
>>> quo(x**2 - 1, x - 1)
x + 1
```

sympy.polys.polytools.exquo(f, g, *gens, **args)
Compute polynomial exact quotient of f and g.
Examples

```python
>>> from sympy import exquo
>>> from sympy.abc import x

>>> exquo(x**2 - 1, x - 1)
x + 1

>>> exquo(x**2 + 1, 2*x - 4)
Traceback (most recent call last):
...  
ExactQuotientFailed: 2*x - 4 does not divide x**2 + 1
```

`sympy.polys.polytools.half_gcdex(f, g, *gens, **args)`

Half extended Euclidean algorithm of f and g.

Returns \( (s, h) \) such that \( h = \gcd(f, g) \) and \( s*f = h \pmod{g} \).

Examples

```python
>>> from sympy import half_gcdex
>>> from sympy.abc import x

>>> half_gcdex(x**4 - 2*x**3 - 6*x**2 + 12*x + 15, x**3 + x**2 - 4*x - 4)
(3/5 - x/5, x + 1)
```

`sympy.polys.polytools.gcdex(f, g, *gens, **args)`

Extended Euclidean algorithm of f and g.

Returns \( (s, t, h) \) such that \( h = \gcd(f, g) \) and \( s*f + t*g = h \).

Examples

```python
>>> from sympy import gcdex
>>> from sympy.abc import x

>>> gcdex(x**4 - 2*x**3 - 6*x**2 + 12*x + 15, x**3 + x**2 - 4*x - 4)
(3/5 - x/5, x**2/5 - 6*x/5 + 2, x + 1)
```

`sympy.polys.polytools.invert(f, g, *gens, **args)`

Invert f modulo g when possible.
Examples

```python
>>> from sympy import invert, S, mod_inverse
>>> from sympy.abc import x

>>> invert(x**2 - 1, 2*x - 1)
-4/3

>>> invert(x**2 - 1, x - 1)
Traceback (most recent call last):
...  
NotInvertible: zero divisor
```

For more efficient inversion of Rationals, use the `mod_inverse` (page 1053) function:

```python
>>> mod_inverse(3, 5)
2
>>> (S(2)/5).invert(S(7)/3)
5/2
```

See also:
- `sympy.core.numbers.mod_inverse` (page 1053)
- `sympy.polys.polytools.subresultants(f, g, *gens, **args)`
  Compute subresultant PRS of f and g.

Examples

```python
>>> from sympy import subresultants
>>> from sympy.abc import x

>>> subresultants(x**2 + 1, x**2 - 1)
[x**2 + 1, x**2 - 1, -2]
```

- `sympy.polys.polytools.resultant(f, g, *gens, includePRS=False, **args)`
  Compute resultant of f and g.

Examples

```python
>>> from sympy import resultant
>>> from sympy.abc import x

>>> resultant(x**2 + 1, x**2 - 1)
4
```

- `sympy.polys.polytools.discriminant(f, *gens, **args)`
  Compute discriminant of f.
Examples

```python
>>> from sympy import discriminant
>>> from sympy.abc import x

>>> discriminant(x**2 + 2*x + 3)
-8
```

```python
sympy.polys.polytools.terms_gcd(f, *gens, **args)
```

Remove GCD of terms from `f`.

If the `deep` flag is `True`, then the arguments of `f` will have terms_gcd applied to them.

If a fraction is factored out of `f` and `f` is an Add, then an unevaluated Mul will be returned so that automatic simplification does not redistribute it. The hint `clear`, when set to `False`, can be used to prevent such factoring when all coefficients are not fractions.

Examples

```python
>>> from sympy import terms_gcd, cos
>>> from sympy.abc import x, y

>>> terms_gcd(x**6*y**2 + x**3*y, x, y)
x**3*y*(x**3*y + 1)
```

The default action of polys routines is to expand the expression given to them. `terms_gcd` follows this behavior:

```python
>>> terms_gcd((3+3*x)*(x+x*y))
3*x*(x*y + x + y + 1)
```

If this is not desired then the hint `expand` can be set to `False`. In this case the expression will be treated as though it were comprised of one or more terms:

```python
>>> terms_gcd((3+3*x)*(x+x*y), expand=False)
(3*x + 3)*(x*y + x)
```

In order to traverse factors of a Mul or the arguments of other functions, the `deep` hint can be used:

```python
>>> terms_gcd((3 + 3*x)*(x + x*y), expand=False, deep=True)
3*x*(x + 1)*(y + 1)
```

```python
>>> terms_gcd(cos(x + x*y), deep=True)
cos(x*(y + 1))
```

Rationals are factored out by default:

```python
>>> terms_gcd(x + y/2)
(2*x + y)/2
```

Only the `y`-term had a coefficient that was a fraction; if one does not want to factor out the 1/2 in cases like this, the flag `clear` can be set to `False`:

5.8. Topics
>>> terms_gcd(x + y/2, clear=False)
  x + y/2
>>> terms_gcd(x*y/2 + y**2, clear=False)
  y*(x/2 + y)

The clear flag is ignored if all coefficients are fractions:

>>> terms_gcd(x/3 + y/2, clear=False)
  (2*x + 3*y)/6

See also:

sympy.core.exprtools.gcd_terms (page 1116), sympy.core.exprtools.factor_terms (page 1117)

sympy.polys.polytools.cofactors(f, g, *gens, **args)
  Compute GCD and cofactors of f and g.
  Returns polynomials (h, cff, cfg) such that h = gcd(f, g), and cff = quo(f, h) and cfg = quo(g, h) are, so called, cofactors of f and g.

Examples

>>> from sympy import cofactors
>>> from sympy.abc import x

>>> cofactors(x**2 - 1, x**2 - 3*x + 2)
  (x - 1, x + 1, x - 2)

sympy.polys.polytools.gcd(f, g=None, *gens, **args)
  Compute GCD of f and g.

Examples

>>> from sympy import gcd
>>> from sympy.abc import x

>>> gcd(x**2 - 1, x**2 - 3*x + 2)
  x - 1

sympy.polys.polytools.gcd_list(seq, *gens, **args)
  Compute GCD of a list of polynomials.
Examples

```python
>>> from sympy import gcd_list
>>> from sympy.abc import x

>>> gcd_list([x**3 - 1, x**2 - 1, x**2 - 3*x + 2])
x - 1
```

sympy.polys.polytools.lcm($f$, $g$=None, *gens, **args)

Compute LCM of $f$ and $g$.

Examples

```python
>>> from sympy import lcm
>>> from sympy.abc import x

>>> lcm(x**2 - 1, x**2 - 3*x + 2)
x**3 - 2*x**2 - x + 2
```

sympy.polys.polytools.lcm_list($seq$, *gens, **args)

Compute LCM of a list of polynomials.

Examples

```python
>>> from sympy import lcm_list
>>> from sympy.abc import x

>>> lcm_list([x**3 - 1, x**2 - 1, x**2 - 3*x + 2])
x**5 - x**4 - 2*x**3 - x**2 + x + 2
```

sympy.polys.polytools.trunc($f$, $p$, *gens, **args)

Reduce $f$ modulo a constant $p$.

Examples

```python
>>> from sympy import trunc
>>> from sympy.abc import x

>>> trunc(2*x**3 + 3*x**2 + 5*x + 7, 3)
-x**3 - x + 1
```

sympy.polys.polytools.monic($f$, *gens, **args)

Divide all coefficients of $f$ by $\text{LC}(f)$.
```
Examples

```python
>>> from sympy import monic
>>> from sympy.abc import x

>>> monic(3*x**2 + 4*x + 2)
x**2 + 4*x/3 + 2/3
```

sympy.polys.polytools.content(f, *gens, **args)
Compute GCD of coefficients of f.

```
Examples

```python
>>> from sympy import content
>>> from sympy.abc import x

>>> content(6*x**2 + 8*x + 12)
2
```

sympy.polys.polytools.primitive(f, *gens, **args)
Compute content and the primitive form of f.

```
Examples

```python
>>> from sympy.polys.polytools import primitive
>>> from sympy.abc import x

>>> primitive(6*x**2 + 8*x + 12)
(2, 3*x**2 + 4*x + 6)

>>> eq = (2 + 2*x)*x + 2

Expansion is performed by default:

```python
>>> primitive(eq)
(2, x**2 + x + 1)
```

Set expand to False to shut this off. Note that the extraction will not be recursive; use the as_contentPrimitive method for recursive, non-destructive Rational extraction.

```python
>>> primitive(eq, expand=False)
(1, x*(2*x + 2) + 2)

>>> eq.as_content_primitive()
(2, x*(x + 1) + 1)
```

sympy.polys.polytools.compose(f, g, *gens, **args)
Compute functional composition f(g).
Examples

```python
>>> from sympy import compose
>>> from sympy.abc import x

>>> compose(x**2 + x, x - 1)
```

```python
x**2 - x
```

`sympy.polys.polytools.decompose(f, *gens, **args)`

Compute functional decomposition of f.

Examples

```python
>>> from sympy import decompose
>>> from sympy.abc import x

>>> decompose(x**4 + 2*x**3 - x - 1)
```

```python
[x**2 - x - 1, x**2 + x]
```

`sympy.polys.polytools.sturm(f, *gens, **args)`

Compute Sturm sequence of f.

Examples

```python
>>> from sympy import sturm
>>> from sympy.abc import x

>>> sturm(x**3 - 2*x**2 + x - 3)
```

```python
[x**3 - 2*x**2 + x - 3, 3*x**2 - 4*x + 1, 2*x/9 + 25/9, -2079/4]
```

`sympy.polys.polytools.gff_list(f, *gens, **args)`

Compute a list of greatest factorial factors of f.

Note that the input to ff() and rf() should be Poly instances to use the definitions here.

Examples

```python
>>> from sympy import gff_list, ff, Poly
>>> from sympy.abc import x

>>> f = Poly(x**5 + 2*x**4 - x**3 - 2*x**2, x)

>>> gff_list(f)
```

```python
[(Poly(x, x, domain='ZZ'), 1), (Poly(x + 2, x, domain='ZZ'), 4)]
```

```python
>>> (ff(Poly(x), 1)*ff(Poly(x + 2), 4)) == f
```

True

5.8. Topics 2445
```python
>>> f = Poly(x**12 + 6*x**11 - 11*x**10 - 56*x**9 + 220*x**8 + 208*x**7 -
1401*x**6 + 1090*x**5 + 2715*x**4 - 6720*x**3 - 1092*x**2 +
-5040*x, x)
```
```
>>> gff_list(f)
[[(Poly(x**3 + 7, x, domain='ZZ'), 2), (Poly(x**2 + 5*x, x, domain='ZZ'),
-3)]
```
```
>>> ff(Poly(x**3 + 7, x), 2)*ff(Poly(x**2 + 5*x, x), 3) == f
True
```
```
sympy.polys.polytools.gff(f, *gens, **args)
    Compute greatest factorial factorization of f.
```
```
sympy.polys.polytools.sqf_norm(f, *gens, **args)
    Compute square-free norm of f.
    Returns s, f, r, such that g(x) = f(x-sa) and r(x) = Norm(g(x)) is a square-free polynomial over K, where a is the algebraic extension of the ground domain.
```
```
Examples
```
```python
>>> from sympy import sqf_norm, sqrt
>>> from sympy.abc import x
```
```
>>> sqf_norm(x**2 + 1, extension=[sqrt(3)])
(1, x**2 - 2*sqrt(3)*x + 4, x**4 - 4*x**2 + 16)
```
```
sympy.polys.polytools.sqf_part(f, *gens, **args)
    Compute square-free part of f.
```
```
Examples
```
```python
>>> from sympy import sqf_part
>>> from sympy.abc import x
```
```
>>> sqf_part(x**3 - 3*x - 2)
x**2 - x - 2
```
```
sympy.polys.polytools.sqf_list(f, *gens, **args)
    Compute a list of square-free factors of f.
```
SymPy Documentation, Release 1.12.1

Examples

```python
>>> from sympy import sqf_list
>>> from sympy.abc import x

>>> sqf_list(2*x**5 + 16*x**4 + 50*x**3 + 76*x**2 + 56*x + 16)
(2, [(x + 1, 2), (x + 2, 3)])
```

**sympy.polys.polytools.sqf**(*f*, *gens*, **args**)

Compute square-free factorization of *f*.

Examples

```python
>>> from sympy import sqf
>>> from sympy.abc import x

>>> sqf(2*x**5 + 16*x**4 + 50*x**3 + 76*x**2 + 56*x + 16)
2*(x + 1)**2*(x + 2)**3
```

**sympy.polys.polytools.factor_list**(*f*, *gens*, **args**)

Compute a list of irreducible factors of *f*.

Examples

```python
>>> from sympy import factor_list
>>> from sympy.abc import x, y

>>> factor_list(2*x**5 + 2*x**4*y + 4*x**3 + 4*x**2*y + 2*x + 2*y)
(2, [(x + y, 1), (x**2 + 1, 2)])
```

**sympy.polys.polytools.factor**(*f*, *gens*, *deep=False*, **args**)

Compute the factorization of expression, *f*, into irreducibles. (To factor an integer into primes, use factorint.)

There two modes implemented: symbolic and formal. If *f* is not an instance of Poly (page 2453) and generators are not specified, then the former mode is used. Otherwise, the formal mode is used.

In symbolic mode, factor() (page 2447) will traverse the expression tree and factor its components without any prior expansion, unless an instance of Add (page 1062) is encountered (in this case formal factorization is used). This way factor() (page 2447) can handle large or symbolic exponents.

By default, the factorization is computed over the rationals. To factor over other domain, e.g. an algebraic or finite field, use appropriate options: extension, modulus or domain.

5.8. Topics 2447
Examples

```python
>>> from sympy import factor, sqrt, exp
>>> from sympy.abc import x, y

>>> factor(2*x**5 + 2*x**4*y + 4*x**3 + 4*x**2*y + 2*x + 2*y)
2*(x + y)*(x**2 + 1)**2

>>> factor(x**2 + 1)
(x**2 + 1)

>>> factor(x**2 + 1, modulus=2)
(x + 1)**2

>>> factor(x**2 + 1, gaussian=True)
(x - I)*(x + I)

>>> factor(x**2 - 2, extension=sqrt(2))
(x - sqrt(2))*(x + sqrt(2))

>>> factor((x**2 - 1)/(x**2 + 4*x + 4))
(x - 1)*(x + 1)/(x + 2)**2

>>> factor((x**2 + 4*x + 4)**10000000*(x**2 + 1))
(x + 2)**20000000*(x**2 + 1)

By default, factor deals with an expression as a whole:

```python
>>> eq = 2**((x**2 + 2*x + 1)
>>> factor(eq)
2**((x + 1)**2)
```

If the deep flag is True then subexpressions will be factored:

```python
>>> factor(eq, deep=True)
2**((x + 1)**2)
```

If the fraction flag is False then rational expressions will not be combined. By default it is True.

```python
>>> factor(5*x + 3*exp(2 - 7*x), deep=True)
(5*x*exp(7*x) + 3*exp(2))*exp(-7*x)

>>> factor(5*x + 3*exp(2 - 7*x), deep=True, fraction=False)
5*x + 3*exp(2)*exp(-7*x)
```

See also:

* sympy.ntheory.factor_.factorint (page 1539)
* sympy.polys.polytools.intervals(F, all=False, eps=None, inf=None, sup=None, strict=False, fast=False, sqf=False)

Compute isolating intervals for roots of f.
Examples

```python
>>> from sympy import intervals
>>> from sympy.abc import x

>>> intervals(x**2 - 3)
[((-2, -1), 1), ((1, 2), 1)]
>>> intervals(x**2 - 3, eps=1e-2)
[((-26/15, -19/11), 1), ((19/11, 26/15), 1)]
```

**sympy.polys.polytools.refine_root**

Refine an isolating interval of a root to the given precision.

Examples

```python
>>> from sympy import refine_root
>>> from sympy.abc import x

>>> refine_root(x**2 - 3, 1, 2, eps=1e-2)
(19/11, 26/15)
```

**sympy.polys.polytools.count_roots**

Return the number of roots of *f* in [inf, sup] interval.

If one of inf or sup is complex, it will return the number of roots in the complex rectangle with corners at inf and sup.

Examples

```python
>>> from sympy import count_roots, I
>>> from sympy.abc import x

>>> count_roots(x**4 - 4, -3, 3)
2
>>> count_roots(x**4 - 4, 0, 1 + 3*I)
1
```

**sympy.polys.polytools.real_roots**

Return a list of real roots with multiplicities of *f*.
Examples

```python
>>> from sympy import real_roots
>>> from sympy.abc import x

>>> real_roots(2*x**3 - 7*x**2 + 4*x + 4)
[-1/2, 2, 2]
```

`sympy.polys.polytools.nroots(f, n=15, maxsteps=50, cleanup=True)`
Compute numerical approximations of roots of `f`.

Examples

```python
>>> from sympy import nroots
>>> from sympy.abc import x

>>> nroots(x**2 - 3, n=15)
[-1.73205080756887729352744634151, 1.73205080756887729352744634151]
```

`sympy.polys.polytools.ground_roots(f, *gens, **args)`
Compute roots of `f` by factorization in the ground domain.

Examples

```python
>>> from sympy import ground_roots
>>> from sympy.abc import x

>>> ground_roots(x**6 - 4*x**4 + 4*x**3 - x**2)
{0: 2, 1: 2}
```

`sympy.polys.polytools.nth_power_roots_poly(f, n, *gens, **args)`
Construct a polynomial with n-th powers of roots of `f`.

Examples

```python
>>> from sympy import nth_power_roots_poly, factor, roots
>>> from sympy.abc import x

>>> f = x**4 - x**2 + 1
>>> g = factor(nth_power_roots_poly(f, 2))

>>> g
(x**2 - x + 1)**2
```
```python
>>> R_f = [ (r*r*2).expand() for r in roots(f) ]
>>> R_g = roots(g).keys()
```

```python
>>> set(R_f) == set(R_g)
True
```

### sympy.polys.polytools.cancel(f, *gens, _signsimp=True, **args)

Cancel common factors in a rational function f.

**Examples**

```python
>>> from sympy import cancel, sqrt, Symbol, together
>>> from sympy.abc import x
>>> A = Symbol('A', commutative=False)
```

```python
>>> cancel((2*x**2 - 2)/(x**2 - 2*x + 1))
(2*x + 2)/(x - 1)
```

```python
>>> cancel((sqrt(3) + sqrt(15)*A)/(sqrt(2) + sqrt(10)*A))
sqrt(6)/2
```

Note: due to automatic distribution of Rationals, a sum divided by an integer will appear as a sum. To recover a rational form use `together` on the result:

```python
>>> cancel(x/2 + 1)
x/2 + 1
```

```python
>>> together(_)
(x + 2)/2
```

### sympy.polys.polytools.reduced(f, G, *gens, **args)

Reduces a polynomial f modulo a set of polynomials G.

Given a polynomial f and a set of polynomials \( G = (g_1, \ldots, g_n) \), computes a set of quotients \( q = (q_1, \ldots, q_n) \) and the remainder \( r \) such that \( f = q_1 g_1 + \ldots + q_n g_n + r \), where \( r \) vanishes or \( r \) is a completely reduced polynomial with respect to \( G \).

**Examples**

```python
>>> from sympy import reduced
>>> from sympy.abc import x, y
```

```python
>>> reduced(2*x**4 + y**2 - x**2 + y**3, [x**3 - x, y**3 - y])
([2*x, 1], x**2 + y**2 + y)
```

### sympy.polys.polytools.groebner(F, *gens, **args)

Computes the reduced Groebner basis for a set of polynomials.

Use the order argument to set the monomial ordering that will be used to compute the basis. Allowed orders are lex, grlex and grevlex. If no order is specified, it defaults to lex.
For more information on Groebner bases, see the references and the docstring of `solve_poly_system()` (page 903).

**Examples**

Example taken from [1].

```python
>>> from sympy import groebner
>>> from sympy.abc import x, y

>>> F = [x*y - 2*y, 2*y**2 - x**2]

>>> groebner(F, x, y, order='lex')
GroebnerBasis([x**2 - 2*y**2, x*y - 2*y, y**3 - 2*y], x, y, domain='ZZ', order='lex')

>>> groebner(F, x, y, order='grlex')
GroebnerBasis([y**3 - 2*y, x**2 - 2*y**2, x*y - 2*y], x, y, domain='ZZ', order='grlex')

>>> groebner(F, x, y, order='grevlex')
GroebnerBasis([y**3 - 2*y, x**2 - 2*y**2, x*y - 2*y], x, y, domain='ZZ', order='grevlex')
```

By default, an improved implementation of the Buchberger algorithm is used. Optionally, an implementation of the F5B algorithm can be used. The algorithm can be set using the method flag or with the `sympy.polys.polyconfig.setup()` (page 2725) function.

```python
>>> F = [x**2 - x - 1, (2*x - 1) * y - (x**10 - (1 - x)**10)]

>>> groebner(F, x, y, method='buchberger')
GroebnerBasis([x**2 - x - 1, y - 55], x, y, domain='ZZ', order='lex')

>>> groebner(F, x, y, method='f5b')
GroebnerBasis([x**2 - x - 1, y - 55], x, y, domain='ZZ', order='lex')
```

**References**

1. [Buchberger01]
2. [Cox97]

[Buchberger01], [Cox97]

`sympy.polys.polytools.is_zero_dimensional(F, *gens, **args)`

Checks if the ideal generated by a Groebner basis is zero-dimensional.

The algorithm checks if the set of monomials not divisible by the leading monomial of any element of F is bounded.
References

class sympy.polys.polytools.Poly(rep, *gens, **args)
Generic class for representing and operating on polynomial expressions.
See Polynomial Manipulation (page 2416) for general documentation.
Poly is a subclass of Basic rather than Expr but instances can be converted to Expr with the as_expr() (page 2457) method.
Deprecated since version 1.6: Combining Poly with non-Poly objects in binary operations is deprecated. Explicitly convert both objects to either Poly or Expr first. See Mixing Poly and non-polynomial expressions in binary operations (page 228).

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

Create a univariate polynomial:

```python
>>> Poly(x*(x**2 + x - 1)**2)
Poly(x**5 + 2*x**4 - x**3 - 2*x**2 + x, x, domain='ZZ')
```

Create a univariate polynomial with specific domain:

```python
>>> from sympy import sqrt
>>> Poly(x**2 + 2*x + sqrt(3), domain='R')
Poly(1.0*x**2 + 2.0*x + 1.73205080756888, x, domain='RR')
```

Create a multivariate polynomial:

```python
>>> Poly(y*x**2 + x*y + 1)
Poly(x**2*y + x*y + 1, x, y, domain='ZZ')
```

Create a univariate polynomial, where y is a constant:

```python
>>> Poly(y*x**2 + x*y + 1, x)
Poly(y*x**2 + y*x + 1, x, domain='ZZ[y]')
```

You can evaluate the above polynomial as a function of y:

```python
>>> Poly(y*x**2 + x*y + 1, x).eval(2)
6*y + 1
```

See also:
sympy.core.expr.Expr (page 999)
EC(order=None)
Returns the last non-zero coefficient of f.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**3 + 2*x**2 + 3*x, x).EC()
3
```

**EM(order=None)**

Returns the last non-zero monomial of \( f \).

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(4*x**2 + 2*x*y**2 + x*y + 3*y, x, y).EM()
x**0*y**1
```

**ET(order=None)**

Returns the last non-zero term of \( f \).

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(4*x**2 + 2*x*y**2 + x*y + 3*y, x, y).ET()
(x**0*y**1, 3)
```

**LC(order=None)**

Returns the leading coefficient of \( f \).

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(4*x**3 + 2*x**2 + 3*x, x).LC()
4
```

**LM(order=None)**

Returns the leading monomial of \( f \).

The Leading monomial signifies the monomial having the highest power of the principal generator in the expression \( f \).
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(4*x**2 + 2*x*y**2 + x*y + 3*y, x, y).LM()
x**2*y**0

LT(order=None)
Returns the leading term of f.
The Leading term signifies the term having the highest power of the principal generator in the expression f along with its coefficient.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(4*x**2 + 2*x*y**2 + x*y + 3*y, x, y).LT()
(x**2*y**0, 4)

TC()
Returns the trailing coefficient of f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**3 + 2*x**2 + 3*x, x).TC()
0

abs()
Make all coefficients in f positive.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 - 1, x).abs()
Poly(x**2 + 1, x, domain='ZZ')

add(g)
Add two polynomials f and g.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 + 1, x).add(Poly(x - 2, x))
Poly(x**2 + x - 1, x, domain='ZZ')

>>> Poly(x**2 + 1, x) + Poly(x - 2, x)
Poly(x**2 + x - 1, x, domain='ZZ')
```

**add_ground** (*coeff*)

Add an element of the ground domain to f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x + 1).add_ground(2)
Poly(x + 3, x, domain='ZZ')
```

**all_coeffs**

Returns all coefficients from a univariate polynomial f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**3 + 2*x - 1, x).all_coeffs()
[1, 0, 2, -1]
```

**all_monoms**

Returns all monomials from a univariate polynomial f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**3 + 2*x - 1, x).all_monoms()
[(3,), (2,), (1,), (0,)]
```

See also:

*all_terms* (page 2457)
all_roots\((multiple=True, radicals=True)\)

Return a list of real and complex roots with multiplicities.

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(2*x**3 - 7*x**2 + 4*x + 4).all_roots()
[-1/2, 2, 2]

>>> Poly(x**3 + x + 1).all_roots()
[CRootOf(x**3 + x + 1, 0),
 CRootOf(x**3 + x + 1, 1),
 CRootOf(x**3 + x + 1, 2)]
```

all_terms()

Returns all terms from a univariate polynomial \(f\).

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**3 + 2*x - 1, x).all_terms()
[((3,), 1), ((2,), 0), ((1,), 2), ((0,), -1)]
```

as_dict\((native=False, zero=False)\)

Switch to a dict representation.

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(x**2 + 2*x*y**2 - y, x, y).as_dict()
{(0, 1): -1, (1, 2): 2, (2, 0): 1}
```

as_expr\(*gens\)

Convert a Poly instance to an Expr instance.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> f = Poly(x**2 + 2*x*y**2 - y, x, y)

>>> f.as_expr()
x**2 + 2*x*y**2 - y
>>> f.as_expr({x: 5})
10*y**2 - y + 25
>>> f.as_expr(5, 6)
379
```

**as_list**(native=False)
Switch to a list representation.

**as_poly**(gens, **args)
Converts self to a polynomial or returns None.

```python
>>> from sympy import sin
>>> from sympy.abc import x

>>> print((x**2 + x*y).as_poly())
Poly(x**2 + x*y, x, y, domain='ZZ')

>>> print((x**2 + x*y).as_poly(x, y))
Poly(x**2 + x*y, x, y, domain='ZZ')

>>> print((x**2 + sin(y)).as_poly(x, y))
None
```

**cancel**(g, include=False)
Cancel common factors in a rational function f/g.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(2*x**2 - 2, x).cancel(Poly(x**2 - 2*x + 1, x))
(1, Poly(2*x + 2, x, domain='ZZ'), Poly(x - 1, x, domain='ZZ'))

>>> Poly(2*x**2 - 2, x).cancel(Poly(x**2 - 2*x + 1, x), include=True)
(Poly(2*x + 2, x, domain='ZZ'), Poly(x - 1, x, domain='ZZ'))
```

**clear_denoms**(convert=False)
Clear denominators, but keep the ground domain.
Examples

```python
>>> from sympy import Poly, S, QQ
>>> from sympy.abc import x

>>> f = Poly(x/2 + S(1)/3, x, domain=QQ)
>>> f.clear_denoms()
(6, Poly(3*x + 2, x, domain='QQ'))
>>> f.clear_denoms(convert=True)
(6, Poly(3*x + 2, x, domain='ZZ'))
```

coeff_monomial(monom)

Returns the coefficient of monom in f if there, else None.

Examples

```python
>>> from sympy import Poly, exp
>>> from sympy.abc import x, y

>>> p = Poly(24*x*y*exp(8) + 23*x, x, y)

>>> p.coeff_monomial(x)
23
>>> p.coeff_monomial(y)
0
>>> p.coeff_monomial(x*y)
24*exp(8)
```

Note that Expr.coeff() behaves differently, collecting terms if possible; the Poly must be converted to an Expr to use that method, however:

```python
>>> p.as_expr().coeff(x)
24*y*exp(8) + 23
>>> p.as_expr().coeff(y)
24*x*exp(8)
>>> p.as_expr().coeff(x*y)
24*exp(8)
```

See also:

nth (page 2483)

more efficient query using exponents of the monomial’s generators

coeffs(order=None)

Returns all non-zero coefficients from f in lex order.
Examples

```python
from sympy import Poly
from sympy.abc import x

Poly(x**3 + 2*x + 3, x).coeffs()
```

[1, 2, 3]

See also:
all_coeffs (page 2456), coeff_monomial (page 2459), nth (page 2483)

cofactors(g)
Returns the GCD of f and g and their cofactors.
Returns polynomials (h, cff, cfg) such that h = gcd(f, g), and cff = quo(f, h) and cfg = quo(g, h) are, so called, cofactors of f and g.

Examples

```python
from sympy import Poly

Poly(x**2 - 1, x).cofactors(Poly(x**2 - 3*x + 2, x))
```

(Poly(x - 1, x, domain='ZZ'),
 Poly(x + 1, x, domain='ZZ'),
 Poly(x - 2, x, domain='ZZ'))

compose(g)
Computes the functional composition of f and g.

Examples

```python
from sympy import Poly

Poly(x**2 + x, x).compose(Poly(x - 1, x))
```

Poly(x**2 - x, x, domain='ZZ')

content()
Returns the GCD of polynomial coefficients.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(6*x**2 + 8*x + 12, x).content()
2
```

count_roots\(\text{inf=None, sup=None}\)

Return the number of roots of \(f\) in \([\text{inf}, \text{sup}]\) interval.

Examples

```python
>>> from sympy import Poly, I
>>> from sympy.abc import x

>>> Poly(x**4 - 4, x).count_roots(-3, 3)
2
>>> Poly(x**4 - 4, x).count_roots(0, 1 + 3*I)
1
```

decompose()

Computes a functional decomposition of \(f\).

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**6*y**2 + x**3 + 1, x, y).deflate()
((3, 2), Poly(x**2*y + x + 1, x, y, domain='ZZ'))
```

deflate()

Reduce degree of \(f\) by mapping \(x_i^{**m}\) to \(y_i\).

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(x**6*y**2 + x**3 + 1, x, y).deflate()
((3, 2), Poly(x**2*y + x + 1, x, y, domain='ZZ'))
```

degree\(\text{gen=0}\)

Returns degree of \(f\) in \(x_\_i\).

The degree of 0 is negative infinity.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(x**2 + y*x + 1, x, y).degree()
2
>>> Poly(x**2 + y*x + y, x, y).degree(y)
1
>>> Poly(0, x).degree()
-oo
```

**degree_list()**
Returns a list of degrees of f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(x**2 + y*x + 1, x, y).degree_list()
(2, 1)
```

**diff(*specs, **kwargs)**
Computes partial derivative of f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(x**2 + 2*x + 1, x).diff()
Poly(2*x + 2, x, domain='ZZ')

>>> Poly(x*y**2 + x, x, y).diff((0, 0), (1, 1))
Poly(2*x*y, x, y, domain='ZZ')
```

**discriminant()**
Computes the discriminant of f.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 + 2*x + 3, x).discriminant()
-8
```

dispersion\((g=\text{None})\)

Compute the dispersion of polynomials.

For two polynomials \(f(x)\) and \(g(x)\) with \(\deg f > 0\) and \(\deg g > 0\) the dispersion \(\text{dis}(f,g)\) is defined as:

\[
\text{dis}(f,g) := \max\{J(f,g) \cup \{0\}
= \max\{\{a \in \mathbb{N}| \gcd(f(x), g(x + a)) \neq 1\} \cup \{0\}\}
\]

and for a single polynomial \(\text{dis}(f) := \text{dis}(f,f)\).

Examples

```python
>>> from sympy import poly
>>> from sympy.polys.dispersion import dispersion, dispersionset
>>> from sympy.abc import x

Dispersion set and dispersion of a simple polynomial:

```python
>>> fp = poly((x - 3)*(x + 3), x)
>>> sorted(dispersionset(fp))
[0, 6]
>>> dispersion(fp)
6
```

Note that the definition of the dispersion is not symmetric:

```python
>>> fp = poly(x**4 - 3*x**2 + 1, x)
>>> gp = fp.shift(-3)
>>> sorted(dispersionset(fp, gp))
[2, 3, 4]
>>> dispersion(fp, gp)
4
>>> sorted(dispersionset(gp, fp))
[]
>>> dispersion(gp, fp)
-oo
```

Computing the dispersion also works over field extensions:

```python
>>> from sympy import sqrt
>>> fp = poly(x**2 + sqrt(5)*x - 1, x, domain='QQ<sqrt(5)>')
>>> gp = poly(x**2 + (2 + sqrt(5))*x + sqrt(5), x, domain='QQ<sqrt(5)>')
```

(continues on next page)
We can even perform the computations for polynomials having symbolic coefficients:

```
>>> from sympy.abc import a
>>> fp = poly((x - 3)*(x + 3), x)
```

```
[0, 6]
```

```
>>> dispersion(fp)
6
```

3. [Abramov71]
4. [Man93]

[ManWright94], [Koepf98], [Abramov71], [Man93]

**dispersionset**\((g=None)\)

Compute the dispersion set of two polynomials.

For two polynomials \(f(x)\) and \(g(x)\) with \(\deg f > 0\) and \(\deg g > 0\) the dispersion set \(J(f, g)\) is defined as:

\[
J(f, g) := \{a \in \mathbb{N}_0 | \gcd(f(x), g(x + a)) \neq 1\} = \{a \in \mathbb{N}_0 | \deg \gcd(f(x), g(x + a)) \geq 1\}
\]

For a single polynomial one defines \(J(f) := J(f, f)\).

Examples

```
>>> from sympy import poly
>>> from sympy.polys.dispersion import dispersion, dispersionset
>>> from sympy.abc import x
```

Dispersion set and dispersion of a simple polynomial:

```
>>> dispersionset(fp)
[0, 1]
```

```
>>> dispersion(fp)
6
```
Note that the definition of the dispersion is not symmetric:

```python
>>> fp = poly(x**4 - 3*x**2 + 1, x)
>>> gp = fp.shift(-3)
>>> sorted(dispersionset(fp, gp))
[2, 3, 4]
>>> dispersion(fp, gp)
4
>>> sorted(dispersionset(gp, fp))
[]
>>> dispersion(gp, fp)
-oo
```

Computing the dispersion also works over field extensions:

```python
>>> from sympy import sqrt
>>> fp = poly(x**2 + sqrt(5)*x - 1, x, domain='QQ<sqrt(5)>')
>>> gp = poly(x**2 + (2 + sqrt(5))*x + sqrt(5), x, domain='QQ<sqrt(5)>')
>>> sorted(dispersionset(fp, gp))
[2]
>>> sorted(dispersionset(gp, fp))
[1, 4]
```

We can even perform the computations for polynomials having symbolic coefficients:

```python
>>> from sympy.abc import a
>>> fp = poly(4*x**4 + (4*a + 8)*x**3 + (a**2 + 6*a + 4)*x**2 + (a**2 - 2*a)*x, x)
>>> sorted(dispersionset(fp))
[0, 1]
```

See also:

dispersion (page 2463)

[ManWright94], [Koepf98], [Abramov71], [Man93]

**div(g, auto=True)**

Polynomial division with remainder of f by g.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x
```

```python
>>> Poly(x**2 + 1, x).div(Poly(2*x - 4, x))
(Poly(1/2*x + 1, x, domain='QQ'), Poly(5, x, domain='QQ'))
```

```python
>>> Poly(x**2 + 1, x).div(Poly(2*x - 4, x), auto=False)
(Poly(0, x, domain='ZZ'), Poly(x**2 + 1, x, domain='ZZ'))
```

**property domain**

Get the ground domain of a `Poly` (page 2453)

**Returns**

`Domain` (page 2584):

Ground domain of the `Poly` (page 2453).

Examples

```python
>>> from sympy import Poly, Symbol
```

```python
>>> x = Symbol('x')
>>> p = Poly(x**2 + x)
>>> p
Poly(x**2 + x, x, domain='ZZ')
>>> p.domain
ZZ
```

eject(*gens)

Eject selected generators into the ground domain.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y
```

```python
>>> f = Poly(x**2*y + x*y**3 + x*y + 1, x, y)
```

```python
>>> f.eject(x)
Poly(x*y**3 + (x**2 + x)*y + 1, y, domain='ZZ[x]')
>>> f.eject(y)
Poly(y*x**2 + (y**3 + y)*x + 1, x, domain='ZZ[y]')
```

eval(x, a=None, auto=True)

Evaluate f at a in the given variable.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y, z

>>> Poly(x**2 + 2*x + 3, x).eval(2)
11

>>> Poly(2*x*y + 3*x + y + 2, x, y).eval(x, 2)
Poly(5*y + 8, y, domain='ZZ')

>>> f = Poly(2*x*y + 3*x + y + 2*z, x, y, z)

>>> f.eval({x: 2})
Poly(5*y + 2*z + 6, y, z, domain='ZZ')
>>> f.eval({x: 2, y: 5})
Poly(2*z + 31, z, domain='ZZ')
>>> f.eval({x: 2, y: 5, z: 7})
45

>>> f.eval((2, 5))
Poly(2*z + 31, z, domain='ZZ')
>>> f(2, 5)
Poly(2*z + 31, z, domain='ZZ')
```

**exclude()**
Remove unnecessary generators from f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import a, b, c, d, x

>>> Poly(a + x, a, b, c, d, x).exclude()
Poly(a + x, a, x, domain='ZZ')
```

**exquo(g, auto=True)**
Computes polynomial exact quotient of f by g.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 - 1, x).exquo(Poly(x - 1, x))
Poly(x + 1, x, domain='ZZ')
```
```python
>>> Poly(x**2 + 1, x).exquo(Poly(2*x - 4, x))
Traceback (most recent call last):
...  
ExactQuotientFailed: 2*x - 4 does not divide x**2 + 1
```

**exquo_ground**(coeff)

Exact quotient of f by a an element of the ground domain.

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(2*x + 4).exquo_ground(2)
P(x + 2, x, domain='ZZ')

>>> Poly(2*x + 3).exquo_ground(2)
Traceback (most recent call last):
...  
ExactQuotientFailed: 2 does not divide 3 in ZZ
```

**factor_list**()

Returns a list of irreducible factors of f.

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> f = 2*x**5 + 2*x**4*y + 4*x**3 + 4*x**2*y + 2*x + 2*y
>>> Poly(f).factor_list()
(2, [(Poly(x + y, x, y, domain='ZZ'), 1),
    (Poly(x**2 + 1, x, y, domain='ZZ'), 2)])
```

**factor_list_include**()

Returns a list of irreducible factors of f.

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> f = 2*x**5 + 2*x**4*y + 4*x**3 + 4*x**2*y + 2*x + 2*y
```
>>> Poly(f).factor_list_include()
[(Poly(2*x + 2*y, x, y, domain='ZZ'), 1),
 (Poly(x**2 + 1, x, y, domain='ZZ'), 2)]

**property free_symbols**
Free symbols of a polynomial expression.

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y, z
```

```python
>>> Poly(x**2 + 1).free_symbols
{x}
>>> Poly(x**2 + y).free_symbols
{x, y}
>>> Poly(x**2 + y, x).free_symbols
{x, y}
>>> Poly(x**2 + y, x, z).free_symbols
{x, y}
```

**property free_symbols_in_domain**
Free symbols of the domain of self.

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y
```

```python
>>> Poly(x**2 + 1).free_symbols_in_domain
set()
>>> Poly(x**2 + y).free_symbols_in_domain
set()
>>> Poly(x**2 + y, x).free_symbols_in_domain
{y}
```

**classmethod from_dict**(rep, *gens, **args)
Construct a polynomial from a dict.

**classmethod from_expr**(rep, *gens, **args)
Construct a polynomial from an expression.

**classmethod from_list**(rep, *gens, **args)
Construct a polynomial from a list.

**classmethod from_poly**(rep, *gens, **args)
Construct a polynomial from a polynomial.

**galois_group**(by_name=False, max_tries=30, randomize=False)
Compute the Galois group of this polynomial.

5.8. Topics
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x
>>> f = Poly(x**4 - 2)
>>> G, _ = f.galois_group(by_name=True)
>>> print(G)
S4TransitiveSubgroups.D4
```

See also:
`sympy.polys.numberfields.galoisgroups.galois_group` (page 2792)

**gcd**

Returns the polynomial GCD of \( f \) and \( g \).

Examples

```python
>>> from sympy import Poly
>>> Poly(x**2 - 1, x).gcd(Poly(x**2 - 3*x + 2, x))
Poly(x - 1, x, domain='ZZ')
```

**gcdex**\((g, auto=True)\)

Extended Euclidean algorithm of \( f \) and \( g \).

Returns \((s, t, h)\) such that \( h = \text{gcd}(f, g) \) and \( s*f + t*g = h \).

Examples

```python
>>> Poly(x**4 - 2*x**3 - 6*x**2 + 12*x + 15)
>>>
```

```python
>>> Poly(f).gcdex(Poly(g))
(Poly(-1/5*x + 3/5, x, domain='QQ'),
 Poly(1/5*x**2 - 6/5*x + 2, x, domain='QQ'),
 Poly(x + 1, x, domain='QQ'))
```

property **gen**

Return the principal generator.
**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 + 1, x).gen
x
```

**get_domain()**

Get the ground domain of f.

**get_modulus()**

Get the modulus of f.

**Examples**

```python
>>> from sympy import Poly

>>> Poly(x**2 + 1, modulus=2).get_modulus()
2
```

**gff_list()**

Computes greatest factorial factorization of f.

**Examples**

```python
>>> from sympy import Poly

>>> f = x**5 + 2*x**4 - x**3 - 2*x**2

>>> Poly(f).gff_list()
[(Poly(x, x, domain='ZZ'), 1), (Poly(x + 2, x, domain='ZZ'), 4)]
```

**ground_roots()**

Compute roots of f by factorization in the ground domain.

**Examples**

```python
>>> from sympy import Poly

>>> Poly(x**6 - 4*x**4 + 4*x**3 - x**2).ground_roots()
{0: 2, 1: 2}
```
half_gcdex\((g, auto=True)\)

Half extended Euclidean algorithm of \(f\) and \(g\).
Returns \((s, h)\) such that \(h = \text{gcd}(f, g)\) and \(sf = h \pmod g\).

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> f = x**4 - 2*x**3 - 6*x**2 + 12*x + 15
>>> g = x**3 + x**2 - 4*x - 4

>>> Poly(f).half_gcdex(Poly(g))
(Poly(-1/5*x + 3/5, x, domain='QQ'), Poly(x + 1, x, domain='QQ'))
```

has_only_gens\(*gens\)

Return True if Poly\((f, *gens)\) retains ground domain.

**Examples**

```python
>>> from sympy import Poly

>>> from sympy.abc import x, y, z

>>> Poly(x*y + 1, x, y, z).has_only_gens(x, y)
True
>>> Poly(x*y + z, x, y, z).has_only_gens(x, y)
False
```

homogeneous_order()

Returns the homogeneous order of \(f\).
A homogeneous polynomial is a polynomial whose all monomials with non-zero coefficients have the same total degree. This degree is the homogeneous order of \(f\). If you only want to check if a polynomial is homogeneous, then use Poly. is_homogeneous() (page 2475).

**Examples**

```python
>>> from sympy import Poly

>>> from sympy.abc import x, y

>>> f = Poly(x**5 + 2*x**3*y**2 + 9*x*y**4)
>>> f.homogeneous_order()
5
```
homogenize(s)

Returns the homogeneous polynomial of f.

A homogeneous polynomial is a polynomial whose all monomials with non-zero coefficients have the same total degree. If you only want to check if a polynomial is homogeneous, then use Poly.is_homogeneous() (page 2475). If you want not only to check if a polynomial is homogeneous but also compute its homogeneous order, then use Poly.homogeneous_order() (page 2472).

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y, z

>>> f = Poly(x**5 + 2*x**2*y**2 + 9*x*y**3)
>>> f.homogenize(z)
Poly(x**5 + 2*x**2*y**2*z + 9*x*y**3*z, x, y, z, domain='ZZ')
```

inject(front=False)

Inject ground domain generators into f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> f = Poly(x**2*y + x*y**3 + x*y + 1, x)

>>> f.inject()
Poly(x**2*y + x*y**3 + x*y + 1, x, y, domain='ZZ')

>>> f.inject(front=True)
Poly(y**3*x + y*x**2 + y*x + 1, y, x, domain='ZZ')
```

integrate(*specs, **args)

Computes indefinite integral of f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(x**2 + 2*x + 1, x).integrate()
Poly(1/3*x**3 + x**2 + x, x, domain='QQ')

>>> Poly(x*y**2 + x, x, y).integrate((0, 1), (1, 0))
Poly(1/2*x**2*y**2 + 1/2*x**2, x, y, domain='QQ')
```
**intervals** *(all=False, eps=None, inf=None, sup=None, fast=False, sqf=False)*

Compute isolating intervals for roots of \( f \).

For real roots the Vincent-Akritas-Strzebonski (VAS) continued fractions method is used.

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 - 3, x).intervals()
[((-2, -1), 1), ((1, 2), 1)]

>>> Poly(x**2 - 3, x).intervals(eps=1e-2)
[((-26/15, -19/11), 1), ((19/11, 26/15), 1)]
```

**References**

**invert** *(g, auto=True)*

Invert \( f \) modulo \( g \) when possible.

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 - 1, x).invert(Poly(2*x - 1, x))
Poly(-4/3, x, domain='QQ')

>>> Poly(x**2 - 1, x).invert(Poly(x - 1, x))
Traceback (most recent call last):
... NotInvertible: zero divisor
```

**property is_cyclotomic**

Returns True if \( f \) is a cyclotomic polynomial.

**Examples**

```python
>>> from sympy import Poly

>>> f = x**16 + x**14 - x**10 + x**8 - x**6 + x**2 + 1

>>> Poly(f).is_cyclotomic
False
```
```python
>>> g = x**16 + x**14 - x**10 - x**8 - x**6 + x**2 + 1
```

```python
>>> Poly(g).is_cyclotomic
True
```

**property is_ground**

Returns True if f is an element of the ground domain.

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y
```

```python
>>> Poly(x, x).is_ground
False
>>> Poly(2, x).is_ground
True
>>> Poly(y, x).is_ground
True
```

**property is_homogeneous**

Returns True if f is a homogeneous polynomial.

A homogeneous polynomial is a polynomial whose all monomials with non-zero coefficients have the same total degree. If you want not only to check if a polynomial is homogeneous but also compute its homogeneous order, then use `Poly.homogeneous_order()` (page 2472).

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y
```

```python
>>> Poly(x**2 + x*y, x, y).is_homogeneous
True
>>> Poly(x**3 + x*y, x, y).is_homogeneous
False
```

**property is_irreducible**

Returns True if f has no factors over its domain.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 + x + 1, x, modulus=2).is_irreducible
True
>>> Poly(x**2 + 1, x, modulus=2).is_irreducible
False
```

**property is_linear**

Returns True if $f$ is linear in all its variables.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(x + y + 2, x, y).is_linear
True
>>> Poly(x*y + 2, x, y).is_linear
False
```

**property is_monic**

Returns True if the leading coefficient of $f$ is one.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x + 2, x).is_monic
True
>>> Poly(2*x + 2, x).is_monic
False
```

**property is_monomial**

Returns True if $f$ is zero or has only one term.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(3*x**2, x).is_monomial
True
>>> Poly(3*x**2 + 1, x).is_monomial
False
```
property is_multivariate
Returns True if f is a multivariate polynomial.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(x**2 + x + 1, x).is_multivariate
False
>>> Poly(x*y**2 + x*y + 1, x, y).is_multivariate
True
>>> Poly(x*y**2 + x*y + 1, x).is_multivariate
False
>>> Poly(x**2 + x + 1, x, y).is_multivariate
True
```

property is_one
Returns True if f is a unit polynomial.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(0, x).is_one
False
>>> Poly(1, x).is_one
True
```

property is_primitive
Returns True if GCD of the coefficients of f is one.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(2*x**2 + 6*x + 12, x).is_primitive
False
>>> Poly(x**2 + 3*x + 6, x).is_primitive
True
```

property is_quadratic
Returns True if f is quadratic in all its variables.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(x*y + 2, x, y).is_quadratic
True
>>> Poly(x*y**2 + 2, x, y).is_quadratic
False
```

property is_sqf
Returns True if \( f \) is a square-free polynomial.

Examples

```python
>>> from sympy import Poly

>>> from sympy.abc import x

>>> Poly(x**2 - 2*x + 1, x).is_sqf
False
>>> Poly(x**2 - 1, x).is_sqf
True
```

property is_univariate
Returns True if \( f \) is a univariate polynomial.

Examples

```python
>>> from sympy import Poly

>>> from sympy.abc import x, y

>>> Poly(x**2 + x + 1, x).is_univariate
True
>>> Poly(x*y**2 + x*y + 1, x, y).is_univariate
False
>>> Poly(x*y**2 + x*y + 1, x).is_univariate
True
>>> Poly(x**2 + x + 1, x, y).is_univariate
False
```

property is_zero
Returns True if \( f \) is a zero polynomial.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(0, x).is_zero
True
>>> Poly(1, x).is_zero
False
```

`l1_norm()`

Returns l1 norm of f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(-x**2 + 2*x - 3, x).l1_norm()
6
```

`lcm(g)`

Returns polynomial LCM of f and g.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 - 1, x).lcm(Poly(x**2 - 3*x + 2, x))
Poly(x**3 - 2*x**2 - x + 2, x, domain='ZZ')
```

`length()`

Returns the number of non-zero terms in f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 + 2*x - 1).length()
3
```

`lift()`

Convert algebraic coefficients to rationals.
Examples

```python
>>> from sympy import Poly, I
>>> from sympy.abc import x

>>> Poly(x**2 + I*x + 1, x, extension=I).lift()
Poly(x**4 + 3*x**2 + 1, x, domain='QQ')
```

**ltrim(gen)**

Remove dummy generators from f that are to the left of specified gen in the generators as ordered. When gen is an integer, it refers to the generator located at that position within the tuple of generators of f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y, z

>>> Poly(y**2 + y*z**2, x, y, z).ltrim(y)
Poly(y**2 + y*z**2, x, y, z, domain='ZZ')
>>> Poly(z, x, y, z).ltrim(-1)
Poly(z, z, domain='ZZ')
```

**make_monic_over_integers_by_scaling_roots()**

Turn any univariate polynomial over QQ (page 2609) or ZZ (page 2605) into a monic polynomial over ZZ (page 2605), by scaling the roots as necessary.

**Returns**

Pair (g, c)

- g is the polynomial
- c is the integer by which the roots had to be scaled

**Explanation**

This operation can be performed whether or not f is irreducible; when it is, this can be understood as determining an algebraic integer generating the same field as a root of f.

Examples

```python
>>> from sympy import Poly, S
>>> from sympy.abc import x

>>> f = Poly(x**2/2 + S(1)/4 * x + S(1)/8, x, domain='QQ')
>>> f.make_monic_over_integers_by_scaling_roots()
(Poly(x**2 + 2*x + 4, x, domain='ZZ'), 4)
```

**match(*args, **kwargs)**

Match expression from Poly. See Basic.match()
max_norm()

Returns maximum norm of f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(-x**2 + 2*x - 3, x).max_norm()
3
```

monic(auto=True)

Divides all coefficients by LC(f).

Examples

```python
>>> from sympy import Poly, ZZ
>>> from sympy.abc import x

>>> Poly(3*x**2 + 6*x + 9, x, domain=ZZ).monic()
Poly(x**2 + 2*x + 3, x, domain='QQ')

>>> Poly(3*x**2 + 4*x + 2, x, domain=ZZ).monic()
Poly(x**2 + 4/3*x + 2/3, x, domain='QQ')
```

monoms(order=None)

Returns all non-zero monomials from f in lex order.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(x**2 + 2*x*y**2 + x*y + 3*y, x, y).monoms()
[(2, 0), (1, 2), (1, 1), (0, 1)]
```

See also:

- all_monom (page 2456)

mul(g)

Multiply two polynomials f and g.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 + 1, x).mul(Poly(x - 2, x))
Poly(x**3 - 2*x**2 + x - 2, x, domain='ZZ')

>>> Poly(x**2 + 1, x)*Poly(x - 2, x)
Poly(x**3 - 2*x**2 + x - 2, x, domain='ZZ')
```

**mul_ground**(coeff)

Multiply f by an element of the ground domain.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x + 1).mul_ground(2)
Poly(2*x + 2, x, domain='ZZ')
```

**neg**()

Negate all coefficients in f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 - 1, x).neg()
Poly(-x**2 + 1, x, domain='ZZ')

>>> -Poly(x**2 - 1, x)
Poly(-x**2 + 1, x, domain='ZZ')
```

**classmethod new**(rep, *gens)

Construct `Poly` (page 2453) instance from raw representation.

**norm**()

Computes the product, Norm(f), of the conjugates of a polynomial f defined over a number field K.
Examples

```python
>>> from sympy import Poly, sqrt
>>> from sympy.abc import x
```
```python
>>> a, b = sqrt(2), sqrt(3)
```
A polynomial over a quadratic extension. Two conjugates $x - a$ and $x + a$.
```python
>>> f = Poly(x - a, x, extension=a)
>>> f.norm()
Poly(x**2 - 2, x, domain='QQ')
```
A polynomial over a quartic extension. Four conjugates $x - a$, $x - a$, $x + a$ and $x + a$.
```python
>>> f = Poly(x - a, x, extension=(a, b))
>>> f.norm()
Poly(x**4 - 4*x**2 + 4, x, domain='QQ')
```

`nroots(n=15, maxsteps=50, cleanup=True)`

Compute numerical approximations of roots of $f$.

**Parameters**
- `n` ... the number of digits to calculate
- `maxsteps` ... the maximum number of iterations to do

If the accuracy `n` cannot be reached in `maxsteps`, it will raise an exception. You need to rerun with higher `maxsteps`.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x
```
```python
>>> Poly(x**2 - 3).nroots(n=15)
[-1.73205080756888, 1.73205080756888]
```
```python
>>> Poly(x**2 - 3).nroots(n=30)
[-1.73205080756887729352744634151, 1.73205080756887729352744634151]
```

`nth(*N)`

Returns the $n$-th coefficient of $f$ where $N$ are the exponents of the generators in the term of interest.
Examples

```python
>>> from sympy import Poly, sqrt
>>> from sympy.abc import x, y

>>> Poly(x**3 + 2*x**2 + 3*x, x).nth(2)
2
>>> Poly(x**3 + 2*x*y**2 + y**2, x, y).nth(1, 2)
2
>>> Poly(4*sqrt(x)*y)
Poly(4*y*(sqrt(x)), y, sqrt(x), domain='ZZ')
>>> _.nth(1, 1)
4
```

See also:

- `coeff_monomial` (page 2459)

**nth_power_roots_poly** *(n)*

Construct a polynomial with n-th powers of roots of f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> f = Poly(x**4 - x**2 + 1)

>>> f.nth_power_roots_poly(2)
Poly(x**4 - 2*x**3 + 3*x**2 - 2*x + 1, x, domain='ZZ')
>>> f.nth_power_roots_poly(3)
Poly(x**4 + 2*x**3 + 1, x, domain='ZZ')
>>> f.nth_power_roots_poly(4)
Poly(x**4 + 2*x**3 + 3*x**2 + 2*x + 1, x, domain='ZZ')
>>> f.nth_power_roots_poly(12)
Poly(x**4 - 4*x**3 + 6*x**2 - 4*x + 1, x, domain='ZZ')
```

**property one**

Return one polynomial with self’s properties.

**pdiv**(g)

Polynomial pseudo-division of f by g.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 + 1, x).pdiv(Poly(2*x - 4, x))
(Poly(2*x + 4, x, domain='ZZ'), Poly(20, x, domain='ZZ'))
```

**per**(rep, gens=None, remove=None)

Create a Poly out of the given representation.

Examples

```python
>>> from sympy import Poly, ZZ
>>> from sympy.abc import x, y

>>> from sympy.polys.polyclasses import DMP

>>> a = Poly(x**2 + 1)

>>> a.per(DMP([ZZ(1), ZZ(1)], ZZ), gens=[y])
Poly(y + 1, y, domain='ZZ')
```

**pexquo**(g)

Polynomial exact pseudo-quotient of f by g.

Examples

```python
>>> from sympy import Poly

>>> from sympy.abc import x

>>> Poly(x**2 - 1, x).pexquo(Poly(2*x - 2, x))
Poly(2*x + 2, x, domain='ZZ')

>>> Poly(x**2 + 1, x).pexquo(Poly(2*x - 4, x))
Traceback (most recent call last):
...
ExactQuotientFailed: 2*x - 4 does not divide x**2 + 1
```

**pow**(n)

Raise f to a non-negative power n.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x - 2, x).pow(3)
Poly(x**3 - 6*x**2 + 12*x - 8, x, domain='ZZ')

>>> Poly(x**3 - 6*x**2 + 12*x - 8, x, domain='ZZ')
```

**pquo(g)**

Polynomial pseudo-quotient of f by g.

See the Caveat note in the function prem(f, g).

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 + 1, x).pquo(Poly(2*x - 4, x))
Poly(2*x + 4, x, domain='ZZ')

>>> Poly(x**2 - 1, x).pquo(Poly(2*x - 2, x))
Poly(2*x + 2, x, domain='ZZ')
```

**prem(g)**

Polynomial pseudo-remainder of f by g.

**Caveat:** The function prem(f, g, x) can be safely used to compute
in Z[x] only subresultant polynomial remainder sequences (prs’s).

To safely compute Euclidean and Sturmian prs’s in Z[x] employ anyone of the corresponding functions found in the module sympy.polys.subresultants_qq_zz. The functions in the module with suffix _pg compute prs’s in Z[x] employing rem(f, g, x), whereas the functions with suffix _amv compute prs’s in Z[x] employing rem_z(f, g, x).

The function rem_z(f, g, x) differs from prem(f, g, x) in that to compute the remainder polynomials in Z[x] it premultiplies the dividend times the absolute value of the leading coefficient of the divisor raised to the power degree(f, x) - degree(g, x) + 1.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 + 1, x).prem(Poly(2*x - 4, x))
Poly(20, x, domain='ZZ')
```

**primitive()**

Returns the content and a primitive form of f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(2*x**2 + 8*x + 12, x).primitive()
(2, Poly(x**2 + 4*x + 6, x, domain='ZZ'))
```

**quo(g, auto=True)**

Computes polynomial quotient of f by g.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 + 1, x).quo(Poly(2*x - 4, x))
Poly(1/2*x + 1, x, domain='QQ')

>>> Poly(x**2 - 1, x).quo(Poly(x - 1, x))
Poly(x + 1, x, domain='ZZ')
```

**quo_ground(coeffs)**

Quotient of f by a an element of the ground domain.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(2*x + 4).quo_ground(2)
Poly(x + 2, x, domain='ZZ')

>>> Poly(2*x + 3).quo_ground(2)
Poly(x + 1, x, domain='ZZ')
```
rat_clear_denoms\((g)\)
Clear denominators in a rational function \(f/g\).

**Examples**

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> f = Poly(x**2/y + 1, x)
>>> g = Poly(x**3 + y, x)

>>> p, q = f.rat_clear_denoms(g)

>>> p
Poly(x**2 + y, x, domain='ZZ[y]')

>>> q
Poly(y*x**3 + y**2, x, domain='ZZ[y]')
```

real_roots\((multiple=True, radicals=True)\)
Return a list of real roots with multiplicities.

**Examples**

```python
>>> from sympy import Poly

>>> Poly(2*x**3 - 7*x**2 + 4*x + 4).real_roots()
[-1/2, 2, 2]

>>> Poly(x**3 + x + 1).real_roots()
[CRootOf(x**3 + x + 1, 0)]
```

refine_root\((s, t, eps=None, steps=None, fast=False, check_sqf=False)\)
Refine an isolating interval of a root to the given precision.

**Examples**

```python
>>> from sympy import Poly

>>> Poly(x**2 - 3, x).refine_root(1, 2, eps=1e-2)
(19/11, 26/15)
```

rem\((g, auto=True)\)
Computes the polynomial remainder of \(f\) by \(g\).
Examples

```python
from sympy import Poly
from sympy.abc import x

>>> Poly(x**2 + 1, x).rem(Poly(2*x - 4, x))
Poly(5, x, domain='ZZ')

>>> Poly(x**2 + 1, x).rem(Poly(2*x - 4, x), auto=False)
Poly(x**2 + 1, x, domain='ZZ')
```

`reorder(*gens, **args)`

Efficiently apply new order of generators.

Examples

```python
from sympy import Poly
from sympy.abc import x, y

>>> Poly(x**2 + x*y**2, x, y).reorder(y, x)
Poly(y**2*x + x**2, y, x, domain='ZZ')
```

`replace(x, y=None, **_ignore)`

Replace x with y in generators list.

Examples

```python
from sympy import Poly
from sympy.abc import x, y

>>> Poly(x**2 + 1, x).replace(x, y)
Poly(y**2 + 1, y, domain='ZZ')
```

`resultant(g, includePRS=False)`

Computes the resultant of f and g via PRS.

If includePRS=True, it includes the subresultant PRS in the result. Because the PRS is used to calculate the resultant, this is more efficient than calling `subresultants()` (page 2440) separately.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> f = Poly(x**2 + 1, x)

>>> f.resultant(Poly(x**2 - 1, x))
4
>>> f.resultant(Poly(x**2 - 1, x), includePRS=True)
(4, [Poly(x**2 + 1, x, domain='ZZ'), Poly(x**2 - 1, x, domain='ZZ'), Poly(-2, x, domain='ZZ')])
```

`retract(field=None)`
Recalculate the ground domain of a polynomial.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> f = Poly(x**2 + 1, x, domain='QQ[y]')

>>> f.revert()
Poly(1, x, domain='ZZ')
>>> f.revert(field=True)
Poly(1, x, domain='QQ')
```

`revert(n)`
Compute \( f^{-1} \mod x^n \).

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(1, x).revert(2)
Poly(1, x, domain='ZZ')

>>> Poly(1 + x, x).revert(1)
Poly(1, x, domain='ZZ')

>>> Poly(x**2 - 2, x).revert(2)
Traceback (most recent call last):
...
NotReversible: only units are reversible in a ring
```
>>> Poly(1/x, x).revert(1)
Traceback (most recent call last):
...  
PolynomialError: 1/x contains an element of the generators set

root(index, radicals=True)
Get an indexed root of a polynomial.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> f = Poly(2*x**3 - 7*x**2 + 4*x + 4)
>>> f.root(0)
-1/2
>>> f.root(1)
2
>>> f.root(2)
2
>>> f.root(3)
Traceback (most recent call last):
...  
IndexError: root index out of [-3, 2] range, got 3
```

```python
>>> Poly(x**5 + x + 1).root(0)
CRootOf(x**3 - x**2 + 1, 0)
```

same_root(a, b)
Decide whether two roots of this polynomial are equal.

Raises
DictError
If the domain of the polynomial is not ZZ (page 2605), QQ (page 2609), RR (page 2626), or CC (page 2627).

MultivariatePolynomialError
If the polynomial is not univariate.

PolynomialError
If the polynomial is of degree < 2.
Examples

```python
>>> from sympy import Poly, cyclotomic_poly, exp, I, pi
>>> f = Poly(cyclotomic_poly(5))
>>> r0 = exp(2*I*pi/5)
>>> indices = [i for i, r in enumerate(f.all_roots()) if f.same_root(r, r0)]
>>> print(indices)
[3]
```

**set_domain**(domain)
Set the ground domain of f.

**set_modulus**(modulus)
Set the modulus of f.

Examples

```python
>>> from sympy import Poly

>>> from sympy.abc import x

>>> Poly(5*x**2 + 2*x - 1, x).set_modulus(2)
Poly(x**2 + 1, x, modulus=2)
```

**shift**(a)
Efficiently compute Taylor shift \( f(x + a) \).

Examples

```python
>>> from sympy import Poly

>>> from sympy.abc import x

>>> Poly(x**2 - 2*x + 1, x).shift(2)
Poly(x**2 + 2*x + 1, x, domain='ZZ')
```

**slice**(x, m, n=None)
Take a continuous subsequence of terms of f.

**sqf_list**(all=False)
Returns a list of square-free factors of f.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> f = 2*x**5 + 16*x**4 + 50*x**3 + 76*x**2 + 56*x + 16

>>> Poly(f).sqf_list()
(2, [(Poly(x + 1, x, domain='ZZ'), 2),
     (Poly(x + 2, x, domain='ZZ'), 3)])

>>> Poly(f).sqf_list(all=True)
(2, [(Poly(1, x, domain='ZZ'), 1),
     (Poly(x + 1, x, domain='ZZ'), 2),
     (Poly(x + 2, x, domain='ZZ'), 3)])
```

**sqf_list_include** *(all=False)*

Returns a list of square-free factors of \( f \).

Examples

```python
>>> from sympy import Poly, expand
>>> from sympy.abc import x

>>> f = expand(2*(x + 1)**3*x**4)

>>> f
2*x**7 + 6*x**6 + 6*x**5 + 2*x**4

>>> Poly(f).sqf_list_include()
[(Poly(2, x, domain='ZZ'), 1),
 (Poly(x + 1, x, domain='ZZ'), 3),
 (Poly(x, x, domain='ZZ'), 4)]

>>> Poly(f).sqf_list_include(all=True)
[(Poly(2, x, domain='ZZ'), 1),
 (Poly(1, x, domain='ZZ'), 2),
 (Poly(x + 1, x, domain='ZZ'), 3),
 (Poly(x, x, domain='ZZ'), 4)]
```

**sqf_norm**

Computes square-free norm of \( f \).

Returns \( s, f, r \), such that \( g(x) = f(x-sa) \) and \( r(x) = \text{Norm}(g(x)) \) is a square-free polynomial over \( K \), where \( a \) is the algebraic extension of the ground domain.
Examples

```python
>>> from sympy import Poly, sqrt
>>> from sympy.abc import x

>>> s, f, r = Poly(x**2 + 1, x, extension=[sqrt(3)]).sqf_norm()

>>> s
1
>>> f
Poly(x**2 - 2*sqrt(3)*x + 4, x, domain='QQ<sqrt(3)>')
>>> r
Poly(x**4 - 4*x**2 + 16, x, domain='QQ')
```

**sqf_part()**
Computes square-free part of f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**3 - 3*x - 2, x).sqf_part()
Poly(x**2 - x - 2, x, domain='ZZ')
```

**sqr()**
Square a polynomial f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x - 2, x).sqr()
Poly(x**2 - 4*x + 4, x, domain='ZZ')

>>> Poly(x - 2, x)**2
Poly(x**2 - 4*x + 4, x, domain='ZZ')
```

**sturm**(auto=True)
Computes the Sturm sequence of f.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x
```

```python
>>> Poly(x**3 - 2*x**2 + x - 3, x).sturm()
```

```python
[Poly(x**3 - 2*x**2 + x - 3, x, domain='QQ'),
 Poly(3*x**2 - 4*x + 1, x, domain='QQ'),
 Poly(2/9*x + 25/9, x, domain='QQ'),
 Poly(-2079/4, x, domain='QQ')]
```

**sub**

Subtract two polynomials f and g.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x
```

```python
>>> Poly(x**2 + 1, x).sub(Poly(x - 2, x))
```

```
Poly(x**2 - x + 3, x, domain='ZZ')
```

**sub_ground**(coeff)

Subtract an element of the ground domain from f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x
```

```python
>>> Poly(x + 1).sub_ground(2)
```

```
Poly(x - 1, x, domain='ZZ')
```

**subresultants**

Computes the subresultant PRS of f and g.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> Poly(x**2 + 1, x).subresultants(Poly(x**2 - 1, x))
[Poly(x**2 + 1, x, domain='ZZ'),
 Poly(x**2 - 1, x, domain='ZZ'),
 Poly(-2, x, domain='ZZ')]
```

terms(order=None)

Returns all non-zero terms from f in lex order.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(x**2 + 2*x*y**2 + x*y + 3*y, x, y).terms()
[((2, 0), 1), ((1, 2), 2), ((1, 1), 1), ((0, 1), 3)]
```

See also:

`all_terms` (page 2457)

terms_gcd()

Remove GCD of terms from the polynomial f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(x**6*y**2 + x**3*y, x, y).terms_gcd()
((3, 1), Poly(x**3*y + 1, x, y, domain='ZZ'))
```

termwise(func, *gens, **args)

Apply a function to all terms of f.

Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x

>>> def func(k, coeff):
...     k = k[0]
...     return coeff//10**(2-k)
```
>>> Poly(x**2 + 20*x + 400).termwise(func)
Poly(x**2 + 2*x + 4, x, domain='ZZ')

**to_exact()**
Make the ground domain exact.

**Examples**

```python
>>> from sympy import Poly, RR
>>> from sympy.abc import x

>>> Poly(x**2 + 1.0, x, domain=RR).to_exact()
Poly(x**2 + 1, x, domain='QQ')
```

**to_field()**
Make the ground domain a field.

**Examples**

```python
>>> from sympy import Poly, ZZ
>>> from sympy.abc import x

>>> Poly(x**2 + 1, x, domain=ZZ).to_field()
Poly(x**2 + 1, x, domain='QQ')
```

**to_ring()**
Make the ground domain a ring.

**Examples**

```python
>>> from sympy import Poly, QQ
>>> from sympy.abc import x

>>> Poly(x**2 + 1, domain=QQ).to_ring()
Poly(x**2 + 1, x, domain='ZZ')
```

**total_degree()**
Returns the total degree of f.
Examples

```python
>>> from sympy import Poly
>>> from sympy.abc import x, y

>>> Poly(x**2 + y*x + 1, x, y).total_degree()
2
>>> Poly(x + y**5, x, y).total_degree()
5
```

transform(p, q)

Efficiently evaluate the functional transformation \( q^n * f(p/q) \).

Examples

```python
>>> from sympy import Poly

>>> from sympy.abc import x

>>> Poly(x**2 - 2*x + 1, x).transform(Poly(x + 1, x), Poly(x - 1, x))
Poly(4, x, domain='ZZ')
```

trunc(p)

Reduce \( f \) modulo a constant \( p \).

Examples

```python
>>> from sympy import Poly

>>> from sympy.abc import x

>>> Poly(2*x**3 + 3*x**2 + 5*x + 7, x).trunc(3)
Poly(-x**3 - x + 1, x, domain='ZZ')
```

unify(g)

Make \( f \) and \( g \) belong to the same domain.

Examples

```python
>>> from sympy import Poly

>>> from sympy.abc import x

>>> f, g = Poly(x/2 + 1), Poly(2*x + 1)

>>> f
Poly(1/2*x + 1, x, domain='QQ')
>>> g
Poly(2*x + 1, x, domain='ZZ')
```
>>> F, G = f.unify(g)

>>> F
Poly(1/2*x + 1, x, domain='QQ')
>>> G
Poly(2*x + 1, x, domain='QQ')

**property unit**
Return unit polynomial with self's properties.

**property zero**
Return zero polynomial with self's properties.

class sympy.polys.polytools.PurePoly(rep, *gens, **args)
Class for representing pure polynomials.

**property free_symbols**
Free symbols of a polynomial.

**Examples**

```python
>>> from sympy import PurePoly
>>> from sympy.abc import x, y

>>> PurePoly(x**2 + 1).free_symbols
set()
>>> PurePoly(x**2 + y).free_symbols
set()
>>> PurePoly(x**2 + y, x).free_symbols
{y}
```

class sympy.polys.polytools.GroebnerBasis(F, *gens, **args)
Represents a reduced Groebner basis.

**contains**(poly)
Check if poly belongs the ideal generated by self.

**Examples**

```python
>>> from sympy import groebner
>>> from sympy.abc import x, y

>>> f = 2*x**3 + y**3 + 3*y
>>> G = groebner([x**2 + y**2 - 1, x*y - 2])

>>> G.contains(f)
True
>>> G.contains(f + 1)
False
```
**fglm**(order)

Convert a Groebner basis from one ordering to another.

The FGLM algorithm converts reduced Groebner bases of zero-dimensional ideals from one ordering to another. This method is often used when it is infeasible to compute a Groebner basis with respect to a particular ordering directly.

**Examples**

```python
>>> from sympy.abc import x, y
>>> from sympy import groebner

>>> F = [x**2 - 3*y - x + 1, y**2 - 2*x + y - 1]
>>> G = groebner(F, x, y, order='grlex')

>>> list(G.fglm('lex'))
[2*x - y**2 - y + 1, y**4 + 2*y**3 - 3*y**2 - 16*y + 7]

>>> list(groebner(F, x, y, order='lex'))
[2*x - y**2 - y + 1, y**4 + 2*y**3 - 3*y**2 - 16*y + 7]
```

**References**

[R742]

**property is_zero_dimensional**

Checks if the ideal generated by a Groebner basis is zero-dimensional.

The algorithm checks if the set of monomials not divisible by the leading monomial of any element of F is bounded.

**References**

**reduce**(expr, auto=True)

Reduces a polynomial modulo a Groebner basis.

Given a polynomial f and a set of polynomials G = (g_1, ..., g_n), computes a set of quotients q = (q_1, ..., q_n) and the remainder r such that f = q_1*f_1 + ... + q_n*f_n + r, where r vanishes or r is a completely reduced polynomial with respect to G.
Examples

```python
>>> from sympy import groebner, expand
>>> from sympy.abc import x, y

>>> f = 2*x**4 - x**2 + y**3 + y**2
>>> G = groebner([x**3 - x, y**3 - y])
>>> G.reduce(f)
([2*x, 1], x**2 + y**2 + y)
```

```python
>>> Q, r = _
>>> expand(sum(q*g for q, g in zip(Q, G)) + r)
2*x**4 - x**2 + y**3 + y**2
>>> _ == f
True
```

Extra polynomial manipulation functions

`sympy.polys.polyfuncs.symmetrize(F, *gens, **args)`
Rewrite a polynomial in terms of elementary symmetric polynomials.

A symmetric polynomial is a multivariate polynomial that remains invariant under any variable permutation, i.e., if \( f = f(x_1, x_2, ..., x_n) \), then \( f = f(x_{i_1}, x_{i_2}, ..., x_{i_n}) \), where \((i_1, i_2, ..., i_n)\) is a permutation of \((1, 2, ..., n)\) (an element of the group \(S_n\)).

Returns a tuple of symmetric polynomials \((f_1, f_2, ..., f_n)\) such that \( f = f_1 + f_2 + ... + f_n \).

Examples

```python
>>> from sympy.polys.polyfuncs import symmetrize
>>> from sympy.abc import x, y

>>> symmetrize(x**2 + y**2)
(-2*x*y + (x + y)**2, 0)
```

```python
>>> symmetrize(x**2 + y**2, formal=True)
(s1**2 - 2*s2, 0, [(s1, x + y), (s2, x*y)])
```

```python
>>> symmetrize(x**2 - y**2)
(-2*x*y + (x + y)**2, -2*y**2)
```

```python
>>> symmetrize(x**2 - y**2, formal=True)
(s1**2 - 2*s2, -2*y**2, [(s1, x + y), (s2, x*y)])
```

`sympy.polys.polyfuncs.horner(f, *gens, **args)`
Rewrite a polynomial in Horner form.
Among other applications, evaluation of a polynomial at a point is optimal when it is applied using the Horner scheme ([1]).

**Examples**

```python
>>> from sympy.polys.polyfuncs import horner
>>> from sympy.abc import x, y, a, b, c, d, e

>>> horner(9*x**4 + 8*x**3 + 7*x**2 + 6*x + 5)
x*(x*(x*(9*x + 8) + 7) + 6) + 5

>>> horner(a*x**4 + b*x**3 + c*x**2 + d*x + e)
e + x*(d + x*(c + x*(a*x + b)))

>>> f = 4*x**2*y**2 + 2*x**2*y + 2*x*y**2 + x*y

>>> horner(f, wrt=x)
x*x*y*(4*y + 2) + y*(2*y + 1)

>>> horner(f, wrt=y)
y*x*y*(4*x + 2) + x*(2*x + 1)
```

**References**

sympy.polys.polyfuncs.interpolate(data, x)

Construct an interpolating polynomial for the data points evaluated at point x (which can be symbolic or numeric).

**Examples**

```python
>>> from sympy.polys.polyfuncs import interpolate
>>> from sympy.abc import a, b, x

A list is interpreted as though it were paired with a range starting from 1:

```python
>>> interpolate([1, 4, 9, 16], x)
x**2
```

This can be made explicit by giving a list of coordinates:

```python
>>> interpolate([(1, 1), (2, 4), (3, 9)], x)
x**2
```

The (x, y) coordinates can also be given as keys and values of a dictionary (and the points need not be equispaced):
```python
>>> interpolate([(-1, 2), (1, 2), (2, 5)], x)
x**2 + 1
>>> interpolate({-1: 2, 1: 2, 2: 5}, x)
x**2 + 1
```

If the interpolation is going to be used only once then the value of interest can be passed instead of passing a symbol:

```python
>>> interpolate([1, 4, 9], 5)
25
```

Symbolic coordinates are also supported:

```python
>>> [(i, interpolate((a, b), i)) for i in range(1, 4)]
[(1, a), (2, b), (3, -a + 2*b)]
```

```python
sympy.polys.polyfuncts.viete(f, roots=None, *gens, **args)
```

Generate Viete’s formulas for f.

**Examples**

```python
>>> from sympy.polys.polyfuncts import viete
>>> from sympy import symbols

>>> x, a, b, c, r1, r2 = symbols('x,a:c,r1:3')

>>> viete(a*x**2 + b*x + c, [r1, r2], x)
[[(r1 + r2, -b/a), (r1*r2, c/a)]
```

**Domain constructors**

```python
sympy.polys.constructor.construct_domain(obj, **args)
```

Construct a minimal domain for a list of expressions.

**Parameters**

- **obj**: list or dict
  
The expressions to build a domain for.

- **args**: keyword arguments
  
  Options that affect the choice of domain.

**Returns**

- (K, elements): Domain and list of domain elements
  
  The domain K that can represent the expressions and the list or dict of domain elements representing the same expressions as elements of K.
**Explanation**

Given a list of normal SymPy expressions (of type `Expr` (page 999)) `construct_domain` will find a minimal `Domain` (page 2584) that can represent those expressions. The expressions will be converted to elements of the domain and both the domain and the domain elements are returned.

**Examples**

Given a list of `Integer` (page 1038) `construct_domain` will return the domain `ZZ` (page 2605) and a list of integers as elements of `ZZ` (page 2605).

```python
>>> from sympy import construct_domain, S
>>> expressions = [S(2), S(3), S(4)]
>>> K, elements = construct_domain(expressions)
>>> K
ZZ
>>> elements
[2, 3, 4]
>>> type(elements[0])
<class 'int'>
>>> type(expressions[0])
<class 'sympy.core.numbers.Integer'>
```

If there are any `Rational` (page 1036) then `QQ` (page 2609) is returned instead.

```python
>>> construct_domain([S(1)/2, S(3)/4])
(QQ, [1/2, 3/4])
```

If there are symbols then a polynomial ring `K[x]` (page 2627) is returned.

```python
>>> from sympy import symbols
>>> x, y = symbols('x, y')
>>> construct_domain([2*x + 1, S(3)/4])
(QQ[x], [2*x + 1, 3/4])
>>> construct_domain([2*x + 1, y])
(ZZ[x,y], [2*x + 1, y])
```

If any symbols appear with negative powers then a rational function field `K(x)` (page 2629) will be returned.

```python
>>> construct_domain([y/x, x/(1 - y)])
(ZZ(x,y), [y/x, -x/(y - 1)])
```

Irrational algebraic numbers will result in the `EX` (page 2630) domain by default. The keyword argument `extension=True` leads to the construction of an algebraic number field `QQ<a>` (page 2619).

```python
>>> from sympy import sqrt
>>> construct_domain([sqrt(2)])
(EX, [EX(sqrt(2))])
>>> construct_domain([sqrt(2)], extension=True)
(QQ<sqrt(2)>, [ANP([1, 0], [1, 0, -2], QQ)])
```
See also:

Domain (page 2584), Expr (page 999)

**Monomials encoded as tuples**

```python
class sympy.polys.monomials.Monomial(monom, gens=None)
```

Class representing a monomial, i.e. a product of powers.

```python
as_expr(*gens)
```

Convert a monomial instance to a SymPy expression.

```python
gcd(other)
```

Greatest common divisor of monomials.

```python
lcm(other)
```

Least common multiple of monomials.

```python
sympy.polys.monomials.itermonomials(variables, max_degrees, min_degrees=None)
```

max_degrees and min_degrees are either both integers or both lists. Unless otherwise specified, min_degrees is either 0 or [0, ..., 0].

A generator of all monomials `monom` is returned, such that either

\[
\text{min_degree} \leq \text{total_degree}(\text{monom}) \leq \text{max_degree}, \quad \text{or} \quad \text{min_degrees}[i] \leq \text{degree_list}(\text{monom})[i] \leq \text{max_degrees}[i], \text{for all } i.
\]

**Case I. max_degrees And min_degrees Are Both Integers**

Given a set of variables `V` and a min_degree `N` and a max_degree `M` generate a set of monomials of degree less than or equal to `N` and greater than or equal to `M`. The total number of monomials in commutative variables is huge and is given by the following formula if `M = 0`:

\[
\frac{(\#V+N)!}{\#V!N!}
\]

For example if we would like to generate a dense polynomial of a total degree `N = 50` and `M = 0`, which is the worst case, in 5 variables, assuming that exponents and all of coefficients are 32-bit long and stored in an array we would need almost 80 GiB of memory! Fortunately most polynomials, that we will encounter, are sparse.

Consider monomials in commutative variables `x` and `y` and non-commutative variables `a` and `b`:

```python
>>> from sympy import symbols
>>> from sympy.polys.monomials import itermonomials
>>> from sympy.polys.orderings import monomial_key
>>> from sympy.abc import x, y

>>> sorted(itermonomials([x, y], 2), key=monomial_key('grlex', [y, x]))
[[1, x, y, x**2, x*y, y**2]]
```

(continues on next page)
(continued from previous page)

```python
>>> sorted(itermonomials([x, y], 3), key=monomial_key('grlex', [y, x]))
[1, x, y, x**2, x*y, y**2, x**2*y, x*y**2, y**3]

>>> a, b = symbols('a, b', commutative=False)
>>> set(itermonomials([a, b, x], 2))
{1, a, a**2, b, b**2, x, x**2, a*b, b*a, x*a, x*b}

>>> sorted(itermonomials([x, y], [2, 1], key=monomial_key('grlex', [y, x])))
[x, y, x**2, x*y, y**2]
```

**Case II. max_degrees And min_degrees Are Both Lists**

If `max_degrees = [d_1, ..., d_n]` and `min_degrees = [e_1, ..., e_n]`, the number of monomials generated is:

\[(d_1 - e_1 + 1)(d_2 - e_2 + 1)\cdots(d_n - e_n + 1)\]

Let us generate all monomials `monom` in variables `x` and `y` such that `1, 2[i] <= degree_list(monom)[i] <= 2, 4[i], i = 0, 1`

```python
>>> from sympy import symbols
>>> from sympy.polys.monomials import itermonomials
>>> from sympy.polys.orderings import monomial_key
>>> from sympy import x, y

>>> sorted(itermonomials([x, y], [2, 4], [1, 2]), reverse=True, key=monomial_key('lex', [x, y]))
[x**2*y**4, x**2*y**3, x**2*y**2, x*y**4, x*y**3, x*y**2]
```

sympy.polys.monomials.monomial_count(V, N)

Computes the number of monomials.

The number of monomials is given by the following formula:

\[
\frac{(#V + N)!}{#V!N!}
\]

where `N` is a total degree and `V` is a set of variables.

**Examples**

```python
>>> from sympy.polys.monomials import itermonomials, monomial_count
>>> from sympy.polys.orderings import monomial_key
>>> from sympy import x, y

>>> monomial_count(2, 2)
6
```
```python
>>> M = list(itermonomials([x, y], 2))
>>> sorted(M, key=monomial_key('grlex', [y, x]))
[1, x, y, x**2, x*y, y**2]
>>> len(M)
6
```

### Orderings of monomials

```python
class sympy.polys.orderings.MonomialOrder
    Base class for monomial orderings.
class sympy.polys.orderings.LexOrder
    Lexicographic order of monomials.
class sympy.polys.orderings.GradedLexOrder
    Graded lexicographic order of monomials.
class sympy.polys.orderings.ReversedGradedLexOrder
    Reversed graded lexicographic order of monomials.
```

### Formal manipulation of roots of polynomials

```python
sympy.polys.rootoftools.rootof(f, x, index=None, radicals=True, expand=True)
    An indexed root of a univariate polynomial.
    Returns either a ComplexRootOf (page 2507) object or an explicit expression involving radicals.

    **Parameters**
    - **f**: Expr
      Univariate polynomial.
    - **x**: Symbol, optional
      Generator for f.
    - **index**: int or Integer
    - **radicals**: bool
      Return a radical expression if possible.
    - **expand**: bool
      Expand f.

class sympy.polys.rootoftools.RootOf(f, x, index=None, radicals=True, expand=True)
    Represents a root of a univariate polynomial.
    Base class for roots of different kinds of polynomials. Only complex roots are currently supported.
```
class sympy.polys.rootoftools.ComplexRootOf(f, x, index=None, radicals=False, expand=True)

Represents an indexed complex root of a polynomial.

Roots of a univariate polynomial separated into disjoint real or complex intervals and indexed in a fixed order:

• real roots come first and are sorted in increasing order;
• complex roots come next and are sorted primarily by increasing real part, secondarily by increasing imaginary part.

Currently only rational coefficients are allowed. Can be imported as CRootOf. To avoid confusion, the generator must be a Symbol.

Examples

```python
>>> from sympy import CRootOf, rootof
>>> from sympy.abc import x

CRootOf is a way to reference a particular root of a polynomial. If there is a rational root, it will be returned:

```python
>>> CRootOf(x**2 - 4, 0)
-2
```

Whether roots involving radicals are returned or not depends on whether the radicals flag is true (which is set to True with rootof):

```python
>>> CRootOf(x**2 - 3, 0)
CRootOf(x**2 - 3, 0)
>>> CRootOf(x**2 - 3, 0, radicals=True)
-sqrt(3)
>>> rootof(x**2 - 3, 0)
-sqrt(3)
```

The following cannot be expressed in terms of radicals:

```python
>>> r = rootof(4*x**5 + 16*x**3 + 12*x**2 + 7, 0); r
CRootOf(4*x**5 + 16*x**3 + 12*x**2 + 7, 0)
```

The root bounds can be seen, however, and they are used by the evaluation methods to get numerical approximations for the root.

```python
>>> interval = r._get_interval(); interval
(-1, 0)
>>> r.evalf(2)
-0.98
```

The evalf method refines the width of the root bounds until it guarantees that any decimal approximation within those bounds will satisfy the desired precision. It then stores the refined interval so subsequent requests at or below the requested precision will not have to recompute the root bounds and will return very quickly.

Before evaluation above, the interval was
>>> interval
(-1, 0)

After evaluation it is now

>>> r._get_interval()
(-165/169, -206/211)

To reset all intervals for a given polynomial, the _reset() (page 2511) method can be called from any CRootOf instance of the polynomial:

>>> r._reset()

>>> r._get_interval()
(-1, 0)

The eval_approx() (page 2511) method will also find the root to a given precision but the interval is not modified unless the search for the root fails to converge within the root bounds. And the secant method is used to find the root. (The evalf method uses bisection and will always update the interval.)

>>> r.eval_approx(2)
-0.98

The interval needed to be slightly updated to find that root:

>>> r._get_interval()
(-1, -1/2)

The evalf_rational will compute a rational approximation of the root to the desired accuracy or precision.

>>> r.evalf_rational(n=2)
-69629/71318

>>> t = CRootOf(x**3 + 10*x + 1, 1)

>>> t.evalf_rational(1e-1)
15/256 - 805*I/256

>>> t.evalf_rational(1e-1, 1e-4)
3275/65536 - 414645*I/131072

>>> t.evalf_rational(1e-4, 1e-4)
6545/131072 - 414645*I/131072

>>> t.evalf_rational(n=2)
104755/2097152 - 6634255*I/2097152
Notes

Although a PurePoly can be constructed from a non-symbol generator RootOf instances of non-symbols are disallowed to avoid confusion over what root is being represented.

```python
>>> from sympy import exp, PurePoly
>>> PurePoly(x) == PurePoly(exp(x))
True
>>> CRootOf(x - 1, 0)
1
>>> CRootOf(exp(x) - 1, 0) # would correspond to x == 0
Traceback (most recent call last):
... sympy.polys.polyerrors.PolynomialError: generator must be a Symbol
```

See also:

- `eval_approx` (page 2511), `eval_rational` (page 2512)
- **classmethod** `_all_roots**(poly, use_cache=True)**
  Get real and complex roots of a composite polynomial.
- **classmethod** `_complexes_index**(complexes, index)**
  Map initial complex root index to an index in a factor where the root belongs.
- **classmethod** `_complexes_sorted**(complexes)**
  Make complex isolating intervals disjoint and sort roots.
- **classmethod** `_count_roots**(roots)**
  Count the number of real or complex roots with multiplicities.
- **classmethod** `_get_complexes**(factors, use_cache=True)**
  Compute complex root isolating intervals for a list of factors.
- **classmethod** `_get_complexes_sqf**(currentfactor, use_cache=True)**
  Get complex root isolating intervals for a square-free factor.
- **classmethod** `_get_interval**
  Internal function for retrieving isolation interval from cache.
- **classmethod** `_get_reals**(factors, use_cache=True)**
  Compute real root isolating intervals for a list of factors.
_get_reals_sqf(currentfactor, use_cache=\text{True})
Get \text{real} root isolating intervals for a \text{square-free} factor.

_get_roots(method, poly, radicals)
Return \text{postprocessed} roots of specified kind.

_indexed_root(poly, index, lazy=\text{False})
Get a \text{root} of a \text{composite} polynomial by \text{index}.

_new(poly, index)
Construct new \text{CRootOf} object from \text{raw} data.

_postprocess_root(root, radicals)
Return the \text{root} if it is \text{trivial} or a \text{CRootOf} object.

_preprocess_roots(poly)
Take \text{heroic} measures to make \text{poly} compatible with \text{CRoot0f}.

_real_roots(poly)
Get \text{real} roots of a \text{composite} polynomial.

_reals_index(reals, index)
Map initial \text{real} root index to an \text{index} in a \text{factor} where the \text{root} belongs.

_reals_sorted(reals)
Make real isolating intervals disjoint and \text{sort} roots.

_refine_complexes(complexes)
Return complexes such that no bounding \text{rectangles} of non-conjugate roots would \text{intersect}. In addition, assure that neither ay nor by is 0 to guarantee that non-\text{real} roots are distinct from \text{real} roots in terms of the y-bounds.

_reset()
Reset all intervals

_roots_trivial(poly, radicals)
Compute \text{roots} in linear, quadratic and \text{binomial} cases.

_set_interval(interval)
Internal function for updating \text{isolation interval} in \text{cache}.

_all_roots(poly, radicals=\text{True})
Get \text{real} and \text{complex} roots of a polynomial.

clear_cache()
Reset cache for \text{reals} and \text{complexes}.

The intervals used to approximate a \text{root} instance are updated as needed. When a request is made to see the intervals, the most current values are shown. \text{clear_cache} will reset all \text{CRoot0f} instances back to their original state.

See also:
_reset (page 2511)

eval_approx(n, return_mpmath=\text{False})
Evaluate this \text{complex} root to the \text{given} precision.

This uses secant \text{method} and root \text{bounds} are used to both generate an \text{initial} guess and to check that the \text{root} returned is \text{valid}. If ever the \text{method} converges outside the \text{root} \text{bounds}, the \text{bounds} will be made \text{smaller} and \text{updated}.
eval_rational($dx=None$, $dy=None$, $n=15$)

Return a Rational approximation of self that has real and imaginary component approximations that are within $dx$ and $dy$ of the true values, respectively. Alternatively, $n$ digits of precision can be specified.

The interval is refined with bisection and is sure to converge. The root bounds are updated when the refinement is complete so recalculation at the same or lesser precision will not have to repeat the refinement and should be much faster.

The following example first obtains Rational approximation to $1e-8$ accuracy for all roots of the 4-th order Legendre polynomial. Since the roots are all less than 1, this will ensure the decimal representation of the approximation will be correct (including rounding) to 6 digits:

```python
>>> from sympy import legendre_poly, Symbol
>>> x = Symbol("x")
>>> p = legendre_poly(4, x, polys=True)
>>> r = p.real_roots()[0]
>>> r.eval_rational(10**-8).n(6)
0.861136
```

It is not necessary to a two-step calculation, however: the decimal representation can be computed directly:

```python
>>> r.evalf(17)
0.86113631159405258
```

classmethod real_roots($poly$, $radicals=True$)

Get real roots of a polynomial.

class sympy.polys.rootoftools.RootSum($expr$, $func=None$, $x=None$, $auto=True$, $quadratic=False$)

Represents a sum of all roots of a univariate polynomial.

classmethod new($poly$, $func$, $auto=True$)

Construct new RootSum instance.

**Symbolic root-finding algorithms**

sympy.polys.polyroots.roots($f$, $*gens$, $auto=True$, $cubics=True$, $trig=False$, $quartics=True$, $quintics=False$, $multiple=False$, $filter=None$, $predicate=None$, $strict=False$, $**flags$)

Computes symbolic roots of a univariate polynomial.

Given a univariate polynomial $f$ with symbolic coefficients (or a list of the polynomial's coefficients), returns a dictionary with its roots and their multiplicities.

Only roots expressible via radicals will be returned. To get a complete set of roots use RootOf class or numerical methods instead. By default cubic and quartic formulas are used in the algorithm. To disable them because of unreadable output set cubics=False or quartics=False respectively. If cubic roots are real but are expressed in terms of complex numbers (casus irreducibilis [1]) the trig flag can be set to True to have the solutions returned in terms of cosine and inverse cosine functions.
To get roots from a specific domain set the `filter` flag with one of the following specifiers: Z, Q, R, I, C. By default all roots are returned (this is equivalent to setting `filter='C'`).

By default a dictionary is returned giving a compact result in case of multiple roots. However to get a list containing all those roots set the `multiple` flag to True; the list will have identical roots appearing next to each other in the result. (For a given Poly, the `all_roots` method will give the roots in sorted numerical order.)

If the `strict` flag is True, `UnsolvableFactorError` will be raised if the roots found are known to be incomplete (because some roots are not expressible in radicals).

**Examples**

```python
>>> from sympy import Poly, roots, degree
>>> from sympy.abc import x, y

>>> roots(x**2 - 1, x)
{-1: 1, 1: 1}

>>> p = Poly(x**2-1, x)
>>> roots(p)
{-1: 1, 1: 1}

>>> p = Poly(x**2-y, x, y)

>>> roots(Poly(p, x))
{-sqrt(y): 1, sqrt(y): 1}

>>> roots(x**2 - y, x)
{-sqrt(y): 1, sqrt(y): 1}

>>> roots([1, 0, -1])
{-1: 1, 1: 1}
```

`roots` will only return roots expressible in radicals. If the given polynomial has some or all of its roots inexpressible in radicals, the result of `roots` will be incomplete or empty respectively.

Example where result is incomplete:

```python
>>> roots((x-1)*(x**5-x+1), x)
{1: 1}
```

In this case, the polynomial has an unsolvable quintic factor whose roots cannot be expressed by radicals. The polynomial has a rational root (due to the factor \((x - 1)\)), which is returned since `roots` always finds all rational roots.

Example where result is empty:

```python
>>> roots(x**7-3*x**2+1, x)
{}
Here, the polynomial has no roots expressible in radicals, so `roots` returns an empty dictionary.

The result produced by `roots` is complete if and only if the sum of the multiplicity of each root is equal to the degree of the polynomial. If `strict=True`, `UnsolvableFactorError` will be raised if the result is incomplete.

The result can be be checked for completeness as follows:

```python
>>> f = x**3 - 2*x**2 + 1
>>> sum(roots(f, x).values()) == degree(f, x)
True
>>> f = (x-1)*(x**5 - x + 1)
>>> sum(roots(f, x).values()) == degree(f, x)
False
```

**References**

[R743]

**Special polynomials**

sympy.polys.specialpolys.swinnerton_dyer_poly(n, x=None, polys=False)

Generates n-th Swinnerton-Dyer polynomial in \( x \).

**Parameters**

- **n**: int
  - \( n \) decides the order of polynomial

- **x**: optional

- **polys**: bool, optional
  - polys=True returns an expression, otherwise (default) returns an expression.

sympy.polys.specialpolys.interpolating_poly(n, x, X='x', Y='y')

Construct Lagrange interpolating polynomial for \( n \) data points. If a sequence of values are given for \( X \) and \( Y \) then the first \( n \) values will be used.

sympy.polys.specialpolys.cyclotomic_poly(n, x=None, polys=False)

Generates cyclotomic polynomial of order \( n \) in \( x \).

**Parameters**

- **n**: int
  - \( n \) decides the order of polynomial

- **x**: optional

- **polys**: bool, optional
  - polys=True returns an expression, otherwise (default) returns an expression.
sympy.polys.specialpolys.symmetric_poly(n, *gens, polys=False)
Generates symmetric polynomial of order \( n \).

**Parameters**

- **polys**: bool, optional (default: False)
  Returns a Poly object when polys=True, otherwise (default) returns an expression.

sympy.polys.specialpolys.random_poly(x, n, inf, sup, domain=ZZ, polys=False)
Generates a polynomial of degree \( n \) with coefficients in \([\text{inf}, \text{sup}]\).

**Parameters**

- **x**
  \( x \) is the independent term of polynomial

- **n** : int
  \( n \) decides the order of polynomial

- **inf**
  Lower limit of range in which coefficients lie

- **sup**
  Upper limit of range in which coefficients lie

- **domain** : optional
  Decides what ring the coefficients are supposed to belong. Default is set to Integers.

- **polys** : bool, optional
  polys=True returns an expression, otherwise (default) returns an expression.

**Orthogonal polynomials**

sympy.polys.orthopolys.chebyshevt_poly(n, x=None, polys=False)
Generates the Chebyshev polynomial of the first kind \( T_n(x) \).

**Parameters**

- **n** : int
  Degree of the polynomial.

- **x** : optional

- **polys** : bool, optional
  If True, return a Poly, otherwise (default) return an expression.

sympy.polys.orthopolys.chebyshevu_poly(n, x=None, polys=False)
Generates the Chebyshev polynomial of the second kind \( U_n(x) \).

**Parameters**

- **n** : int
  Degree of the polynomial.
Generates the Gegenbauer polynomial $C_n^{(a)}(x)$.

**Parameters**
- n : int
  Degree of the polynomial.
- x : optional
- a
  Decides minimal domain for the list of coefficients.
- polys : bool, optional
  If True, return a Poly, otherwise (default) return an expression.

Generates the Hermite polynomial $H_n(x)$.

**Parameters**
- n : int
  Degree of the polynomial.
- x : optional
- polys : bool, optional
  If True, return a Poly, otherwise (default) return an expression.

Generates the probabilist’s Hermite polynomial $He_n(x)$.

**Parameters**
- n : int
  Degree of the polynomial.
- x : optional
- polys : bool, optional
  If True, return a Poly, otherwise (default) return an expression.

Generates the Jacobi polynomial $P_n^{(a,b)}(x)$.

**Parameters**
- n : int
  Degree of the polynomial.
- a
  Lower limit of minimal domain for the list of coefficients.
- b
  Upper limit of minimal domain for the list of coefficients.
**sympy.polys.orthopolys.legendre_poly**(*n*, *x=None, polys=False*)

Generates the Legendre polynomial $P_n(x)$.

**Parameters**
- **n**: int
  - Degree of the polynomial.
- **x**: optional
- **polys**: bool, optional
  - If True, return a Poly, otherwise (default) return an expression.

**sympy.polys.orthopolys.laguerre_poly**(*n*, *x=None, alpha=0, polys=False*)

Generates the Laguerre polynomial $L_n^{(\alpha)}(x)$.

**Parameters**
- **n**: int
  - Degree of the polynomial.
- **x**: optional
- **alpha**: optional
  - Decides minimal domain for the list of coefficients.
- **polys**: bool, optional
  - If True, return a Poly, otherwise (default) return an expression.

**sympy.polys.orthopolys.spherical_bessel_fn**(*n*, *x=None, polys=False*)

Coefficients for the spherical Bessel functions.

These are only needed in the jn() function.

The coefficients are calculated from:

$$
fn(0, z) = 1/z 
fn(1, z) = 1/z^2 
fn(n-1, z) + fn(n+1, z) =\ (2*n+1)/z * fn(n, z)
$$

**Parameters**
- **n**: int
  - Degree of the polynomial.
- **x**: optional
- **polys**: bool, optional
  - If True, return a Poly, otherwise (default) return an expression.
Examples

```python
>>> from sympy.polys.orthopolys import spherical_bessel_fn as fn
>>> from sympy import Symbol

>>> z = Symbol("z")
>>> fn(1, z)
z**(-2)
>>> fn(2, z)
-1/z + 3/z**3
>>> fn(3, z)
-6/z**2 + 15/z**4
>>> fn(4, z)
1/z - 45/z**3 + 105/z**5
```

Appell sequences

sympy.polys.appellseqs.bernoulli_poly($n$, $x=None$, polys=False)

Generates the Bernoulli polynomial $B_n(x)$.

$B_n(x)$ is the unique polynomial satisfying

$$
\int_x^{x+1} B_n(t) \, dt = x^n.
$$

Based on this, we have for nonnegative integer $s$ and integer $a$ and $b$

$$
\sum_{k=a}^{b} k^s = \frac{B_{s+1}(b+1) - B_{s+1}(a)}{s+1}
$$

which is related to Jakob Bernoulli’s original motivation for introducing the Bernoulli numbers, the values of these polynomials at $x = 1$.

Parameters

- $n$ : int
  Degree of the polynomial.
- $x$ : optional
- polys : bool, optional
  If True, return a Poly, otherwise (default) return an expression.

Examples

```python
>>> from sympy import summation
>>> from sympy.abc import x

>>> from sympy.polys import bernoulli_poly

>>> bernoulli_poly(5, x)
x**5 - 5*x**4/2 + 5*x**3/3 - x/6
```
```python
>>> def psum(p, a, b):
...     return (bernoulli_poly(p+1, b+1) - bernoulli_poly(p+1, a)) / (p+1)
>>> psum(4, -6, 27)
3144337
>>> summation(x**4, (x, -6, 27))
3144337
```
\[ E_n(x) = -\frac{G_{n+1}(x)}{n+1} \]

**Parameters**
- **n**: int
  - Degree of the polynomial.
- **x**: optional
- **polys**: bool, optional
  - If True, return a Poly, otherwise (default) return an expression.

**See also:**
*sympy.functions.combinatorial.numbers.euler* (page 489)
*sympy.polys.appellseqs.andre_poly*(*n*, *x=None*, *polys=False*)

Generates the Andre polynomial \( A_n(x) \).

This is the Appell sequence where the constant coefficients form the sequence of Euler numbers \( \text{euler}(n) \). As such they have integer coefficients and parities matching the parity of \( n \).

Luschny calls these the *Swiss-knife polynomials* because their values at 0 and 1 can be simply transformed into both the Bernoulli and Euler numbers. Here they are called the Andre polynomials because \( |A_n(n \mod 2)| \) for \( n \geq 0 \) generates what Luschny calls the Andre numbers, A000111 in the OEIS.

**Parameters**
- **n**: int
  - Degree of the polynomial.
- **x**: optional
- **polys**: bool, optional
  - If True, return a Poly, otherwise (default) return an expression.
Examples

```python
>>> from sympy import bernoulli, euler, genocchi
>>> from sympy import x
>>> from sympy.polys import andre_poly
>>> andre_poly(9, x)
-x**9 + 36*x**7 - 630*x**5 + 5124*x**3 - 12465*x
```

```python
>>> [andre_poly(n, 0) for n in range(11)]
[1, 0, -1, 0, 5, 0, -61, 0, 1385, 0, -50521]
```

```python
>>> [euler(n) for n in range(11)]
[1, 0, -1, 0, 5, 0, -61, 0, 1385, 0, -50521]
```

```python
>>> [andre_poly(n-1, 1) * n / (4**n - 2**n) for n in range(1, 11)]
[1/2, 1/6, 0, -1/30, 0, 1/42, 0, -1/30, 0, 5/66]
```

```python
>>> [bernoulli(n) for n in range(1, 11)]
[1/2, 1/6, 0, -1/30, 0, 1/42, 0, -1/30, 0, 5/66]
```

```python
>>> [-andre_poly(n-1, -1) * n / (-2)**(n-1) for n in range(1, 11)]
[-1, -1, 0, 1, 0, -3, 0, 17, 0, -155]
```

```python
>>> [genocchi(n) for n in range(1, 11)]
[-1, -1, 0, 1, 0, -3, 0, 17, 0, -155]
```

```python
>>> [abs(andre_poly(n, n%2)) for n in range(11)]
[1, 1, 1, 2, 5, 16, 61, 272, 1385, 7936, 50521]
```

References

[R745]
Examples

```python
>>> from sympy import together, exp
>>> from sympy.abc import x, y, z

>>> together(1/x + 1/y)
(x + y)/(x*y)

>>> together(1/x + 1/y + 1/z)
(x*y + x*z + y*z)/(x*y*z)

>>> together(1/(x*y) + 1/y**2)
(x + y)/(x*y**2)

>>> together(1/(1 + 1/x) + 1/(1 + 1/y))
(x*(y + 1) + y*(x + 1))/((x + 1)*(y + 1))

>>> together(exp(1/x + 1/y))
exp(1/y + 1/x)

>>> together(exp(1/x + 1/y), deep=True)
exp((x + y)/(x*y))

>>> together(1/exp(x) + 1/(x*exp(x)))
(x + 1)*exp(-x)/x

>>> together(1/exp(2*x) + 1/(x*exp(3*x)))
(x*exp(x) + 1)*exp(-3*x)/x
```

Partial fraction decomposition

`sympy.polys.partfrac.apart(f, x=None, full=False, **options)`

Compute partial fraction decomposition of a rational function.

Given a rational function \( f \), computes the partial fraction decomposition of \( f \). Two algorithms are available: One is based on the undetermined coefficients method, the other is Bronstein’s full partial fraction decomposition algorithm.

The undetermined coefficients method (selected by full=False) uses polynomial factorization (and therefore accepts the same options as factor) for the denominator. Per default it works over the rational numbers, therefore decomposition of denominators with non-rational roots (e.g. irrational, complex roots) is not supported by default (see options of factor).

Bronstein’s algorithm can be selected by using full=True and allows a decomposition of denominators with non-rational roots. A human-readable result can be obtained via `doit()` (see examples below).
Examples

```python
>>> from sympy.polys.partfrac import apart
>>> from sympy.abc import x, y
```

By default, using the undetermined coefficients method:

```python
>>> apart(y/(x + 2)/(x + 1), x)
-y/(x + 2) + y/(x + 1)
```

The undetermined coefficients method does not provide a result when the denominators roots are not rational:

```python
>>> apart(y/(x**2 + x + 1), x)
y/(x**2 + x + 1)
```

You can choose Bronstein’s algorithm by setting `full=True`:

```python
>>> apart(y/(x**2 + x + 1), x, full=True)
RootSum(_w**2 + _w + 1, Lambda(_a, (-2*_a*y/3 - y/3)/(-_a + x)))
```

Calling `doit()` yields a human-readable result:

```python
>>> apart(y/(x**2 + x + 1), x, full=True).doit()
(-y/3 - 2*y*(-1/2 - sqrt(3)*I/2)/3)/(x + 1/2 + sqrt(3)*I/2) + (-y/3 - 2*y*(-1/2 + sqrt(3)*I/2)/3)/(x + 1/2 - sqrt(3)*I/2)
```

See also:

- `apart_list` (page 2523), `assemble_partfrac_list` (page 2525)

-sympy.polys.partfrac.apart_list(f, x=None, dummies=None, **options)-

Compute partial fraction decomposition of a rational function and return the result in structured form.

Given a rational function $f$ compute the partial fraction decomposition of $f$. Only Bronstein’s full partial fraction decomposition algorithm is supported by this method. The return value is highly structured and perfectly suited for further algorithmic treatment rather than being human-readable. The function returns a tuple holding three elements:

- The first item is the common coefficient, free of the variable $x$ used for decomposition. (It is an element of the base field $K$.)
- The second item is the polynomial part of the decomposition. This can be the zero polynomial. (It is an element of $K[x]$.)
- The third part itself is a list of quadruples. Each quadruple has the following elements in this order:

  - The (not necessarily irreducible) polynomial $D$ whose roots $w_i$ appear in the linear denominator of a bunch of related fraction terms. (This item can also be a list of explicit roots. However, at the moment `apart_list` never returns a result this way, but the related `assemble_partfrac_list` function accepts this format as input.)
  - The numerator of the fraction, written as a function of the root $w$
  - The linear denominator of the fraction excluding its power exponent, written as a function of the root $w$.  

5.8. Topics 2523
On can always rebuild a plain expression by using the function `assemble_partfrac_list`.

**Examples**

A first example:

```python
>>> from sympy.polys.partfrac import apart_list, assemble_partfrac_list
>>> from sympy.abc import x, t

>>> f = (2*x**3 - 2*x) / (x**2 - 2*x + 1)
>>> pfd = apart_list(f)
>>> pfd
(1,
Poly(2*x + 4, x, domain='ZZ'),
[(Poly(_w - 1, _w, domain='ZZ'), Lambda(_a, 4), Lambda(_a, -_a + x), 1)])

>>> assemble_partfrac_list(pfd)
2*x + 4 + 4/(x - 1)
```

Second example:

```python
>>> f = (-2*x - 2*x**2) / (3*x**2 - 6*x)
>>> pfd = apart_list(f)
>>> pfd
(-1,
Poly(2/3, x, domain='QQ'),
[(Poly(_w - 2, _w, domain='ZZ'), Lambda(_a, 2), Lambda(_a, -_a + x), 1)])

>>> assemble_partfrac_list(pfd)
-2/3 - 2/(x - 2)
```

Another example, showing symbolic parameters:

```python
>>> pfd = apart_list(t/(x**2 + x + t), x)
>>> pfd
(1,
Poly(0, x, domain='ZZ[t]'),
[(Poly(_w**2 + _w + t, _w, domain='ZZ[t]'),
Lambda(_a, -2*_a*t/(4*t - 1) - t/(4*t - 1)),
Lambda(_a, -_a + x), 1)])

>>> assemble_partfrac_list(pfd)
RootSum(_w**2 + _w + t, Lambda(_a, (-2*_a*t/(4*t - 1) - t/(4*t - 1))/(-_a + x)))
```

This example is taken from Bronstein’s original paper:
```python
>>> f = 36 / (x**5 - 2*x**4 - 2*x**3 + 4*x**2 + x - 2)
>>> pfd = apart_list(f)
>>> pfd
(1,
 Poly(0, x, domain='ZZ'),
 [(Poly(_w - 2, _w, domain='ZZ'), Lambda(_a, 4), Lambda(_a, -_a + x), 1),
  (Poly(_w**2 - 1, _w, domain='ZZ'), Lambda(_a, -3*_a - 6), Lambda(_a, -_a + x), 2),
  (Poly(_w + 1, _w, domain='ZZ'), Lambda(_a, -4), Lambda(_a, -_a + x), 1))

>>> assemble_partfrac_list(pfd)
-4/(x + 1) - 3/(x + 1)**2 - 9/(x - 1)**2 + 4/(x - 2)
```

See also:

`apart` (page 2522), `assemble_partfrac_list` (page 2525)

References

[R746]
sympy.polys.partfrac.assemble_partfrac_list(partial_list)

Reassemble a full partial fraction decomposition from a structured result obtained by the function `apart_list`.

Examples

This example is taken from Bronstein’s original paper:

```python
>>> from sympy.polys.partfrac import apart_list, assemble_partfrac_list
>>> from sympy.abc import x

>>> f = 36 / (x**5 - 2*x**4 - 2*x**3 + 4*x**2 + x - 2)
>>> pfd = apart_list(f)
>>> pfd
(1,
 Poly(0, x, domain='ZZ'),
 [(Poly(_w - 2, _w, domain='ZZ'), Lambda(_a, 4), Lambda(_a, -_a + x), 1),
  (Poly(_w**2 - 1, _w, domain='ZZ'), Lambda(_a, -3*_a - 6), Lambda(_a, -_a + x), 2),
  (Poly(_w + 1, _w, domain='ZZ'), Lambda(_a, -4), Lambda(_a, -_a + x), 1))

>>> assemble_partfrac_list(pfd)
-4/(x + 1) - 3/(x + 1)**2 - 9/(x - 1)**2 + 4/(x - 2)
```

If we happen to know some roots we can provide them easily inside the structure:

```python
>>> pfd = apart_list(2/(x**2-2))
>>> pfd
(1,
 Poly(0, x, domain='ZZ'),
 (continues on next page)
```
\.\[(Poly(_w**2 - 2, _w, domain='ZZ'),
 Lambda(_a, _a/2),
 Lambda(_a, -_a + x),
 1))\]

\[
\text{>>=} \quad \text{pfda} = \text{assemble_partfrac_list(pfd)}
\[
\text{>>=} \quad \text{pfda}
\]
\[
\text{RootSum(_w**2 - 2, Lambda(_a, _a/(-_a + x)))/2}
\]

\[
\text{>>=} \quad \text{pfda}.\text{doit()}
\]
\[
-\sqrt{2}/(2*(x + \sqrt{2})) + \sqrt{2}/(2*(x - \sqrt{2}))
\]

\[
\text{>>=} \quad \text{from sympy import Dummy, Poly, Lambda, sqrt}
\]
\[
\text{>>=} \quad a = \text{Dummy("a")}
\]
\[
\text{>>=} \quad \text{pfdf} = (1, \text{Poly(0, x, domain='ZZ')}, \text{[[[sqrt(2), -sqrt(2)], Lambda(a, a/(-a + x), 1)]])}
\]

\[
\text{>>=} \quad \text{assemble_partfrac_list(pfde)}
\]
\[
-\sqrt{2}/(2*(x + \sqrt{2})) + \sqrt{2}/(2*(x - \sqrt{2}))
\]

\text{See also:} 
\text{apart (page 2522), apart_list (page 2523)}

\text{Dispersion of Polynomials}

\text{sympy.polys.dispersion.dispersionset}(p, q=\text{None}, *\text{gens}, **\text{args})
\text{Compute the dispersion set of two polynomials.}

\text{For two polynomials } f(x) \text{ and } g(x) \text{ with } \text{deg } f > 0 \text{ and } \text{deg } g > 0 \text{ the dispersion set } J(f,g) \text{ is defined as:}

\[
J(f,g) := \{a \in \mathbb{N}_0 \mid \text{gcd}(f(x), g(x + a)) \neq 1\}
\]
\[
= \{a \in \mathbb{N}_0 \mid \text{deg gcd}(f(x), g(x + a)) \geq 1\}
\]

\text{For a single polynomial one defines } J(f) := J(f,f).

\text{Examples}

\[
\text{>>=} \quad \text{from sympy import poly}
\]
\[
\text{>>=} \quad \text{from sympy.polys.dispersion import dispersion, dispersionset}
\]
\[
\text{>>=} \quad \text{from sympy.abc import x}
\]

\text{Dispersion set and dispersion of a simple polynomial:}

\[
\text{>>=} \quad \text{fp} = \text{poly((x - 3)*(x + 3), x)}
\]
\[
\text{>>=} \quad \text{sorted(dispersionset(fp))}
\]
\[
[0, 6]
\]
\[
\text{>>=} \quad \text{dispersion(fp)}
\]
\[
6
\]
Note that the definition of the dispersion is not symmetric:

```python
>>> fp = poly(x**4 - 3*x**2 + 1, x)
>>> gp = fp.shift(-3)
>>> sorted(dispersionset(fp, gp))
[2, 3, 4]
>>> dispersion(fp, gp)
4
>>> sorted(dispersionset(gp, fp))
[]
>>> dispersion(gp, fp)
-Infinity
```

Computing the dispersion also works over field extensions:

```python
>>> from sympy import sqrt
>>> fp = poly(x**2 + sqrt(5)*x - 1, x, domain='QQ<sqrt(5)>')
>>> gp = poly(x**2 + (2 + sqrt(5))*x + sqrt(5), x, domain='QQ<sqrt(5)>')
>>> sorted(dispersionset(fp, gp))
[2]
>>> sorted(dispersionset(gp, fp))
[1, 4]
```

We can even perform the computations for polynomials having symbolic coefficients:

```python
>>> from sympy.abc import a
>>> fp = poly(4*x**4 + (4*a + 8)*x**3 + (a**2 + 6*a + 4)*x**2 + (a**2 + 2*a)*x, x)
>>> sorted(dispersionset(fp))
[0, 1]
```

See also:

*dispersion* (page 2527)

References

[R747], [R748], [R749], [R750]

sympy.polys.dispersion.dispersion(p, q=None, *gens, **args)

Compute the dispersion of polynomials.

For two polynomials \(f(x)\) and \(g(x)\) with \(\deg f > 0\) and \(\deg g > 0\) the dispersion \(\text{dis}(f, g)\) is defined as:

\[
\text{dis}(f, g) := \max\{J(f, g) \cup \{0\}\}
= \max\{\{a \in \mathbb{N} | \gcd(f(x), g(x+a)) \neq 1\} \cup \{0\}\}
\]

and for a single polynomial \(\text{dis}(f) := \text{dis}(f, f)\). Note that we make the definition \(\max\{\} := -\infty\).
Examples

```python
>>> from sympy import poly
>>> from sympy.polys.dispersion import dispersion, dispersionset
>>> from sympy.abc import x
```

Dispersion set and dispersion of a simple polynomial:

```python
>>> fp = poly((x - 3)*(x + 3), x)
>>> sorted(dispersionset(fp))
[0, 6]
```
```
```
```
```
```python
Note that the definition of the dispersion is not symmetric:

```python
>>> fp = poly(x**4 - 3*x**2 + 1, x)
>>> gp = fp.shift(-3)
>>> sorted(dispersionset(fp, gp))
[2, 3, 4]
>>> dispersion(fp, gp)
4
```
```
```
```
```python
The maximum of an empty set is defined to be $-\infty$ as seen in this example.
```
```python
Computing the dispersion also works over field extensions:

```python
>>> from sympy import sqrt
>>> fp = poly(x**2 + sqrt(5)*x - 1, x, domain='QQ<sqrt(5)>')
>>> gp = poly(x**2 + (2 + sqrt(5))*x + sqrt(5), x, domain='QQ<sqrt(5)>')
>>> sorted(dispersionset(fp, gp))
[2]
>>> sorted(dispersionset(gp, fp))
[1, 4]
```
```
```
```
```python
We can even perform the computations for polynomials having symbolic coefficients:

```python
>>> from sympy.abc import a
>>> fp = poly(4*x**4 + (4*a + 8)*x**3 + (a**2 + 6*a + 4)*x**2 + (a**2 + a - 2*a)*x, x)
>>> sorted(dispersionset(fp))
[0, 1]
```
```
```
```
```python

```
AGCA - Algebraic Geometry and Commutative Algebra Module

Introduction

Algebraic geometry is a mixture of the ideas of two Mediterranean cultures. It is the superposition of the Arab science of the lightening calculation of the solutions of equations over the Greek art of position and shape. This tapestry was originally woven on European soil and is still being refined under the influence of international fashion. Algebraic geometry studies the delicate balance between the geometrically plausible and the algebraically possible. Whenever one side of this mathematical teeter-totter outweighs the other, one immediately loses interest and runs off in search of a more exciting amusement.

—George R. Kempf (1944 - 2002)

Algebraic Geometry refers to the study of geometric problems via algebraic methods (and sometimes vice versa). While this is a rather old topic, algebraic geometry as understood today is very much a 20th century development. Building on ideas of e.g. Riemann and Dedekind, it was realized that there is an intimate connection between properties of the set of solutions of a system of polynomial equations (called an algebraic variety) and the behavior of the set of polynomial functions on that variety (called the coordinate ring).

As in many geometric disciplines, we can distinguish between local and global questions (and methods). Local investigations in algebraic geometry are essentially equivalent to the study of certain rings, their ideals and modules. This latter topic is also called commutative algebra. It is the basic local toolset of algebraic geometers, in much the same way that differential analysis is the local toolset of differential geometers.

A good conceptual introduction to commutative algebra is [Atiyah69]. An introduction more geared towards computations, and the work most of the algorithms in this module are based on, is [Greuel2008].

This module aims to eventually allow expression and solution of both local and global geometric problems, both in the classical case over a field and in the more modern arithmetic cases. So far, however, there is no geometric functionality at all. Currently the module only provides tools for computational commutative algebra over fields.

All code examples assume:

```python
>>> from sympy import *
>>> x, y, z = symbols('x,y,z')
>>> init_printing(use_unicode=True, wrap_line=False)
```
Reference

In this section we document the usage of the AGCA module. For convenience of the reader, some definitions and examples/explanations are interspersed.

Base Rings

Almost all computations in commutative algebra are relative to a “base ring”. (For example, when asking questions about an ideal, the base ring is the ring the ideal is a subset of.) In principle all polys “domains” can be used as base rings. However, useful functionality is only implemented for polynomial rings over fields, and various localizations and quotients thereof.

As demonstrated in the examples below, the most convenient method to create objects you are interested in is to build them up from the ground field, and then use the various methods to create new objects from old. For example, in order to create the local ring of the nodal cubic $y^2 = x^3$ at the origin, over $\mathbb{Q}$, you do:

```python
>>> lr = QQ.old_poly_ring(x, y, order="ilex") / [y**2 - x**3]
>>> lr
\mathbb{Q}[x, y, order=ilex]
```

Note how the python list notation can be used as a short cut to express ideals. You can use the convert method to return ordinary sympy objects into objects understood by the AGCA module (although in many cases this will be done automatically – for example the list was automatically turned into an ideal, and in the process the symbols $x$ and $y$ were automatically converted into other representations). For example:

```python
>>> X, Y = lr.convert(x), lr.convert(y); X
\langle 3 \ 2 \ 
- x \ + \ y \rangle
```

When no localisation is needed, a more mathematical notation can be used. For example, let us create the coordinate ring of three-dimensional affine space $\mathbb{A}^3$:

```python
>>> ar = QQ.old_poly_ring(x, y, z); ar
\mathbb{Q}[x, y, z]
```

For more details, refer to the following class documentation. Note that the base rings, being domains, are the main point of overlap between the AGCA module and the rest of the polys module. All domains are documented in detail in the polys reference, so we show here only an abridged version, with the methods most pertinent to the AGCA module.

```python
class sympy.polys.domains.ring.Ring
    Represents a ring domain.
```
free_module(rank)
Generate a free module of rank rank over self.

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> QQ.old_poly_ring(x).free_module(2)
QQ[x]**2
```

ideal(*gens)
Generate an ideal of self.

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> QQ.old_poly_ring(x).ideal(x**2)
<x**2>
```

quotient_ring(e)
Form a quotient ring of self.
Here e can be an ideal or an iterable.

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> QQ.old_poly_ring(x).quotient_ring(QQ.old_poly_ring(x).ideal(x**2))
QQ[x]/<x**2>
>>> QQ.old_poly_ring(x).quotient_ring([x**2])
QQ[x]/<x**2>
```

The division operator has been overloaded for this:

```python
>>> QQ.old_poly_ring(x) / [x**2]
QQ[x]/<x**2>
```

sympy.polys.domains.polynomialring.PolynomialRing(domain_or_ring, symbols=None, order=None)
A class for representing multivariate polynomial rings.

class sympy.polys.domains.quotientring.QuotientRing(ring, ideal)
Class representing (commutative) quotient rings.

You should not usually instantiate this by hand, instead use the constructor from the base ring in the construction.

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> I = QQ.old_poly_ring(x).ideal(x**3 + 1)
>>> QQ.old_poly_ring(x).quotient_ring(I)
QQ[x]/<x**3 + 1>
```

Shorter versions are possible:

```python
>>> QQ.old_poly_ring(x) / I
QQ[x]/<x**3 + 1>
```
>>> QQ.old_poly_ring(x)/[x**3 + 1]
QQ[x]/<x**3 + 1>

Attributes:
- ring - the base ring
- base_ideal - the ideal used to form the quotient

Modules, Ideals and their Elementary Properties

Let $A$ be a ring. An $A$-module is a set $M$, together with two binary operations $+: M \times M \to M$ and $\cdot : R \times M \to M$ called addition and scalar multiplication. These are required to satisfy certain axioms, which can be found in e.g. [Atiyah69]. In this way modules are a direct generalisation of both vector spaces ($A$ being a field) and abelian groups ($A = \mathbb{Z}$). A submodule of the $A$-module $M$ is a subset $N \subset M$, such that the binary operations restrict to $N$, and $N$ becomes an $A$-module with these operations.

The ring $A$ itself has a natural $A$-module structure where addition and multiplication in the module coincide with addition and multiplication in the ring. This $A$-module is also written as $A$. An $A$-submodule of $A$ is called an ideal of $A$. Ideals come up very naturally in algebraic geometry. More general modules can be seen as a technically convenient “elbow room” beyond talking only about ideals.

If $M, N$ are $A$-modules, then there is a natural (componentwise) $A$-module structure on $M \times N$. Similarly there are $A$-module structures on cartesian products of more components. (For the categorically inclined: the cartesian product of finitely many $A$-modules, with this $A$-module structure, is the finite biproduct in the category of all $A$-modules. With infinitely many components, it is the direct product (but the infinite direct sum has to be constructed differently).) As usual, repeated product of the $A$-module $M$ is denoted $M, M^2, M^3 \ldots$, or $M^I$ for arbitrary index sets $I$.

An $A$-module $M$ is called free if it is isomorphic to the $A$-module $A^I$ for some (not necessarily finite) index set $I$ (refer to the next section for a definition of isomorphism). The cardinality of $I$ is called the rank of $M$; one may prove this is well-defined. In general, the AGCA module only works with free modules of finite rank, and other closely related modules. The easiest way to create modules is to use member methods of the objects they are made up from. For example, let us create a free module of rank 4 over the coordinate ring of $A^2$ we created above, together with a submodule:

```python
>>> F = ar.free_module(4) ; F
4
QQ[x, y, z]

>>> S = F.submodule([1, x, x**2, x**3], [0, 1, 0, y]) ; S
\[
\begin{bmatrix}
1 & x & x & x \\
0 & 1 & 0 & y
\end{bmatrix}
\]
```

Note how python lists can be used as a short-cut notation for module elements (vectors). As usual, the convert method can be used to convert sympy/python objects into the internal AGCA representation (see detailed reference below).

Here is the detailed documentation of the classes for modules, free modules, and submodules:
class sympy.polys.agca.modules.Module(ring)
    Abstract base class for modules.
    Do not instantiate - use ring explicit constructors instead:

    >>> from sympy import QQ
    >>> from sympy.abc import x
    >>> QQ.old_poly_ring(x).free_module(2)
    QQ[x]**2

Attributes:
    • dtype - type of elements
    • ring - containing ring

Non-implemented methods:
    • submodule
    • quotient_module
    • is_zero
    • is_submodule
    • multiply_ideal

The method convert likely needs to be changed in subclasses.

contains(elem)
    Return True if elem is an element of this module.

convert(elem, M=None)
    Convert elem into internal representation of this module.
    If M is not None, it should be a module containing it.

identity_hom()
    Return the identity homomorphism on self.

is submodule(other)
    Returns True if other is a submodule of self.

is_zero()
    Returns True if self is a zero module.

multiply_ideal(other)
    Multiply self by the ideal other.

quotient_module(other)
    Generate a quotient module.

submodule(*gens)
    Generate a submodule.

subset(other)
    Returns True if other is is a subset of self.
Examples

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> F = QQ.old_poly_ring(x).free_module(2)
>>> F.subset([(1, x), (x, 2)])
True
>>> F.subset([(1/x, x), (x, 2)])
False
```

class sympy.polys.agca.modules.FreeModule(ring, rank)

Abstract base class for free modules.

Additional attributes:

- rank - rank of the free module

Non-implemented methods:

- submodule

basis()

Return a set of basis elements.

Examples

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> QQ.old_poly_ring(x).free_module(3).basis()
([1, 0, 0], [0, 1, 0], [0, 0, 1])
```

convert(elem, M=None)

Convert elem into the internal representation.

This method is called implicitly whenever computations involve elements not in the internal representation.

Examples

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> F = QQ.old_poly_ring(x).free_module(2)
>>> F.convert([1, 0])
[1, 0]
```

dtype

alias of FreeModuleElement (page 2536)

identity_hom()

Return the identity homomorphism on self.
Examples

```python
>>> from sympy import x
>>> from sympy import QQ
>>> QQ.old_poly_ring(x).free_module(2).identity_hom()
Matrix([[1, 0],
        [0, 1]], : QQ[x]**2 -> QQ[x]**2)
```

`is_submodule(other)`
Returns True if other is a submodule of self.

Examples

```python
>>> from sympy import x
>>> from sympy import QQ
>>> F = QQ.old_poly_ring(x).free_module(2)
>>> M = F.submodule([2, x])
>>> F.is_submodule(F)
True
>>> F.is_submodule(M)
True
>>> M.is_submodule(F)
False
```

`is_zero()`
Returns True if self is a zero module.

(If, as this implementation assumes, the coefficient ring is not the zero ring, then this is equivalent to the rank being zero.)

Examples

```python
>>> from sympy import QQ
>>> QQ.old_poly_ring(x).free_module(0).is_zero()
True
>>> QQ.old_poly_ring(x).free_module(1).is_zero()
False
```

`multiply_ideal(other)`
Multiply self by the ideal other.
Examples

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> I = QQ.old_poly_ring(x).ideal(x)
>>> F = QQ.old_poly_ring(x).free_module(2)
>>> F.multiply_ideal(I)
<[x, 0], [0, x]>
```

`quotient_module(submodule)`

Return a quotient module.

Examples

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> M = QQ.old_poly_ring(x).free_module(2)
>>> M.quotient_module(M.submodule([1, x], [x, 2]))
QQ[x]**2/<[1, x], [x, 2]>
```

Or more concisely, using the overloaded division operator:

```python
>>> QQ.old_poly_ring(x).free_module(2) / [[1, x], [x, 2]]
QQ[x]**2/<[1, x], [x, 2]>
```

class sympy.polys.agca.modules.FreeModuleElement(module, data)

Element of a free module. Data stored as a tuple.

class sympy.polys.agca.modules.SubModule(gens, container)

Base class for submodules.

Attributes:

- container - containing module
- gens - generators (subset of containing module)
- rank - rank of containing module

Non-implemented methods:

- _contains
- _syzygies
- _in_terms_of_generators
- _intersect
- _module_quotient

Methods that likely need change in subclasses:

- reduce_element

convert(elem, M=None)

Convert elem into the internal representation.

Mostly called implicitly.
Examples

```python
>>> from sympy import QQ
>>> QQ.old_poly_ring(x).free_module(2).submodule([x, x]).inclusion_hom()
Matrix([1, 0], : <[x, x]> -> QQ[x]**2)
```

inclusion_hom()  
Return a homomorphism representing the inclusion map of self.  
That is, the natural map from self to self.container.

Examples

```python
>>> from sympy import QQ
>>> QQ.old_poly_ring(x).free_module(2).submodule([x, x]).inclusion_hom()
Matrix([1, 0], : <[x, x]> -> QQ[x]**2)
```

intersec(other, **options)  
Returns the intersection of self with submodule other.
Examples

```python
>>> from sympy.abc import x, y
>>> from sympy import QQ

>>> F = QQ.old_poly_ring(x, y).free_module(2)
>>> F.submodule([x, x]).intersect(F.submodule([y, y]))
<[x*y, x*y]>
```

Some implementation allow further options to be passed. Currently, to only one implemented is relations=True, in which case the function will return a triple \((\text{res}, \text{rela}, \text{relb})\), where \(\text{res}\) is the intersection module, and \(\text{rela}\) and \(\text{relb}\) are lists of coefficient vectors, expressing the generators of \(\text{res}\) in terms of the generators of \(\text{self}(\text{rela})\) and \(\text{other}(\text{relb})\).

```python
>>> F.submodule([x, x]).intersect(F.submodule([y, y]), relations=True)
((<[x*y, x*y]>, [(y,)], [(x,)]))
```

The above result says: the intersection module is generated by the single element \((-xy, -xy) = -y(x, x) = -x(y, y)\), where \((x, x)\) and \((y, y)\) respectively are the unique generators of the two modules being intersected.

**is_full_module()**

Return True if self is the entire free module.

Examples

```python
>>> from sympy.abc import x
>>> from sympy import QQ

>>> F = QQ.old_poly_ring(x).free_module(2)
>>> F.submodule([x, 1]).is_full_module()
False
>>> F.submodule([1, 1], [1, 2]).is_full_module()
True
```

**is_submodule(other)**

Returns True if other is a submodule of self.

```python
>>> from sympy.abc import x
>>> from sympy import QQ

>>> F = QQ.old_poly_ring(x).free_module(2)
>>> M = F.submodule([2, x])
>>> N = M.submodule([2*x, x**2])
>>> M.is_submodule(M)
True
>>> M.is_submodule(N)
True
>>> N.is_submodule(M)
False
```

**is_zero()**

Return True if self is a zero module.
Examples

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> F = QQ.old_poly_ring(x).free_module(2)
>>> F.submodule([x, 1]).is_zero()
False
>>> F.submodule([0, 0]).is_zero()
True
```

`module_quotient(other, **options)`

Returns the module quotient of self by submodule other.

That is, if self is the module $M$ and other is $N$, then return the ideal \( \{ f \in R | fN \subset M \} \).

Examples

```python
>>> from sympy import QQ
>>> from sympy.abc import x, y
>>> F = QQ.old_poly_ring(x, y).free_module(2)
>>> S = F.submodule([x*y, x*y])
>>> T = F.submodule([x, x])
>>> S.module_quotient(T)
<y>
```

Some implementations allow further options to be passed. Currently, the only one implemented is `relations=True`, which may only be passed if other is principal. In this case the function will return a pair `(res, rel)` where `res` is the ideal, and `rel` is a list of coefficient vectors, expressing the generators of the ideal, multiplied by the generator of other in terms of generators of self.

```python
>>> S.module_quotient(T, relations=True)
(<y>, [[1]])
```

This means that the quotient ideal is generated by the single element $y$, and that $y(x, x) = 1(x, xy)$, $(x, x)$ and $(xy, xy)$ being the generators of $T$ and $S$, respectively.

`multiply_ideal(I)`

Multiply self by the ideal $I$.

Examples
**quotient_module**(*other, **opts*)

Return a quotient module.

This is the same as taking a submodule of a quotient of the containing module.

**Examples**

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> F = QQ.old_poly_ring(x).free_module(2)
>>> S1 = F.submodule([x, 1])
>>> S2 = F.submodule([x**2, x])
>>> S1.quotient_module(S2)
<[x, 1] + [x**2, x]>>
```

Or more coincisely, using the overloaded division operator:

```python
>>> F.submodule([x, 1]) / [(x**2, x)]
<[x, 1] + [x**2, x]>>
```

**reduce_element**(*x*)

Reduce the element *x* of our ring modulo the ideal *self*.

Here “reduce” has no specific meaning, it could return a unique normal form, simplify the expression a bit, or just do nothing.

**submodule**(*gens*)

Generate a submodule.

**Examples**

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> M = QQ.old_poly_ring(x).free_module(2).submodule([x, 1])
>>> M.submodule([x**2, x])
<[x**2, x]>
```

**syzygy_module**(***opts*)

Compute the syzygy module of the generators of *self*.

Suppose *M* is generated by \(f_1, \ldots, f_n\) over the ring \(R\). Consider the homomorphism \(\phi : R^n \to M\), given by sending \((r_1, \ldots, r_n) \to r_1 f_1 + \cdots + r_n f_n\). The syzygy module is defined to be the kernel of \(\phi\).
Examples

The syzygy module is zero iff the generators generate freely a free submodule:

```python
>>> from sympy.abc import x, y
>>> from sympy import QQ

>>> QQ.old_poly_ring(x).free_module(2).submodule([1, 0], [1, 1]).
    .syzygy_module().is_zero()
True
```

A slightly more interesting example:

```python
>>> M = QQ.old_poly_ring(x, y).free_module(2).submodule([2*x], [y, 2*y])
>>> S = QQ.old_poly_ring(x, y).free_module(2).submodule([y, -x])
>>> M.syzygy_module() == S
True
```

union(other)

Returns the module generated by the union of self and other.

Examples

```python
>>> from sympy.abc import x
>>> from sympy import QQ

>>> F = QQ.old_poly_ring(x).free_module(1)
>>> M = F.submodule([x**2 + x]) # <x(x+1)>
>>> N = F.submodule([x**2 - 1]) # <(x-1)(x+1)>
>>> M.union(N) == F.submodule([x+1])
True
```

Ideals are created very similarly to modules. For example, let’s verify that the nodal cubic is indeed singular at the origin:

```python
>>> I = lr.ideal(x, y)
>>> I == lr.ideal(x)
False
>>> I == lr.ideal(y)
False
```

We are using here the fact that a curve is non-singular at a point if and only if the maximal ideal of the local ring is principal, and that in this case at least one of \(x\) and \(y\) must be generators.

This is the detailed documentation of the class ideal. Please note that most of the methods regarding properties of ideals (primality etc.) are not yet implemented.

```python
class sympy.polys.agca.ideals.Ideal

Abstract base class for ideals.

Do not instantiate - use explicit constructors in the ring class instead:
```
```python
>>> from sympy import QQ
>>> from sympy.abc import x
>>> QQ.old_poly_ring(x).ideal(x+1)
<x + 1>
```

Attributes

- ring - the ring this ideal belongs to

Non-implemented methods:

- `contains_elem`
- `contains_ideal`
- `quotient`
- `intersect`
- `union`
- `product`
- `is_whole_ring`
- `is_zero`
- `is_prime`, `is_maximal`, `is_primary`, `is_radical`
- `is_principal`
- `height`, `depth`
- `radical`

Methods that likely should be overridden in subclasses:

- `reduce_element`

`contains(elem)`

Return True if `elem` is an element of this ideal.

**Examples**

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> QQ.old_poly_ring(x).ideal(x+1, x-1).contains(3)
True
>>> QQ.old_poly_ring(x).ideal(x**2, x**3).contains(x)
False
```

depth()

Compute the depth of self.

height()

Compute the height of self.

intersect(J)

Compute the intersection of self with ideal J.
Examples

```python
>>> from sympy.abc import x, y
>>> from sympy import QQ
>>> R = QQ.old_poly_ring(x, y)
>>> R.ideal(x).intersect(R.ideal(y))
<x*y>
```

- `is_maximal()`: Return True if self is a maximal ideal.
- `is_primary()`: Return True if self is a primary ideal.
- `is_prime()`: Return True if self is a prime ideal.
- `is_principal()`: Return True if self is a principal ideal.
- `is_radical()`: Return True if self is a radical ideal.
- `is_whole_ring()`: Return True if self is the whole ring.
- `is_zero()`: Return True if self is the zero ideal.
- `product(J)`: Compute the ideal product of self and J.
  That is, compute the ideal generated by products $xy$, for $x$ an element of self and $y \in J$.

Examples

```python
>>> from sympy.abc import x, y
>>> from sympy import QQ
>>> QQ.old_poly_ring(x, y).ideal(x).product(QQ.old_poly_ring(x, y).ideal(y))
<x*y>
```

- `quotient(J, **opts)`: Compute the ideal quotient of self by J.
  That is, if self is the ideal $I$, compute the set $I : J = \{x \in R | xJ \subseteq I\}$.
Examples

```python
>>> from sympy import x, y
>>> from sympy import QQ
>>> R = QQ.old_poly_ring(x, y)
>>> R.ideal(x*y).quotient(R.ideal(x))
<y>
```

**radical()**

Compute the radical of self.

**reduce_element(x)**

Reduce the element x of our ring modulo the ideal self.

Here “reduce” has no specific meaning: it could return a unique normal form, simplify the expression a bit, or just do nothing.

**saturate(J)**

Compute the ideal saturation of self by J.

That is, if self is the ideal I, compute the set \( I : J^\infty = \{ x \in R \mid x J^n \subset I \text{ for some } n \} \).

**subset(other)**

Returns True if other is is a subset of self.

Here other may be an ideal.

Examples

```python
>>> from sympy import x
>>> from sympy import QQ
>>> I = QQ.old_poly_ring(x).ideal(x+1)
>>> I.subset([x**2 - 1, x**2 + 2*x + 1])
True
>>> I.subset([x**2 + 1, x + 1])
False
>>> I.subset(QQ.old_poly_ring(x).ideal(x**2 - 1))
True
```

**union(J)**

Compute the ideal generated by the union of self and J.

Examples

```python
>>> from sympy import x
>>> from sympy import QQ
>>> QQ.old_poly_ring(x).ideal(x**2 - 1).union(QQ.old_poly_ring(x).ideal((x+1)**2)) == QQ.old_poly_ring(x).ideal(x+1)
True
```
containing \( N \), then \( K/N \) is in a natural way a submodule of \( M/N \). Such a module is called a subquotient. Here is the documentation of quotient and subquotient modules:

```python
class sympy.polys.agca.modules.QuotientModule(ring, base, submodule)
    Class for quotient modules.
    Do not instantiate this directly. For subquotients, see the SubQuotientModule class.
    Attributes:
    • base - the base module we are a quotient of
    • killed_module - the submodule used to form the quotient
    • rank of the base
    convert(elem, M=None)
        Convert elem into the internal representation.
        This method is called implicitly whenever computations involve elements not in the internal representation.
```

**Examples**

```python
>>> from sympy import x
>>> from sympy import QQ
>>> F = QQ.old_poly_ring(x).free_module(2) / [(1, 2), (1, x)]
>>> F.convert([1, 0])
[1, 0] + <[1, 2], [1, x]>
```

dtype

    alias of QuotientModuleElement (page 2547)

**identity_hom()**

    Return the identity homomorphism on self.

**Examples**

```python
>>> from sympy import x
>>> from sympy import QQ
>>> M = QQ.old_poly_ring(x).free_module(2) / [(1, 2), (1, x)]
>>> M.identity_hom()
Matrix([[1, 0], [0, 1]], : QQ[x]**2/<[1, 2], [1, x]> -> QQ[x]**2/<[1, 2], [1, x]>
```

**is_submodule(other)**

    Return True if other is a submodule of self.
Examples

>>> from sympy import x
>>> from sympy import QQ
>>> Q = QQ.old_poly_ring(x).free_module(2) / [(x, x)]
>>> S = Q.submodule([1, 0])
>>> Q.is_submodule(S)
True
>>> S.is_submodule(Q)
False

is_zero()

Return True if self is a zero module.

This happens if and only if the base module is the same as the submodule being killed.

Examples

>>> from sympy import x
>>> from sympy import QQ
>>> F = QQ.old_poly_ring(x).free_module(2)
>>> (F/[(1, 0)]).is_zero()
False
>>> (F/[(1, 0), (0, 1)]).is_zero()
True

quotient_hom()

Return the quotient homomorphism to self.

That is, return a homomorphism representing the natural map from self.base to self.

Examples

>>> from sympy import x
>>> from sympy import QQ
>>> M = QQ.old_poly_ring(x).free_module(2) / [(1, 2), (1, x)]
>>> M.quotient_hom()
Matrix([[(1, 0), : QQ[x]**2  ->  QQ[x]**2/<[1, 2], [1, x]>
[0, 1]])

submodule(*gens, **opts)

Generate a submodule.

This is the same as taking a quotient of a submodule of the base module.
Examples

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> Q = QQ.old_poly_ring(x).free_module(2) / [(x, x)]
>>> Q.submodule([x, 0])
<x[x, 0] + <[x, x]>>
```

class sympy.polys.agca.modules.QuotientModuleElement(module, data)
Element of a quotient module.

eq(d1, d2)
Equality comparison.

class sympy.polys.agca.modules.SubQuotientModule(gens, container, **opts)
Submodule of a quotient module.
Equivalently, quotient module of a submodule.

Do not instantiate this, instead use the submodule or quotient_module constructing methods:

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> F = QQ.old_poly_ring(x).free_module(2)
>>> S = F.submodule([1, 0], [1, x])
>>> Q = F/[(1, 0)]
>>> S/[(1, 0)] == Q.submodule([5, x])
True
```
Attributes:
• base - base module we are quotient of
• killed_module - submodule used to form the quotient

is_full_module()
Return True if self is the entire free module.

Examples

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> F = QQ.old_poly_ring(x).free_module(2)
>>> F.submodule([x, 1]).is_full_module()
False
>>> F.submodule([1, 1], [1, 2]).is_full_module()
True
```

quotient_hom()
Return the quotient homomorphism to self.
That is, return the natural map from self.base to self.
Examples

```python
>>> from sympy import x
>>> from sympy import QQ
>>> M = (QQ.old_poly_ring(x).free_module(2) / [(1, x)]).submodule([1, 0])
>>> M.quotient_hom()
Matrix([([1, 0], : <[1, 0], [1, x]> -> <[1, 0] + <[1, x]>, [1, x] + <[1, x]>>
>>> [0, 1]]
```

Module Homomorphisms and Syzygies

Let $M$ and $N$ be $A$-modules. A mapping $f : M \rightarrow N$ satisfying various obvious properties (see [Atiyah69]) is called an $A$-module homomorphism. In this case $M$ is called the domain and $N$ the codomain. The set $\{x \in M | f(x) = 0\}$ is called the kernel $\ker(f)$, whereas the set $\{f(x) | x \in M\}$ is called the image $\im(f)$. The kernel is a submodule of $M$, the image is a submodule of $N$. The homomorphism $f$ is injective if and only if $\ker(f) = 0$ and surjective if and only if $\im(f) = N$. A bijective homomorphism is called an isomorphism. Equivalently, $\ker(f) = 0$ and $\im(f) = N$.

(A related notion, which currently has no special name in the AGCA module, is that of the cokernel, $\text{coker}(f) = N/\im(f)$.)

Suppose now $M$ is an $A$-module. $M$ is called finitely generated if there exists a surjective homomorphism $A^n \rightarrow M$ for some $n$. If such a morphism $f$ is chosen, the images of the standard basis of $A^n$ are called the generators of $M$. The module $\ker(f)$ is called syzygy module with respect to the generators. A module is called finitely presented if it is finitely generated with a finitely generated syzygy module. The class of finitely presented modules is essentially the largest class we can hope to be able to meaningfully compute in.

It is an important theorem that, for all the rings we are considering, all submodules of finitely generated modules are finitely generated, and hence finitely generated and finitely presented modules are the same.

The notion of syzygies, while it may first seem rather abstract, is actually very computational. This is because there exist (fairly easy) algorithms for computing them, and more general questions (kernels, intersections, ...) are often reduced to syzygy computation.

Let us say a few words about the definition of homomorphisms in the AGCA module. Suppose first that $f : M \rightarrow N$ is an arbitrary morphism of $A$-modules. Then if $K$ is a submodule of $M$, $f$ naturally defines a new homomorphism $g : K \rightarrow N$ (via $g(x) = f(x)$), called the restriction of $f$ to $K$. If now $K$ contained in the kernel of $f$, then moreover $f$ defines in a natural homomorphism $g : M/K \rightarrow N$ (same formula as above!), and we say that $f$ descends to $M/K$. Similarly, if $L$ is a submodule of $N$, there is a natural homomorphism $g : M \rightarrow N/L$, we say that $g$ factors through $f$. Finally, if now $L$ contains the image of $f$, then there is a natural homomorphism $g : M \rightarrow L$ (defined, again, by the same formula), and we say $g$ is obtained from $f$ by restriction of codomain. Observe also that each of these four operations is reversible, in the sense that given $g$, one can always (non-uniquely) find $f$ such that $g$ is obtained from $f$ in the above way.

Note that all modules implemented in AGCA are obtained from free modules by taking a succession of submodules and quotients. Hence, in order to explain how to define a homomorphism between arbitrary modules, in light of the above, we need only explain how to define homomorphisms of free modules. But, essentially by the definition of free module, a homomorphism from a free module $A^n$ to any module $M$ is precisely the same as giving $n$ elements of $M$ (the images of the standard basis), and giving an element of a free module
$A^m$ is precisely the same as giving $m$ elements of $A$. Hence a homomorphism of free modules $A^n \rightarrow A^m$ can be specified via a matrix, entirely analogously to the case of vector spaces.

The functions `restrict_domain` etc. of the class `Homomorphism` can be used to carry out the operations described above, and homomorphisms of free modules can in principle be instantiated by hand. Since these operations are so common, there is a convenience function `homomorphism` to define a homomorphism between arbitrary modules via the method outlined above. It is essentially the only way homomorphisms need ever be created by the user.

```python
sympy.polys.agca.homomorphisms.homomorphism(domain, codomain, matrix)
```

Create a homomorphism object.

This function tries to build a homomorphism from `domain` to `codomain` via the matrix `matrix`.

### Examples

```python
>>> from sympy import QQ
>>> from sympy.abc import x
>>> from sympy.polys.agca import homomorphism

>>> R = QQ.old_poly_ring(x)
>>> T = R.free_module(2)

>>> F = R.free_module(2)
>>> h = homomorphism(F, T, [[1, x], [x**2, 0]])
>>> h
Matrix([[1, x**2], : QQ[x]**2 -> QQ[x]**2
[0, x]])

>>> h([[1, 0]])
[1, x]

>>> h([[0, 1]])
[x**2, 0]

>>> h([[1, 1]])
[x**2 + 1, x]
```

If `domain` is a submodule of a free module, then `matrix` determines a homomorphism from the containing free module to `codomain`, and the homomorphism returned is obtained by restriction to `domain`.

```python
>>> S = F.submodule([[1, 0], [0, x]])
>>> homomorphism(S, T, [[1, x], [x**2, 0]])
Matrix([[1, x**2], : <[1, 0], [0, x]> -> QQ[x]**2
[0, 0]])
```

If `domain` is a (sub)quotient $N/K$, then `matrix` determines a homomorphism from $N$ to `codomain`. If the kernel contains $K$, this homomorphism descends to `domain` and is returned; otherwise an exception is raised.
Finally, here is the detailed reference of the actual homomorphism class:

```python
from sympy import QQ
from sympy.abc import x
from sympy.polys.agca import homomorphism
```

```python
F = QQ.old_poly_ring(x).free_module(2)
F = homomorphism(F, F, [[1, 0], [0, 1]])
```

Attributes:
- `ring` - the ring over which we are considering modules
- `domain` - the domain module
- `codomain` - the codomain module
- `_ker` - cached kernel
- `_img` - cached image

Non-implemented methods:
- `_kernel`
- `_image`
- `_restrict_domain`
- `_restrict_codomain`
- `_quotient_domain`
- `_quotient_codomain`
- `_apply`
- `_mul_scalar`
- `_compose`
- `_add`

Traceback (most recent call last):
... ValueError: kernel <[1, 0], [0, 0]> must contain sm, got <[0,x]>

Non-implemented methods:
- `_kernel`
- `_image`
- `_restrict_domain`
- `_restrict_codomain`
- `_quotient_domain`
- `_quotient_codomain`
- `_apply`
- `_mul_scalar`
- `_compose`
- `_add`
image()

Compute the image of self.

That is, if self is the homomorphism $\phi : M \to N$, then compute $im(\phi) = \{\phi(x) | x \in M\}$. This is a submodule of $N$.

Examples

```python
>>> from sympy import QQ
>>> from sympy.abc import x
>>> from sympy.polys.agca import homomorphism

>>> F = QQ.old_poly_ring(x).free_module(2)
>>> homomorphism(F, F, [[1, 0], [x, 0]]).image() == F.submodule([1, 0])
True
```

is_injective()

Return True if self is injective.

That is, check if the elements of the domain are mapped to the same codomain element.

Examples

```python
>>> from sympy import QQ
>>> from sympy.abc import x
>>> from sympy.polys.agca import homomorphism

>>> F = QQ.old_poly_ring(x).free_module(2)
>>> h = homomorphism(F, F, [[1, 0], [x, 0]])
>>> h.is_injective()
False
>>> h.quotient_domain(h.kernel()).is_injective()
True
```

is_isomorphism()

Return True if self is an isomorphism.

That is, check if every element of the codomain has precisely one preimage. Equivalently, self is both injective and surjective.
Examples

```python
>>> from sympy import QQ
>>> from sympy.abc import x
>>> from sympy.polys.agca import homomorphism

>>> F = QQ.old_poly_ring(x).free_module(2)
>>> h = homomorphism(F, F, [[1, 0], [x, 0]])
>>> h = h.restrict_codomain(h.image())
>>> h.is_isomorphism()
False
>>> h.quotient_domain(h.kernel()).is_isomorphism()
True
```

is_surjective()

Return True if self is surjective.
That is, check if every element of the codomain has at least one preimage.

Examples

```python
>>> from sympy import QQ
>>> from sympy.abc import x
>>> from sympy.polys.agca import homomorphism

>>> F = QQ.old_poly_ring(x).free_module(2)
>>> h = homomorphism(F, F, [[1, 0], [x, 0]])
>>> h.is_surjective()
False
>>> h.restrict_codomain(h.image()).is_surjective()
True
```

is_zero()

Return True if self is a zero morphism.
That is, check if every element of the domain is mapped to zero under self.

Examples

```python
>>> from sympy import QQ
>>> from sympy.abc import x
>>> from sympy.polys.agca import homomorphism

>>> F = QQ.old_poly_ring(x).free_module(2)
>>> h = homomorphism(F, F, [[1, 0], [x, 0]])
>>> h.is_zero()
False
>>> h.restrict_domain(F.submodule()).is_zero()
True
```
>>> h.quotient_codomain(h.image()).is_zero()
True

**kernel()**

Compute the kernel of self.

That is, if self is the homomorphism \(\phi : M \rightarrow N\), then compute \(\ker(\phi) = \{ x \in M | \phi(x) = 0 \}\). This is a submodule of \(M\).

**Examples**

```python
>>> from sympy import QQ
>>> from sympy.abc import x
>>> from sympy.polys.agca import homomorphism

>>> F = QQ.old_poly_ring(x).free_module(2)
>>> homomorphism(F, F, [[1, 0], [x, 0]]).kernel()
<x, -1>
```

**quotient_codomain(sm)**

Return self with codomain replaced by codomain/sm.

Here sm must be a submodule of self.codomain.

**Examples**

```python
>>> from sympy import QQ
>>> from sympy.abc import x
>>> from sympy.polys.agca import homomorphism

>>> F = QQ.old_poly_ring(x).free_module(2)
>>> h = homomorphism(F, F, [[1, 0], [x, 0]])
>>> h
Matrix([[1, x], : QQ[x]**2 -> QQ[x]**2
[0, 0]])
>>> h.quotient_codomain(F.submodule([1, 1]))
Matrix([[1, x], : QQ[x]**2 -> QQ[x]**2/<[1, 1]>
[0, 0]])
```

This is the same as composing with the quotient map on the left:

```python
>>> (F/[[1, 1]]).quotient_hom() * h
Matrix([[1, x], : QQ[x]**2 -> QQ[x]**2/<[1, 1]>
[0, 0]])
```
quotient_domain(sm)
    Return self with domain replaced by domain/sm. Here sm must be a submodule of self.kernel().

Examples

>>> from sympy import QQ
>>> from sympy.abc import x
>>> from sympy.polys.agca import homomorphism

>>> F = QQ.old_poly_ring(x).free_module(2)
>>> h = homomorphism(F, F, [[1, 0], [x, 0]])
>>> h
Matrix([1, x], : QQ[x]**2 -> QQ[x]**2
       [0, 0])
>>> h.quotient_domain(F.submodule([-x, 1]))
Matrix([1, x], : QQ[x]**2/<[-x, 1]> -> QQ[x]**2
       [0, 0])

restrict_codomain(sm)
    Return self, with codomain restricted to to sm. Here sm has to be a submodule of self.codomain containing the image.

Examples

>>> from sympy import QQ
>>> from sympy.abc import x
>>> from sympy.polys.agca import homomorphism

>>> F = QQ.old_poly_ring(x).free_module(2)
>>> h = homomorphism(F, F, [[1, 0], [x, 0]])
>>> h
Matrix([1, x], : QQ[x]**2 -> QQ[x]**2
       [0, 0])
>>> h.restrict_codomain(F.submodule([1, 0]))
Matrix([1, x], : QQ[x]**2 -> <[1, 0]>
       [0, 0])

restrict_domain(sm)
    Return self, with the domain restricted to sm. Here sm has to be a submodule of self.domain.
Examples

```python
>>> from sympy import QQ
>>> from sympy.abc import x
>>> from sympy.polys.agca import homomorphism

>>> F = QQ.old_poly_ring(x).free_module(2)
>>> h = homomorphism(F, F, [[1, 0], [x, 0]])
>>> h
Matrix([1, x], : QQ[x]**2 -> QQ[x]**2
[0, 0])

>>> h.restrict_domain(F.submodule([1, 0]))
Matrix([1, x], : <[1, 0]> -> QQ[x]**2
[0, 0])
```

This is the same as just composing on the right with the submodule inclusion:

```python
>>> h * F.submodule([1, 0]).inclusion_hom()
Matrix([1, x], : <[1, 0]> -> QQ[x]**2
[0, 0])
```

Finite Extensions

Let \( A \) be a (commutative) ring and \( B \) an extension ring of \( A \). An element \( t \) of \( B \) is a generator of \( B \) (over \( A \)) if all elements of \( B \) can be represented as polynomials in \( t \) with coefficients in \( A \). The representation is unique if and only if \( t \) satisfies no non-trivial polynomial relation, in which case \( B \) can be identified with a (univariate) polynomial ring over \( A \).

The polynomials having \( t \) as a root form a non-zero ideal in general. The most important case in practice is that of an ideal generated by a single monic polynomial. If \( t \) satisfies such a polynomial relation, then its highest power \( t^n \) can be written as linear combination of lower powers. It follows, inductively, that all higher powers of \( t \) also have such a representation. Hence the lower powers \( t^i \) \((i = 0, \ldots, n - 1)\) form a basis of \( B \), which is then called a finite extension of \( A \), or, more precisely, a monogenic finite extension as it is generated by a single element \( t \).

```python
class sympy.polys.agca.extensions.MonogenicFiniteExtension\( (\text{mod}) \)
```

Finite extension generated by an integral element.

The generator is defined by a monic univariate polynomial derived from the argument \( \text{mod} \).

A shorter alias is FiniteExtension.
Examples

Quadratic integer ring \( \mathbb{Z}[\sqrt{2}] \):

```python
>>> from sympy import Symbol, Poly
>>> from sympy.polys.agca.extensions import FiniteExtension
>>> x = Symbol('x')
>>> R = FiniteExtension(Poly(x**2 - 2)); R
\mathbb{Z}[x]/(x^2 - 2)
>>> R.rank
2
>>> R(1 + x)*(3 - 2*x)
1 - x
```

Finite field \( GF(5^3) \) defined by the primitive polynomial \( x^3 + x^2 + 2 \) (over \( \mathbb{Z}_5 \)).

```python
>>> F = FiniteExtension(Poly(x**3 + x**2 + 2, modulus=5)); F
GF(5)[x]/(x**3 + x**2 + 2)
>>> F.basis
(1, x, x**2)
>>> F(x + 3)/(x**2 + 2)
-2*x**2 + x + 2
```

Function field of an elliptic curve:

```python
>>> t = Symbol('t')
>>> FiniteExtension(Poly(t**2 - x**3 - x + 1, t, field=True))
\mathbb{Z}(x)[t]/(t**2 - x**3 - x + 1)
```

dtype

alias of `ExtensionElement` (page 2556)

class sympy.polys.agca.extensions.ExtensionElement(rep, ext)

Element of a finite extension.

A class of univariate polynomials modulo the modulus of the extension ext. It is represented by the unique polynomial rep of lowest degree. Both rep and the representation mod of modulus are of class DMP.

inverse()

Multiplicative inverse.

Raises

NotInvertible

If the element is a zero divisor.
Introducing the Domains of the poly module

This page introduces the idea of the “domains” that are used in SymPy’s sympy.polys (page 2435) module. The emphasis is on introducing how to use the domains directly and on understanding how they are used internally as part of the Poly (page 2453) class. This is a relatively advanced topic for a more introductory understanding of the Poly (page 2453) class and the sympy.polys (page 2435) module it is recommended to read Basic functionality of the module (page 2416) instead. The reference documentation for the domain classes is in Reference docs for the Poly Domains (page 2584). Internal functions that make use of the domains are documented in Internals of the Polynomial Manipulation Module (page 2651).

What are the domains?

For most users the domains are only really noticeable in the printed output of a Poly (page 2453):

```python
>>> from sympy import Symbol, Poly
>>> x = Symbol('x')
>>> Poly(x**2 + x)
Poly(x**2 + x, x, domain='ZZ')
>>> Poly(x**2 + x/2)
Poly(x**2 + 1/2*x, x, domain='QQ')
```

We see here that one Poly (page 2453) has domain ZZ (page 2605) representing the integers and the other has domain QQ (page 2609) representing the rationals. These indicate the “domain” from which the coefficients of the polynomial are drawn.

From a high-level the domains represent formal concepts such as the set of integers \( \mathbb{Z} \) or rationals \( \mathbb{Q} \). The word “domain” here is a reference to the mathematical concept of an integral domain.

Internally the domains correspond to different computational implementations and representations of the expressions that the polynomials correspond to. The Poly (page 2453) object itself has an internal representation as a list of coefficients and a domain (page 2466) attribute representing the implementation of those coefficients:

```python
>>> p = Poly(x**2 + x/2)
>>> p
Poly(x**2 + 1/2*x, x, domain='QQ')
>>> p.domain
QQ
>>> p.rep
DMP([1, 1/2, 0], QQ, None)
>>> p.rep.rep
[1, 1/2, 0]
>>> type(p.rep.rep[0])
<class 'sympy.external.pythonmpq.PythonMPQ'>
```

Here the domain is QQ (page 2609) which represents the implementation of the rational numbers in the domain system. The Poly (page 2453) instance itself has a Poly.domain (page 2466) attribute QQ (page 2609) and then a list of PythonMPQ (page 2612) coefficients where PythonMPQ (page 2612) is the class that implements the elements of the QQ (page 2609) domain. The list of coefficients [1, 1/2, 0] gives a standardised low-level representation of the polynomial expression \((1)*x**2 + (1/2)*x + (0)\).
This page looks at the different domains that are defined in SymPy, how they are implemented and how they can be used. It introduces how to use the domains and domain elements directly and explains how they are used internally as part of $\texttt{Poly}$ (page 2453) objects. This information is more relevant for development in SymPy than it is for users of the $\texttt{sympy.polys}$ (page 2435) module.

**Representing expressions symbolically**

There are many different ways that a mathematical expression can be represented symbolically. The purpose of the polynomial domains is to provide suitable implementations for different classes of expressions. This section considers the basic approaches to the symbolic representation of mathematical expressions: “tree”, “dense polynomial” and “sparse polynomial”.

**Tree representation**

The most general representation of symbolic expressions is as a tree and this is the representation used for most ordinary SymPy expressions which are instances of $\texttt{Expr}$ (page 999) (a subclass of $\texttt{Basic}$ (page 979)). We can see this representation using the $\texttt{srepr()}$ (page 2253) function:

```python
>>> from sympy import Symbol, srepr
>>> x = Symbol('x')
>>> e = 1 + 1/(2 + x**2)
>>> e
1 + 1/(x**2 + 2)
>>> print(srepr(e))
Add(Integer(1), Pow(Add(Pow(Symbol('x'), Integer(2)), Integer(2)), Integer(-1)))
```

Here the expression $e$ is represented as an $\texttt{Add}$ (page 1062) node which has two children 1 and $1/(x**2 + 2)$. The child 1 is represented as an $\texttt{Integer}$ (page 1038) and the other child is represented as a $\texttt{Pow}$ (page 1055) with base $x**2 + 2$ and exponent 1. Then $x**2 + 2$ is represented as an $\texttt{Add}$ (page 1062) with children $x**2$ and 2 and so on. In this way the expression is represented as a tree where the internal nodes are operations like $\texttt{Add}$ (page 1062), $\texttt{Mul}$ (page 1058), $\texttt{Pow}$ (page 1055) and so on and the leaf nodes are atomic expression types like $\texttt{Integer}$ (page 1038) and $\texttt{Symbol}$ (page 1028). See *Advanced Expression Manipulation* (page 61) for more about this representation.

The tree representation is core to the architecture of $\texttt{Expr}$ (page 999) in SymPy. It is a highly flexible representation that can represent a very wide range of possible expressions. It can also represent equivalent expressions in different ways e.g.:

```python
>>> e = x*(x + 1)
>>> e
x*(x + 1)
>>> e.expand()
x**2 + x
```

These two expression although equivalent have different tree representations:
Being able to represent the same expression in different ways is both a strength and a weakness. It is useful to be able to convert an expression into different forms for different tasks but having non-unique representations makes it hard to tell when two expressions are equivalent which is in fact very important for many computational algorithms. The most important task is being able to tell when an expression is equal to zero which is undecidable in general (Richardson's theorem) but is decidable in many important special cases.

DUP representation

Restricting the set of allowed expressions to special cases allows for much more efficient symbolic representations. As we already saw Poly (page 2453) can represent a polynomial as a list of coefficients. This means that an expression like \( x^4 + x + 1 \) could be represented simply as \([1, 0, 0, 1, 1]\). This list of coefficients representation of a polynomial expression is known as the "dense univariate polynomial" (DUP) representation. Working within that representation algorithms for multiplication, addition and crucially zero-testing can be much more efficient than with the corresponding tree representations. We can see this representation from a Poly (page 2453) instance by looking at its rep.rep attribute:

```
>>> p = Poly(x**4 + x + 1)
>>> p.rep.rep
[1, 0, 0, 1, 1]
```

In the DUP representation it is not possible to represent the same expression in different ways. There is no distinction between \( x(x + 1) \) and \( x^2 + x \) because both are just \([1, 1, 0]\). This means that comparing two expressions is easy: they are equal if and only if all of their coefficients are equal. Zero-testing is particularly easy: the polynomial is zero if and only if all coefficients are zero (of course we need to have easy zero-testing for the coefficients themselves).

We can make functions that operate on the DUP representation much more efficiently than functions that operate on the tree representation. Many operations with standard sympy expressions are in fact computed by converting to a polynomial representation and then performing the calculation. An example is the factor() (page 2447) function:

```
>>> from sympy import factor
>>> e = 2*x**3 + 10*x**2 + 16*x + 8
>>> e
2*x**3 + 10*x**2 + 16*x + 8
>>> factor(e)
2*(x + 1)*(x + 2)**2
```

Internally factor() (page 2447) will convert the expression from the tree representation into the DUP representation and then use the function dup_factor_list:

```
>>> from sympy import ZZ
>>> from sympy.polys.factortools import dup_factor_list
>>> p = [ZZ(2), ZZ(10), ZZ(16), ZZ(8)]
```

(continues on next page)
There are many more examples of functions with `dup_*` names for operating on the DUP representation that are documented in *Internals of the Polynomial Manipulation Module* (page 2651). There are also functions with the `dmp_*` prefix for operating on multivariate polynomials.

### DMP representation

A multivariate polynomial (a polynomial in multiple variables) can be represented as a polynomial with coefficients that are themselves polynomials. For example \( x^{**2}y + x^{**2} + x^y + y + 1 \) can be represented as polynomial in \( x \) where the coefficients are themselves polynomials in \( y \) i.e.: \((y + 1)*x^{**2} + (y)*x + (y+1)\). Since we can represent a polynomial with a list of coefficients a multivariate polynomial can be represented with a list of lists of coefficients:

```python
from sympy import symbols

x, y = symbols('x, y')
p = Poly(x**2*y + x**2 + x*y + y + 1, x, y, domain='ZZ')
p_poly = p.rep.rep
```

This list of lists of (lists of...) coefficients representation is known as the “dense multivariate polynomial” (DMP) representation.

### Sparse polynomial representation

Instead of lists we can use a dict mapping nonzero monomial terms to their coefficients. This is known as the “sparse polynomial” representation. We can see what this would look like using the `as_dict()` (page 2457) method:

```python
from sympy import symbols

x, y = symbols('x, y')
p = Poly(x**2*y + x**2 + x*y + y + 1, x, y, domain='ZZ')
p_sparse = p.as_dict()
```

The keys of this dict are the exponents of the powers of \( x \) and the values are the coefficients so e.g. \( 7*x**20 \) becomes \((20,): 7\) in the dict. The key is a tuple so that in the multivariate case something like \( 4*x^{**2}*y^{**3} \) can be represented as \((2, 3): 4\). The sparse representation can be more efficient as it avoids the need to store and manipulate the zero coefficients. With a large number of generators (variables) the dense representation becomes particularly inefficient and it is better to use the sparse representation:
SymPy Documentation, Release 1.12.1

(x0, x1, x2, x3, x4, x5, x6, x7, x8, x9)
>>> p = Poly(prod(gens))
>>> p
Poly(x0*x1*x2*x3*x4*x5*x6*x7*x8*x9, x0, x1, x2, x3, x4, x5, x6, x7, x8, x9, \n...domain='ZZ')
>>> p.rep.rep
[[[[[[[[[1, 0], []], [[]], [[[]]], [[[[]]], [[[[]]], [[[[[]]], [[[[[]]], [[[[[]]], [[[[[]]], [[[[[]]], [[[[[]]], []]]]]]]]]]]]]]]]]]]
>>> p.as_dict()
{(1, 1, 1, 1, 1, 1, 1, 1, 1, 1): 1}

The dict representation shown in the last output maps from the monomial which is represented as a tuple of powers \((1, 1, 1, ...)\) i.e. \(x0**1 * x1**1, ...\) to the coefficient 1. Compared to the DMP representation (page 2560) we have a much more flattened data structure: it is a dict with only one key and value. Algorithms for working with sparse representations would likely be much more efficient than dense algorithms for this particular example polynomial.

SymPy’s polynomial module has implementations of polynomial expressions based on both the dense and sparse representations. There are also other implementations of different special classes of expressions that can be used as the coefficients of those polynomials. The rest of this page discusses what those representations are and how to use them.

### Basic usage of domains

Several domains are predefined and ready to be used such as \(\texttt{ZZ}\) (page 2605) and \(\texttt{QQ}\) (page 2609) which represent the ring of integers \(\mathbb{Z}\) and the field of rationals \(\mathbb{Q}\). The \texttt{Domain} (page 2584) object is used to construct elements which can then be used in ordinary arithmetic operations.:.

```python
>>> from sympy import ZZ
>>> z1 = ZZ(2)
>>> z1
2
>>> z1 + z1
4
>>> type(z1)
<class 'int'>
>>> z1 in ZZ
True
```

The basic operations +, -, and * for addition, subtraction and multiplication will work for the elements of any domain and will produce new domain elements. Division with / (Python’s “true division” operator) is not possible for all domains and should not be used with domain elements unless the domain is known to be a field. For example dividing two elements of \(\texttt{ZZ}\) (page 2605) gives a float which is not an element of \(\texttt{ZZ}\) (page 2605):

```python
>>> z1 / z1
1.0
>>> type(z1 / z1)
<class 'float'>
```
Most domains representing non-field rings allow floor and modulo division (remainder) with Python's floor division `//` and modulo division `%` operators. For example with `ZZ` (page 2605):

```python
>>> z1 // z1
1
>>> z1 % z1
0
```

The `QQ` (page 2609) domain represents the field of rational numbers and does allow division:

```python
>>> from sympy import QQ
>>> q1 = QQ(1, 2)
>>> q1
1/2
>>> q2 = QQ(2, 3)
>>> q2
2/3
>>> q1 / q2
3/4
>>> type(q1)
<class 'sympy.external.pythonmpq.PythonMPQ'>
```

In general code that is expected to work with elements of an arbitrary domain should not use the division operators `/`, `//` and `%`. Only the operators `+`, `-`, `*` and `**` (with nonnegative integer exponent) should be assumed to work with arbitrary domain elements. All other operations should be accessed as functions from the `Domain` (page 2584) object:

```python
>>> ZZ.quo(ZZ(5), ZZ(3))  # 5 // 3
1
>>> ZZ.rem(ZZ(5), ZZ(3))  # 5 % 3
2
>>> ZZ.div(ZZ(5), ZZ(3))  # divmod(5, 3)
(1, 2)
>>> QQ.div(QQ(5), QQ(3))
(5/3, 0)
```

The `exquo()` (page 2591) function is used to compute an exact quotient. This is the analogue of `a / b` but where the division is expected to be exact (with no remainder) or an error will be raised:

```python
>>> QQ.exquo(QQ(5), QQ(3))
5/3
>>> ZZ.exquo(ZZ(4), ZZ(2))
2
>>> ZZ.exquo(ZZ(5), ZZ(3))
ExactQuotientFailed: 3 does not divide 5 in ZZ
```

The exact methods and attributes of the domain elements are not guaranteed in general beyond the basic arithmetic operations. It should not be presumed that e.g. `ZZ` (page 2605) will
always be of type int. If gmpy or gmpy2 is installed then the mpz or mpq types are used instead for ZZ (page 2605) and QQ (page 2609):

```python
>>> from sympy import ZZ, QQ
>>> ZZ(2)
mpz(2)
>>> QQ(2, 3)
mpq(2, 3)
```

The mpz type is faster than Python’s standard int type for operations with large integers although for smaller integers the difference is not so significant. The mpq type representing rational numbers is implemented in C rather than Python and is many times faster than the pure Python implementation of QQ (page 2609) that is used when gmpy is not installed.

In general the Python type used for the elements of a domain can be checked from the dtype (page 2590) attribute of the domain. When gmpy is installed the dtype for ZZ (page 2605) is mpz which is not an actual type and cannot be used with isinstance. For this reason the of_type() (page 2596) method can be used to check if an object is an element of dtype (page 2590):

```python
>>> z = ZZ(2)
>>> type(z)
<class 'int'>
>>> ZZ.dtype
<class 'int'>
>>> ZZ.of_type(z)
True
```

## Domain elements vs sympy expressions

Note that domain elements are not of the same type as ordinary sympy expressions which are subclasses of Expr (page 999) such as Integer (page 1038). Ordinary sympy expressions are created with the sympify() (page 970) function:

```python
>>> from sympy import sympify
>>> z1_sympy = sympify(2)  # Normal sympy object
>>> z1_sympy
2
>>> type(z1_sympy)
<class 'sympy.core.numbers.Integer'>
>>> from sympy import Expr
>>> isinstance(z1_sympy, Expr)
True
```

It is important when working with the domains not to mix sympy expressions with domain elements even though it will sometimes work in simple cases. Each domain object has the methods to_sympy() (page 2597) and from_sympy() (page 2593) for converting back and forth between sympy expressions and domain elements:

```python
>>> z_sympy = sympify(2)
>>> z_zz = ZZ.from_sympy(z_sympy)
>>> z_zz
2
```
>>> type(z_sympy)
<class 'sympy.core.numbers.Integer'>
>>> type(z_zz)
<class 'int'>
>>> ZZ.to_sympy(z_zz)
2
>>> type(ZZ.to_sympy(z_zz))
<class 'sympy.core.numbers.Integer'>

Any particular domain will only be able to represent some sympy expressions so conversion will fail if the expression cannot be represented in the domain:

>>> from sympy import sqrt
>>> e = sqrt(2)
>>> e
sqrt(2)
>>> ZZ.from_sympy(e)
Traceback (most recent call last):
... CoercionFailed: expected an integer, got sqrt(2)

We have already seen that in some cases we can use the domain object itself as a constructor e.g. QQ(2). This will generally work provided the arguments given are valid for the dtype (page 2590) of the domain. Although it is convenient to use this in interactive sessions and in demonstrations it is generally better to use the from_sympy() (page 2593) method for constructing domain elements from sympy expressions (or from objects that can be sympified to sympy expressions).

It is important not to mix domain elements with other Python types such as int, float, as well as standard sympy Expr (page 999) expressions. When working in a domain, care should be taken as some Python operations will do this implicitly. For example the sum function will use the regular int value of zero so that sum([a, b]) is effectively evaluated as (0 + a) + b where 0 is of type int.

Every domain is at least a ring if not a field and as such is guaranteed to have two elements in particular corresponding to 1 and 0. The domain object provides domain elements for these as the attributes one and zero (page 2599). These are useful for something like Python’s sum function which allows to provide an alternative object as the “zero”:

>>> ZZ.one
1
>>> ZZ.zero
0
>>> sum([ZZ(1), ZZ(2)]) # don't do this (even it sometimes works)
3
>>> sum([ZZ(1), ZZ(2)], ZZ.zero) # provide the zero from the domain
3

A standard pattern then for performing calculations in a domain is:

1. Start with sympy Expr (page 999) instances representing expressions.
2. Choose an appropriate domain that can represent the expressions.
3. Convert all expressions to domain elements using from_sympy() (page 2593).
4. Perform the calculation with the domain elements.

5. Convert back to Expr (page 999) with `to_sympy()` (page 2597).

Here is an implementation of the sum function that illustrates these steps and sums some integers but performs the calculation using the domain elements rather than standard sympy expressions:

```python
def sum_domain(expressions_sympy):
    # """Sum sympy expressions but performing calculations in domain ZZ""

    # Convert to domain
    expressions_dom = [ZZ.from_sympy(e) for e in expressions_sympy]

    # Perform calculations in the domain
    result_dom = ZZ.zero
    for e_dom in expressions_dom:
        result_dom += e_dom

    # Convert the result back to Expr
    result_sympy = ZZ.to_sympy(result_dom)
    return result_sympy
```

### Gaussian integers and Gaussian rationals

The two example domains that we have seen so far are ZZ (page 2605) and QQ (page 2609) representing the integers and the rationals respectively. There are other simple domains such as ZZ_I (page 2614) and QQ_I (page 2616) representing the Gaussian integers and Gaussian rationals. The Gaussian integers are numbers of the form \( a + b \sqrt{-1} \) where \( a \) and \( b \) are integers. The Gaussian rationals are defined similarly except that \( a \) and \( b \) can be rationals. We can use the Gaussian domains like:

```python
>>> from sympy import ZZ_I, QQ_I, I
>>> z = ZZ_I.from_sympy(1 + 2*I)
>>> z
(1 + 2*I)
>>> z**2
(-3 + 4*I)
```

Note the contrast with the way this calculation works in the tree representation where `expand()` (page 1099) is needed to get the reduced form:

```python
>>> from sympy import expand, I
>>> z = 1 + 2*I
>>> z**2
(1 + 2*I)**2
>>> expand(z**2)
-3 + 4*I
```

The ZZ_I (page 2614) and QQ_I (page 2616) domains are implemented by the classes GaussianIntegerRing (page 2614) and GaussianRationalField (page 2616) and their elements by GaussianInteger (page 2616) and GaussianRational (page 2619) respectively. The internal representation for an element of ZZ_I (page 2614) or QQ_I (page 2616) is simply as a pair \((a, b)\) of elements of ZZ (page 2605) or QQ (page 2609) respectively. The domain
ZZ_I (page 2614) is a ring with similar properties to ZZ (page 2605) whereas QQ_I (page 2616) is a field much like QQ (page 2609):

```python
>>> ZZ.is_Field
False
>>> QQ.is_Field
True
>>> ZZ_I.is_Field
False
>>> QQ_I.is_Field
True
```

Since QQ_I (page 2616) is a field division by nonzero elements is always possible whereas in ZZ_I (page 2614) we have the important concept of the greatest common divisor (GCD):

```python
>>> e1 = QQ_I.from_sympy(1+I)
>>> e2 = QQ_I.from_sympy(2-I/2)
>>> e1/e2
(6/17 + 10/17*I)
>>> ZZ_I.gcd(ZZ_I(5), ZZ_I.from_sympy(1+2*I))
(1 + 2*I)
```

### Finite fields

So far we have seen the domains ZZ (page 2605), QQ (page 2609), ZZ_I (page 2614), and QQ_I (page 2616). There are also domains representing the Finite fields although the implementation of these is incomplete. A finite field GF(p) (page 2602) of prime order can be constructed with FF or GF. A domain for the finite field of prime order p can be constructed with GF(p) (page 2602):

```python
>>> from sympy import GF
>>> K = GF(5)
>>> two = K(2)
>>> two
2 mod 5
>>> two ** 2
4 mod 5
>>> two ** 3
3 mod 5
```

There is also FF as an alias for GF (standing for “finite field” and “Galois field” respectively). These are equivalent and both FF(n) and GF(n) will create a domain which is an instance of FiniteField (page 2602). The associated domain elements will be instances of PythonFiniteField (page 2605) or GMPYFiniteField (page 2605) depending on whether or not gmpy is installed.

Finite fields of order $p^n$ where $n \neq 1$ are not implemented. It is possible to use e.g. GF(6) or GF(9) but the resulting domain is not a field. It is just the integers modulo 6 or 9 and therefore has zero divisors and non-invertible elements:

```python
>>> K = GF(6)
>>> K(3) * K(2)
0 mod 6
```
It would be good to have a proper implementation of prime-power order finite fields but this is not yet available in SymPy (contributions welcome!).

**Real and complex fields**

The fields $RR$ (page 2626) and $CC$ (page 2627) are intended mathematically to correspond to the reals and the complex numbers, $\mathbb{R}$ and $\mathbb{C}$ respectively. The implementation of these uses floating point arithmetic. In practice this means that these are the domains that are used to represent expressions containing floats. Elements of $RR$ (page 2626) are instances of the class `RealElement` (page 2626) and have an `mpf` tuple which is used to represent a float in `mpmath`. Elements of $CC$ (page 2627) are instances of `ComplexElement` (page 2627) and have an `mpc` tuple which is a pair of `mpf` tuples representing the real and imaginary parts. See the `mpmath docs` for more about how floating point numbers are represented:

```python
>>> from sympy import RR, CC
>>> xr = RR(3)
>>> xr
3.0
>>> xr._mpf_
(0, 3, 0, 2)
>>> zc = CC(3+1j)
>>> zc
(3.0 + 1.0j)
>>> zc._mpc_
((0, 3, 0, 2), (0, 1, 0, 1))
```

The use of approximate floating point arithmetic in these domains comes with all of the usual pitfalls. Many algorithms in the `sympy.polys` (page 2435) module are fundamentally designed for exact arithmetic making the use of these domains potentially problematic:

```python
>>> RR('0.1') + RR('0.2') == RR('0.3')
False
```

Since these are implemented using `mpmath` which is a multiprecision library it is possible to create different domains with different working precisions. The default domains $RR$ (page 2626) and $CC$ (page 2627) use 53 binary digits of precision much like standard double precision floating point which corresponds to approximately 15 decimal digits:

```python
>>> from sympy.polys.domains.realfield import RealField
>>> RR.precision
53
>>> RR.dps
15
>>> RR(1) / RR(3)
0.3333333333333333
>>> RR100 = RealField(100)
>>> RR100.precision
100
>>> RR100.dps
29
>>> RR100(1) / RR100(3)
0.33333333333333333333333333333333
```
There is however a bug in the implementation of this so that actually a global precision setting is used by all `RealElement` (page 2626). This means that just creating `RR100` above has altered the global precision and we will need to restore it in the doctest here:

```python
>>> RR(1) / RR(3)  # wrong result!
0.33333333333333333333333333333
>>> dummy = RealField(53)  # hack to restore precision
>>> RR(1) / RR(3)  # restored
0.333333333333333
```

(Obviously that should be fixed!)

**Algebraic number fields**

An algebraic extension of the rationals \( \mathbb{Q} \) is known as an algebraic number field and these are implemented in sympy as \( \mathbb{Q}<a> \) (page 2619). The natural syntax for these would be something like \( \mathbb{Q}(\sqrt{2}) \) however \( \mathbb{Q}() \) is already overloaded as the constructor for elements of \( \mathbb{Q} \) (page 2609). These domains are instead created using the `algebraic_field()` (page 2588) method e.g. \( \mathbb{Q}.algebraic_field(\sqrt{2}) \). The resulting domain will be an instance of `AlgebraicField` (page 2619) with elements that are instances of `ANP` (page 2650).

The printing support for these is less developed but we can use `to_sympy()` (page 2597) to take advantage of the corresponding `Expr` (page 999) printing support:

```python
>>> K = QQ.algebraic_field(sqrt(2))
>>> K
\mathbb{Q}<\sqrt{2}>
>>> b = K.one + K.from_sympy(sqrt(2))
>>> b
ANP([1, 1], [1, 0, -2], QQ)
>>> K.to_sympy(b)
1 + \sqrt{2}
>>> b ** 2
ANP([2, 3], [1, 0, -2], QQ)
>>> K.to_sympy(b**2)
2*\sqrt{2} + 3
```

The raw printed display immediately shows the internal representation of the elements as `ANP` (page 2650) instances. The field \( \mathbb{Q}(\sqrt{2}) \) consists of numbers of the form \( a\sqrt{2} + b \) where \( a \) and \( b \) are rational numbers. Consequently every number in this field can be represented as a pair \((a, b)\) of elements of \( \mathbb{Q} \) (page 2609). The domain element stores these two in a list and also stores a list representation of the minimal polynomial for the extension element \( \sqrt{2} \).

There is a sympy function `minpoly()` (page 2795) that can compute the minimal polynomial of any algebraic expression over the rationals:

```python
>>> from sympy import minpoly, Symbol
>>> x = Symbol('x')
>>> minpoly(sqrt(2), x)
x**2 - 2
```

In the dense polynomial representation as a list of coefficients this polynomial is represented as \([1, 0, -2]\) as seen in the `ANP` (page 2650) display for the elements of \( \mathbb{Q}<\sqrt{2}> \) above.

It is also possible to create an algebraic number field with multiple generators such as \( \mathbb{Q}(\sqrt{2}, \sqrt{3}) \):
Here the algebraic extension \( \mathbb{Q}(\sqrt{2}, \sqrt{3}) \) is converted to the (isomorphic) \( \mathbb{Q}(\sqrt{2} + \sqrt{3}) \) with a single generator \( \sqrt{2} + \sqrt{3} \). It is always possible to find a single generator like this due to the primitive element theorem. There is a sympy function `primitive_element()` (page 2796) that can compute the minimal polynomial for a primitive element of an extension:

```python
>>> from sympy import primitive_element, minpoly
>>> e = primitive_element([[sqrt(2), sqrt(3)]], x)
>>> e[0]
x**4 - 10*x**2 + 1
>>> e[0].subs(x, sqrt(2) + sqrt(3)).expand()
0
```

The minimal polynomial \( x^4 - 10x^2 + 1 \) has the dense list representation \([1, 0, -10, 0, 1]\) as seen in the ANP (page 2650) output above. What the primitive element theorem means is that all algebraic number fields can be represented as an extension of the rationals by a single generator with some minimal polynomial. Calculations over the algebraic number field only need to take advantage of the minimal polynomial and that makes it possible to compute all arithmetic operations and also to carry out higher level operations like factorisation of polynomials.

### Polynomial ring domains

There are also domains implemented to represent a polynomial ring like \( K[x] \) (page 2627) which is the domain of polynomials in the generator \( x \) with coefficients over another domain \( K \):

```python
>>> from sympy import ZZ, symbols
>>> x = symbols('x')
>>> K = ZZ[x]
>>> K
ZZ[x]
>>> x_dom = K(x)
>>> x_dom + K.one
x + 1
```

All the operations discussed before will work with elements of a polynomial ring:

```python
>>> p = x_dom + K.one
>>> p
```

(continues on next page)
The internal representation of elements of \( K[x] \) is different from the way that ordinary sympy (\( \text{Expr} \) (page 999)) expressions are represented. The \( \text{Expr} \) (page 999) representation of any expression is as a tree e.g.:

```python
>>> from sympy import srepr
>>> K = ZZ[x]
>>> p_expr = x**2 + 2*x + 1
>>> p_expr
x**2 + 2*x + 1
>>> srepr(p_expr)
"Add(Pow(Symbol('x'), Integer(2)), Mul(Integer(2), Symbol('x')), Integer(1))"
```

Here the expression is a tree where the top node is an \( \text{Add} \) (page 1062) and its children nodes are \( \text{Pow} \) (page 1055) etc. This tree representation makes it possible to represent equivalent expressions in different ways e.g.:

```python
>>> x = symbols('x')
>>> p_expr = x*(x + 1) + x
>>> p_expr
x*(x + 1) + x
>>> p_expr.expand()
x**2 + 2*x
```

By contrast the domain \( \text{ZZ}[x] \) represents only polynomials and does so by simply storing the non-zero coefficients of the expanded polynomial (the “sparse” polynomial representation). In particular elements of \( \text{ZZ}[x] \) are represented as a Python dict. Their type is \( \text{PolyElement} \) (page 2635) which is a subclass of dict. Converting to a normal dict shows the internal representation:

```python
>>> x = symbols('x')
>>> K = ZZ[x]
>>> x_dom = K(x)
>>> p_dom = K(3)*x_dom**2 + K(2)*x_dom + K(7)
>>> p_dom
3*x**2 + 2*x + 7
>>> dict(p_dom)
{(0,): 7, (1,): 2, (2,): 3}
```

This internal form makes it impossible to represent unexpanded multiplications so any multiplication of elements of \( \text{ZZ}[x] \) will always be expanded:
>>> x = symbols('x')
>>> K = ZZ[x]
>>> x_dom = K(x)
>>> p_expr = x * (x + 1) + x
>>> p_expr
x*(x + 1) + x
>>> p_dom = x_dom * (x_dom + K.one) + x_dom
>>> p_dom
x**2 + 2*x

These same considerations apply to powers:

>>> (x + 1) ** 2
(x + 1)**2
>>> (x_dom + K.one) ** 2
x**2 + 2*x + 1

We can also construct multivariate polynomial rings:

>>> x, y = symbols('x, y')
>>> K = ZZ[x,y]
>>> xk = K(x)
>>> yk = K(y)
>>> xk**2*yk + xk + yk
x**2*y + x + y

It is also possible to construct nested polynomial rings (although it is less efficient). The ring $K[x][y]$ is formally equivalent to $K[x,y]$ although their implementations in sympy are different:

>>> K = ZZ[x][y]
>>> p = K(x**2 + x*y + y**2)
>>> p
y**2 + x*y + x**2
>>> dict(p)
{(0,): x**2, (1,): x, (2,): 1}

Here the coefficients like $x**2$ are instances of PolyElement (page 2635) as well so this is a dict where the values are also dicts. The full representation is more like:

>>> {k: dict(v) for k, v in p.items()}
{(0,): {(2,): 1}, (1,): {(1,): 1}, (2,): {(0,): 1}}

The multivariate ring domain $ZZ[x,y]$ has a more efficient representation as a single flattened dict:

>>> K = ZZ[x,y]
>>> p = K(x**2 + x*y + y**2)
>>> p
x**2 + x*y + y**2
>>> dict(p)
{(0, 2): 1, (1, 1): 1, (2, 0): 1}

The difference in efficiency between these representations grows as the number of generators increases i.e. $ZZ[x,y,z,t,\ldots]$ vs $ZZ[x][y][z][t]$.\ldots
Old (dense) polynomial rings

In the last section we saw that the domain representation of a polynomial ring like \( K[x] \) (page 2627) uses a sparse representation of a polynomial as a dict mapping monomial exponents to coefficients. There is also an older version of \( K[x] \) (page 2627) that uses the dense \textit{DMP representation} (page 2560). We can create these two versions of \( K[x] \) (page 2627) using \texttt{poly_ring()} (page 2596) and \texttt{old_poly_ring()} (page 2596) where the syntax \( K[x] \) is equivalent to \texttt{K.poly_ring(x)}:

```python
>>> K1 = ZZ.poly_ring(x)
>>> K2 = ZZ.old_poly_ring(x)
>>> K1
ZZ[x]
>>> K2
ZZ[x]
>>> K1 == ZZ[x]
True
>>> K2 == ZZ[x]
False
>>> p1 = K1.from_sympy(x**2 + 1)
>>> p2 = K2.from_sympy(x**2 + 1)
>>> p1
x**2 + 1
>>> p2
x**2 + 1
>>> type(K1)
<class 'sympy.polys.domains.polynomialring.PolynomialRing'>
>>> type(p1)
<class 'sympy.polys.rings.PolyElement'>
>>> type(K2)
<class 'sympy.polys.domains.old_polynomialring.GlobalPolynomialRing'>
>>> type(p2)
<class 'sympy.polys.polyclasses.DMP'>
```

The internal representation of the old polynomial ring domain is the \textit{DMP} (page 2643) representation as a list of (lists of) coefficients:

```python
>>> repr(p2)
'DMP([1, 0, 1], ZZ, ZZ[x])'
```

The most notable use of the \textit{DMP} (page 2643) representation of polynomials is as the internal representation used by \texttt{Poly} (page 2453) (this is discussed later in this page of the docs).

\textbf{PolyRing vs PolynomialRing}

You might just want to perform calculations in some particular polynomial ring without being concerned with implementing something that works for arbitrary domains. In that case you can construct the ring more directly with the \texttt{ring()} (page 2632) function:

```python
>>> from sympy import ring
>>> K, xr, yr = ring([x, y], ZZ)
>>> K
```

(continues on next page)
Polynomial ring in x, y over ZZ with lex order

```
>>> xr**2 - yr**2
x**2 - y**2
>>> (xr**2 - yr**2) // (xr - yr)
x + y
```

The object K here represents the ring and is an instance of `PolyRing` (page 2634) but is not a `polys domain` (it is not an instance of a subclass of `Domain` (page 2584) so it cannot be used with `Poly` (page 2453)). In this way the implementation of polynomial rings that is used in the domain system can be used independently of the domain system.

The purpose of the domain system is to provide a unified interface for working with and converting between different representations of expressions. To make the `PolyRing` (page 2634) implementation usable in that context the `PolynomialRing` (page 2627) class is a wrapper around the `PolyRing` (page 2634) class that provides the interface expected in the domain system. That makes this implementation of polynomial rings usable as part of the broader codebase that is designed to work with expressions from different domains. The domain for polynomial rings is a distinct object from the ring returned by `ring()` (page 2632) although both have the same elements:

```
>>> K, xr, yr = ring([x, y], ZZ)
>>> K
Polynomial ring in x, y over ZZ with lex order
>>> K2 = ZZ[x,y]
>>> K2
ZZ[x,y]
>>> K2.ring
Polynomial ring in x, y over ZZ with lex order
>>> K2.ring == K
True
>>> K(x+y)
x + y
>>> K2(x+y)
x + y
>>> type(K(x+y))
<class 'sympy.polys.rings.PolyElement'>
>>> type(K2(x+y))
<class 'sympy.polys.rings.PolyElement'>
>>> K(x+y) == K2(x+y)
True
```

### Rational function fields

Some domains are classified as fields and others are not. The principal difference between a field and a non-field domain is that in a field it is always possible to divide any element by any nonzero element. It is usually possible to convert any domain to a field that contains that domain with the `get_field()` (page 2594) method:

```
>>> from sympy import ZZ, QQ, symbols
>>> x, y = symbols('x, y')
>>> ZZ.is_Field
```

(continues on next page)
This introduces a new kind of domain $K(x)$ (page 2629) representing a rational function field in the generator $x$ over another domain $K$. It is not possible to construct the domain $QQ(x)$ with the ($) syntax so the easiest ways to create it are using the domain methods `frac_field()` (page 2592) ($QQ.frac_field(x)$) or `get_field()` (page 2594) ($QQ[x].get_field()$). The `frac_field()` (page 2592) method is the more direct approach.

The rational function field $K(x)$ (page 2629) is an instance of `RationalField` (page 2610). This domain represents functions of the form $p(x)/q(x)$ for polynomials $p$ and $q$. The domain elements are represented as a pair of polynomials in $K[x]$ (page 2627):

```python
cancellationbetweenthenumeratoranddenominatorisautomaticinthisfield:
```

Computing this cancellation can be slow which makes rational function fields potentially slower than polynomial rings or algebraic fields.

Just like in the case of polynomial rings there is both a new (sparse) and old (dense) version of fraction fields:
Also just like in the case of polynomials rings the implementation of rational function fields can be used independently of the domain system:

```python
>>> from sympy import field
>>> K, xf, yf = field([x, y], ZZ)
>>> xf / (1 - yf)
-x/(y - 1)
```

Here $K$ is an instance of `FracField` (page 2642) rather than `RationalField` (page 2610) as it would be for the domain $ZZ(x,y)$.

### Expression domain

The final domain to consider is the “expression domain” which is known as $EX$ (page 2630). Expressions that cannot be represented using the other domains can be always represented using the expression domain. An element of $EX$ (page 2630) is actually just a wrapper around a `Expr` (page 999) instance:

```python
>>> from sympy import EX
>>> p = EX.from_sympy(1 + x)
>>> p
EX(x + 1)
>>> type(p)
<class 'sympy.polys.domains.expressiondomain.ExpressionDomain.Expression'>
>>> p.ex
x + 1
>>> type(p.ex)
<class 'sympy.core.add.Add'>
```

For other domains the domain representation of expressions is usually more efficient than the tree representation used by `Expr` (page 999). In $EX$ (page 2630) the internal representation is `Expr` (page 999) so it is clearly not more efficient. The purpose of the $EX$ (page 2630) domain is to be able to wrap up arbitrary expressions in an interface that is consistent with the other domains. The $EX$ (page 2630) domain is used as a fallback when an appropriate domain can not be found. Although this does not offer any particular efficiency it does allow the algorithms that are implemented to work over arbitrary domains to be usable when working with expressions that do not have an appropriate domain representation.
Choosing a domain

In the workflow described above the idea is to start with some sympy expressions, choose a domain and convert all the expressions into that domain in order to perform some calculation. The obvious question that arises is how to choose an appropriate domain to represent some sympy expressions. For this there is a function `construct_domain()` (page 2503) which takes a list of expressions and will choose a domain and convert all of the expressions to that domain:

```python
>>> from sympy import construct_domain, Integer
>>> elements_sympy = [Integer(3), Integer(2)]  # elements as Expr instances
>>> elements_sympy
[3, 2]
>>> K, elements_K = construct_domain(elements_sympy)
>>> K
ZZ
>>> elements_K
[3, 2]
>>> type(elements_sympy[0])
<class 'sympy.core.numbers.Integer'>
>>> type(elements_K[0])
<class 'int'>
```

In this example we see that the two integers 3 and 2 can be represented in the domain \( \mathbb{Z} \) (page 2605). The expressions have been converted to elements of that domain which in this case means the int type rather than instances of `Expr` (page 999). It is not necessary to explicitly create `Expr` (page 999) instances when the inputs can be sympified so e.g. `construct_domain([3, 2])` would give the same output as above.

Given more complicated inputs `construct_domain()` (page 2503) will choose more complicated domains:

```python
>>> from sympy import Rational, symbols
>>> x, y = symbols('x, y')
>>> construct_domain([Rational(1, 2), Integer(3)])[0]
QQ
>>> construct_domain([2*x, 3])[0]
ZZ[x]
>>> construct_domain([x/2, 3])[0]
QQ[x]
>>> construct_domain([2/x, 3])[0]
ZZ(x)
>>> construct_domain([x, y])[0]
ZZ[x,y]
```

If any noninteger rational numbers are found in the inputs then the ground domain will be \( \mathbb{Q} \) (page 2609) rather than \( \mathbb{Z} \) (page 2605). If any symbol is found in the inputs then a `PolynomialRing` (page 2627) will be created. A multivariate polynomial ring such as \( \mathbb{Q}[x, y] \) can also be created if there are multiple symbols in the inputs. If any symbols appear in the denominators then a `RationalField` (page 2610) like \( \mathbb{Q}(x) \) will be created instead.

Some of the domains above are fields and others are (non-field) rings. In some contexts it is necessary to have a field domain so that division is possible and for this `construct_domain()` (page 2503) has an option `field=True` which will force the construction of a field domain even if the expressions can all be represented in a non-field ring:
```python
>>> construct_domain([1, 2], field=True)[0]
QQ
>>> construct_domain([2*x, 3], field=True)[0]
ZZ(x)
>>> construct_domain([x/2, 3], field=True)[0]
ZZ(x)
>>> construct_domain([2/x, 3], field=True)[0]
ZZ(x)
>>> construct_domain([-x, y], field=True)[0]
ZZ(x,y)
```

By default, `construct_domain()` (page 2503) will not construct an algebraic extension field and will instead use the `EX` (page 2630) domain (`ExpressionDomain` (page 2630)). The keyword argument `extension=True` can be used to construct an `AlgebraicField` (page 2619) if the inputs are irrational but algebraic:

```python
>>> from sympy import sqrt
def
>>> construct_domain([sqrt(2)][0]
EX
>>> construct_domain([sqrt(2)], extension=True)[0]
QQ<sqrt(2)>
>>> construct_domain([sqrt(2), sqrt(3)], extension=True)[0]
QQ<sqrt(2) + sqrt(3)>
```

When there are algebraically independent transcendents in the inputs a `PolynomialRing` (page 2627) or `RationalField` (page 2610) will be constructed treating those transcendents as generators:

```python
>>> from sympy import sin, cos
```

```python
>>> construct_domain([sin(x), y])[0]
ZZ[y,sin(x)]
```

However, if there is a possibility that the inputs are not algebraically independent then the domain will be `EX` (page 2630):

```python
>>> construct_domain([sin(x), cos(x)])[0]
EX
```

Here `sin(x)` and `cos(x)` are not algebraically independent since `sin(x)**2 + cos(x)**2 = 1`.

### Converting elements between different domains

It is often useful to combine calculations performed over different domains. However, just as it is important to avoid mixing domain elements with normal sympy expressions and other Python types it is also important to avoid mixing elements from different domains. The `convert_from()` (page 2588) method is used to convert elements from one domain into elements of another domain:

```python
>>> num_zz = ZZ(3)
>>> ZZ.of_type(num_zz)
True
```

(continues on next page)
The `convert()` (page 2588) method can be called without specifying the source domain as the second argument e.g.:

```python
>>> QQ.convert(ZZ(2))
2
```

This works because `convert()` (page 2588) can check the type of ZZ(2) and can try to work out what domain (ZZ (page 2605)) it is an element of. Certain domains like ZZ (page 2605) and QQ (page 2609) are treated as special cases to make this work. Elements of more complicated domains are instances of subclasses of `DomainElement` (page 2599) which has a `parent()` (page 2599) method that can identify the domain that the element belongs to. For example in the polynomial ring ZZ[x] we have:

```python
>>> from sympy import ZZ, Symbol
>>> x = Symbol('x')
>>> K = ZZ[x]
>>> K
ZZ[x]
>>> p = K(x) + K.one
>>> p
x + 1
>>> type(p)
<class 'sympy.polys.rings.PolyElement'>
>>> p.parent()
ZZ[x]
>>> p.parent() == K
True
```

It is more efficient though to call `convert_from()` (page 2588) with the source domain specified as the second argument:

```python
>>> QQ.convert_from(ZZ(2), ZZ)
2
```

### Unifying domains

When we want to combine elements from two different domains and perform mixed calculations with them we need to

1. Choose a new domain that can represent all elements of both.
2. Convert all elements to the new domain.
3. Perform the calculation in the new domain.

The key question arising from point 1. is how to choose a domain that can represent the elements of both domains. For this there is the `unify()` (page 2599) method:
>>> x1, K1 = ZZ(2), ZZ
>>> y2, K2 = QQ(3, 2), QQ
>>> K1
ZZ
>>> K2
QQ
>>> K3 = K1.unify(K2)
>>> K3
QQ
>>> x3 = K3.convert_from(x1, K1)
>>> y3 = K3.convert_from(y2, K2)
>>> x3 + y3
7/2

The `unify()` method will find a domain that encompasses both domains so in this example `ZZ.unify(QQ)` gives `QQ` because every element of `ZZ` can be represented as an element of `QQ`. This means that all inputs (x1 and y2) can be converted to the elements of the common domain K3 (as x3 and y3). Once in the common domain we can safely use arithmetic operations like +. In this example one domain is a superset of the other and we see that `K1.unify(K2) == K2` so it is not actually necessary to convert y2. In general though `K1.unify(K2)` can give a new domain that is not equal to either K1 or K2.

The `unify()` method understands how to combine different polynomial ring domains and how to unify the base domain:

```python
>>> ZZ[x].unify(ZZ[y])
ZZ[x,y]
>>> ZZ[x,y].unify(ZZ[y])
ZZ[x,y]
>>> ZZ[x].unify(QQ)
QQ[x]
```

It is also possible to unify algebraic fields and rational function fields as well:

```python
>>> K1 = QQ.algebraic_field(sqrt(2))[x]
>>> K2 = QQ.algebraic_field(sqrt(3))[y]
>>> K1
QQ<sqrt(2)>[x]
>>> K2
QQ<sqrt(3)>[y]
>>> K1.unify(K2)
QQ<sqrt(2) + sqrt(3)>[x,y]
>>> QQ.frac_field(x).unify(ZZ[y])
ZZ(x,y)
```
Internals of a Poly

We are now in a position to understand how the Poly (page 2453) class works internally. This is the public interface of Poly (page 2453):

```python
>>> from sympy import Poly, symbols, ZZ
>>> x, y, z, t = symbols('x, y, z, t')
>>> p = Poly(x**2 + 1, x, domain=ZZ)
>>> p
Poly(x**2 + 1, x, domain='ZZ')
>>> p.gens
(x,)
>>> p.domain
ZZ
>>> p.all_coeffs()
[1, 0, 1]
>>> p.as_expr()
x**2 + 1
```

This is the internal implementation of Poly (page 2453):

```python
>>> d = p.rep  # internal representation of Poly
>>> d
DMP([1, 0, 1], ZZ, None)
>>> d.rep  # internal representation of DMP
[1, 0, 1]
>>> type(d.rep)
<class 'list'>
>>> type(d.rep[0])
<class 'int'>
>>> d.dom
ZZ
```

The internal representation of a Poly (page 2453) instance is an instance of DMP (page 2643) which is the class used for domain elements in the old polynomial ring domain old_poly_ring() (page 2596). This represents the polynomial as a list of coefficients which are themselves elements of a domain and keeps a reference to their domain (ZZ (page 2605) in this example).

Choosing a domain for a Poly

If the domain is not specified for the Poly (page 2453) constructor then it is inferred using construct_domain() (page 2503). Arguments like field=True are passed along to construct_domain() (page 2503):

```python
>>> from sympy import sqrt
>>> Poly(x**2 + 1, x)
Poly(x**2 + 1, x, domain='ZZ')
>>> Poly(x**2 + 1, x, field=True)
Poly(x**2 + 1, x, domain='QQ')
```

(continues on next page)
It is also possible to use the extension argument to specify generators of an extension even if no extension is required to represent the coefficients although this does not work when using `construct_domain()` (page 2503) directly. A list of extension elements will be passed to `primitive_element()` (page 2796) to create an appropriate `AlgebraicField` (page 2619) domain:

```
>>> from sympy import construct_domain
>>> Poly(x**2 + 1, x)
Poly(x**2 + 1, x, domain='ZZ')
>>> Poly(x**2 + 1, x, extension=sqrt(2))
Poly(x**2 + 1, x, domain='QQ<sqrt(2)>')
>>> Poly(x**2 + 1, x, extension=[sqrt(2), sqrt(3)])
Poly(x**2 + 1, x, domain='QQ<sqrt(2) + sqrt(3)>')
>>> construct_domain([1, 0, 1], extension=sqrt(2))[0]
ZZ
```

(Perhaps `construct_domain()` (page 2503) should do the same as `Poly` (page 2453) here...)

### Choosing generators

If there are symbols other than the generators then a polynomial ring or rational function field domain will be created. The domain used for the coefficients in this case is the sparse ("new") polynomial ring:

```
>>> p = Poly(x**2*y + z, x)
>>> p
Poly(y*x**2 + z, x, domain='ZZ[y,z]')
>>> p.gens
(x,)
>>> p.domain
ZZ[y,z]
>>> p.domain == ZZ[y,z]
True
>>> p.domain == ZZ.poly_ring(y, z)
True
>>> p.domain == ZZ.old_poly_ring(y, z)
False
>>> p.rep.rep
[y, 0, z]
>>> p.rep.rep[0]
y
>>> type(p.rep.rep[0])
<class 'sympy.polys.rings.PolyElement'>
>>> dict(p.rep.rep[0])
{(1, 0): 1}
```

What we have here is a strange hybrid of dense and sparse implementations. The `Poly`
(page 2453) instance considers itself to be an univariate polynomial in the generator x but with coefficients from the domain \( \mathbb{Z}[y, z] \). The internal representation of the \texttt{Poly} (page 2453) is a list of coefficients in the “dense univariate polynomial” (DUP) format. However each coefficient is implemented as a sparse polynomial in \( y \) and \( z \).

If we make \( x, y \) and \( z \) all be generators for the \texttt{Poly} (page 2453) then we get a fully dense DMP list of lists representation:

```python
>>> p = Poly(x**2*y + z, x, y, z)
```

```python
def dict(p.rep.rep[0])
{0: 1, (2, 1, 0): 1}
```

On the other hand we can make a \texttt{Poly} (page 2453) with a fully sparse representation by choosing a generator that is not in the expression at all:

```python
>>> p = Poly(x**2*y + z, t)
```

```python
>>> from sympy import pi, exp
```

```python
Poly((exp(x))**2 + (exp(x)) + 1, exp(x), domain='ZZ')
```

If no generators are provided to the \texttt{Poly} (page 2453) constructor then it will attempt to choose generators so that the expression is polynomial in those. In the common case that the expression is a polynomial expression in some symbols then those symbols will be taken as generators. However other non-symbol expressions can also be taken as generators:

```python
Poly(pi*x, x, domain='ZZ')
```

```python
Poly(pi*x, x, domain='ZZ[pi]')
```
Algebraically dependent generators

Taking \( \exp(x) \) or \( \pi \) as generators for a \texttt{Poly} (page 2453) or for its polynomial ring domain is mathematically valid because these objects are transcendental and so the ring extension containing them is isomorphic to a polynomial ring. Since \( x \) and \( \exp(x) \) are algebraically independent it is also valid to use both as generators for the same \texttt{Poly} (page 2453). However some other combinations of generators are invalid such as \( x \) and \( \sqrt{x} \) or \( \sin(x) \) and \( \cos(x) \). These examples are invalid because the generators are not algebraically independent (e.g. \( \sqrt{x} \times 2 = x \) and \( \sin(x) \times 2 + \cos(x) \times 2 = 1 \)). The implementation is not able to detect these algebraic relationships though:

```python
>>> from sympy import sin, cos, sqrt
>>> Poly(x*exp(x))  # fine
Poly(x*(exp(x)), x, exp(x), domain='ZZ')
>>> Poly(sin(x)+cos(x))  # not fine
Poly((cos(x)) + (sin(x)), cos(x), sin(x), domain='ZZ')
>>> Poly(x + sqrt(x))  # not fine
Poly(x + (sqrt(x)), x, sqrt(x), domain='ZZ')
```

Calculations with a \texttt{Poly} (page 2453) such as this are unreliable because zero-testing will not work properly in this implementation:

```python
>>> p1 = Poly(x, x, sqrt(x))
>>> p2 = Poly(sqrt(x), x, sqrt(x))
>>> p1
Poly(x, x, sqrt(x), domain='ZZ')
>>> p2
Poly((sqrt(x)), x, sqrt(x), domain='ZZ')
>>> p3 = p1 - p2**2
>>> p3  # should be zero...
Poly(x - (sqrt(x))**2, x, sqrt(x), domain='ZZ')
>>> p3.as_expr()
0
```

This aspect of \texttt{Poly} (page 2453) could be improved by:

1. Expanding the domain system with new domains that can represent more classes of algebraic extension.
2. Improving the detection of algebraic dependencies in \texttt{construct_domain()} (page 2503).
3. Improving the automatic selection of generators.

Examples of the above are that it would be useful to have a domain that can represent more general algebraic extensions (\texttt{AlgebraicField} (page 2619) is only for extensions of \texttt{QQ} (page 2609)). Improving the detection of algebraic dependencies is harder but at least common cases like \( \sin(x) \) and \( \cos(x) \) could be handled. When choosing generators it should be possible to recognise that \( \sqrt{x} \) can be the only generator for \( x + \sqrt{x} \):

```python
>>> Poly(x + sqrt(x))  # this could be improved!
Poly(x + (sqrt(x)), x, sqrt(x), domain='ZZ')
>>> Poly((sqrt(x)) + x, sqrt(x), domain='ZZ[x]')
```

5.8. Topics
Reference docs for the Poly Domains

This page lists the reference documentation for the domains in the polys module. For a general introduction to the polys module it is recommended to read Basic functionality of the module (page 2416) instead. For an introductory explanation of the what the domain system is and how it is used it is recommended to read Introducing the Domains of the poly module (page 2557). This page lists the reference docs for the Domain (page 2584) class and its subclasses (the specific domains such as ZZ) as well as the classes that represent the domain elements.

Domains

Here we document the various implemented ground domains (see Introducing the Domains of the poly module (page 2557) for more of an explanation). There are three types of Domain (page 2584) subclass: abstract domains, concrete domains, and “implementation domains”. Abstract domains cannot be (usefully) instantiated at all, and just collect together functionality shared by many other domains. Concrete domains are those meant to be instantiated and used in the polynomial manipulation algorithms. In some cases, there are various possible ways to implement the data type the domain provides. For example, depending on what libraries are available on the system, the integers are implemented either using the python built-in integers, or using gmpy. Note that various aliases are created automatically depending on the libraries available. As such e.g. ZZ always refers to the most efficient implementation of the integer ring available.

Abstract Domains

class sympy.polys.domains.domain.Domain

    Superclass for all domains in the polys domains system.

    See Introducing the Domains of the poly module (page 2557) for an introductory explanation of the domains system.

    The Domain (page 2584) class is an abstract base class for all of the concrete domain types. There are many different Domain (page 2584) subclasses each of which has an associated dtype which is a class representing the elements of the domain. The coefficients of a Poly (page 2453) are elements of a domain which must be a subclass of Domain (page 2584).

Examples

The most common example domains are the integers ZZ (page 2605) and the rationals QQ (page 2609).

```python
>>> from sympy import Poly, symbols, Domain
>>> x, y = symbols('x, y')
>>> p = Poly(x**2 + y)
>>> p
Poly(x**2 + y, x, y, domain='ZZ')
>>> p.domain
ZZ
```

(continues on next page)
>>> isinstance(p.domain, Domain)
True
>>> Poly(x**2 + y/2)
Poly(x**2 + 1/2*y, x, y, domain='QQ')

The domains can be used directly in which case the domain object e.g. (ZZ (page 2605) or QQ (page 2609)) can be used as a constructor for elements of dtype.

>>> from sympy import ZZ, QQ
>>> ZZ(2)
2
>>> ZZ.dtype
<class 'int'>
>>> type(ZZ(2))
<class 'int'>
>>> QQ(1, 2)
1/2
>>> type(QQ(1, 2))
<class 'sympy.polys.domains.pythonrational.PythonRational'>

The corresponding domain elements can be used with the arithmetic operations +, -, *, ** and depending on the domain some combination of //, % might be usable. For example in ZZ (page 2605) both // (floor division) and % (modulo division) can be used but / (true division) cannot. Since QQ (page 2609) is a Field (page 2600) its elements can be used with / but // and % should not be used. Some domains have a gcd() (page 2594) method.

>>> ZZ(2) + ZZ(3)
5
>>> ZZ(5) // ZZ(2)
2
>>> ZZ(5) % ZZ(2)
1
>>> QQ(1, 2) / QQ(2, 3)
3/4
>>> ZZ.gcd(ZZ(4), ZZ(2))
2
>>> QQ.gcd(QQ(2,7), QQ(5,3))
1/21
>>> ZZ.is_Field
False
>>> QQ.is_Field
True

There are also many other domains including:
1. GF(p) (page 2602) for finite fields of prime order.
2. RR (page 2626) for real (floating point) numbers.
3. CC (page 2627) for complex (floating point) numbers.
4. QQ<a> (page 2619) for algebraic number fields.
5. K[x] (page 2627) for polynomial rings.
6. $K(x)$ (page 2629) for rational function fields.

7. $EX$ (page 2630) for arbitrary expressions.

Each domain is represented by a domain object and also an implementation class (`dtype`) for the elements of the domain. For example the $K[x]$ (page 2627) domains are represented by a domain object which is an instance of `PolynomialRing` (page 2627) and the elements are always instances of `PolyElement` (page 2635). The implementation class represents particular types of mathematical expressions in a way that is more efficient than a normal SymPy expression which is of type `Expr` (page 999). The domain methods `from_sympy()` (page 2593) and `to_sympy()` (page 2597) are used to convert from `Expr` (page 999) to a domain element and vice versa.

```python
>>> from sympy import Symbol, ZZ, Expr
>>> x = Symbol('x')
>>> K = ZZ[x]  # polynomial ring domain
>>> K
ZZ[x]
>>> type(K)  # class of the domain
<class 'sympy.polys.domains.polynomialring.PolynomialRing'>
>>> K.dtype  # class of the elements
<class 'sympy.polys.rings.PolyElement'>
>>> p_expr = x**2 + 1  # Expr
>>> p_expr
x**2 + 1
>>> type(p_expr)  # Expr
<class 'sympy.core.add.Add'>
>>> isinstance(p_expr, Expr)
True
>>> p_domain = K.from_sympy(p_expr)
>>> p_domain  # domain element
x**2 + 1
>>> type(p_domain)  # PolyElement
<class 'sympy.polys.rings.PolyElement'>
>>> K.to_sympy(p_domain) == p_expr
True
```

The `convert_from()` (page 2588) method is used to convert domain elements from one domain to another.

```python
>>> from sympy import ZZ, QQ
>>> ez = ZZ(2)
>>> eq = QQ.convert_from(ez, ZZ)
>>> type(ez)  # int
<class 'int'>
>>> type(eq)  # PythonRational
<class 'sympy.polys.domains.pythonrational.PythonRational'>
```

Elements from different domains should not be mixed in arithmetic or other operations: they should be converted to a common domain first. The domain method `unify()` (page 2599) is used to find a domain that can represent all the elements of two given domains.

```python
>>> from sympy import ZZ, QQ, symbols
>>> x, y = symbols('x, y')
```

(continues on next page)
If a domain is a Ring (page 2601) then it might have an associated Field (page 2600) and vice versa. The get_field() (page 2594) and get_ring() (page 2594) methods will find or create the associated domain.

See also:

DomainElement (page 2599)
abstract base class for domain elements

construct_domain (page 2503)
construct a minimal domain for some expressions

abs(a)
Absolute value of a, implies __abs__.

add(a, b)
Sum of a and b, implies __add__.

alg_field_from_poly(poly, alias=None, root_index=-1)
Convenience method to construct an algebraic extension on a root of a polynomial, chosen by root index.

Parameters
poly : Poly (page 2453)
The polynomial whose root generates the extension.
alias : str, optional (default=None)
Symbol name for the generator of the extension. E.g. “alpha” or “theta”.
root_index : int, optional (default=-1)
Specifies which root of the polynomial is desired. The ordering is as defined by the `ComplexRootOf` (page 2507) class. The default of -1 selects the most natural choice in the common cases of quadratic and cyclotomic fields (the square root on the positive real or imaginary axis, resp. $e^{2\pi i/n}$).

**Examples**

```python
>>> from sympy import QQ, Poly
>>> from sympy.abc import x
>>> f = Poly(x**2 - 2)
>>> K = QQ.alg_field_from_poly(f)
>>> K.ext.minpoly == f
True
>>> g = Poly(8*x**3 - 6*x - 1)
>>> L = QQ.alg_field_from_poly(g, "alpha")
>>> L.ext.minpoly == g
True
>>> L.to_sympy(L([1, 1, 1]))
alpha**2 + alpha + 1
```

- `algebraic_field(*extension, alias=None)`
  Returns an algebraic field, i.e. $K(\alpha, \ldots)$.

- `almosteq(a, b, tolerance=None)`
  Check if a and b are almost equal.

- `characteristic()`
  Return the characteristic of this domain.

- `cofactors(a, b)`
  Returns GCD and cofactors of a and b.

- `convert(element, base=None)`
  Convert element to self.dtype.

- `convert_from(element, base)`
  Convert element to self.dtype given the base domain.

- `cyclotomic_field(n, ss=False, alias='zeta', gen=None, root_index=-1)`
  Convenience method to construct a cyclotomic field.

**Parameters**

- `n` : int
  Construct the nth cyclotomic field.

- `ss` : boolean, optional (default=False)
  If True, append n as a subscript on the alias string.

- `alias` : str, optional (default="zeta")
  Symbol name for the generator.

- `gen` : `Symbol` (page 1028), optional (default=None)
Desired variable for the cyclotomic polynomial that defines the field. If None, a dummy variable will be used.

**root_index**: int, optional (default=-1)

Specifies which root of the polynomial is desired. The ordering is as defined by the \texttt{ComplexRootOf} (page 2507) class. The default of -1 selects the root $e^{2\pi i/n}$.

### Examples

```python
>>> from sympy import QQ, latex
>>> K = QQ.cyclotomic_field(5)
>>> K.to_sympy(K([-1, 1]))
1 - zeta
>>> L = QQ.cyclotomic_field(7, True)
>>> a = L.to_sympy(L([-1, 1]))
>>> print(a)
1 - zeta7
>>> print(latex(a))
1 - \zeta_{7}
```

**\texttt{denom(a)}**

Returns denominator of a.

**\texttt{div(a, b)}**

Quotient and remainder for a and b. Analogue of \texttt{divmod(a, b)}

**Parameters**

- **a**: domain element
  
  The dividend

- **b**: domain element
  
  The divisor

**Returns**

- \((q, r)\): tuple of domain elements
  
  The quotient and remainder

**Raises**

- \texttt{ZeroDivisionError}: when the divisor is zero.

### Explanation

This is essentially the same as \texttt{divmod(a, b)} except that is more consistent when working over some \texttt{Field} (page 2600) domains such as \texttt{QQ} (page 2609). When working over an arbitrary \texttt{Domain} (page 2584) the \texttt{\texttt{div()}} (page 2589) method should be used instead of \texttt{divmod}.

The key invariant is that if \( q, r = K.\texttt{div(a, b)} \) then \( a = b*q + r \).

The result of \( K.\texttt{div(a, b)} \) is the same as the tuple \((K.\texttt{quo(a, b)}, K.\texttt{rem(a, b)})\) except that if both quotient and remainder are needed then it is more efficient to use \texttt{\texttt{div()}} (page 2589).
Examples

We can use K.div instead of divmod for floor division and remainder.

```python
from sympy import ZZ, QQ

 ZZ.div(ZZ(5), ZZ(2))
(2, 1)
```

If K is a Field (page 2600) then the division is always exact with a remainder of zero (page 2599).

```python
QQ.div(QQ(5), QQ(2))
(5/2, 0)
```

Notes

If gmpy is installed then the gmpy.mpq type will be used as the dtype (page 2590) for QQ (page 2609). The gmpy.mpq type defines divmod in a way that is undesirable so div() (page 2589) should be used instead of divmod.

```python
a = QQ(1)
b = QQ(3, 2)
a mpq(1,1)
b mpq(3,2)
divmod(a, b)
(mpz(0), mpq(1,1))
QQ.div(a, b)
(mpq(2,3), mpq(0,1))
```

Using // or % with QQ (page 2609) will lead to incorrect results so div() (page 2589) should be used instead.

See also:

quo (page 2596)
Analogue of a // b

rem (page 2597)
Analogue of a % b

exquo (page 2591)
Analogue of a / b

drop(*symbols)
Drop generators from this domain.

dtype: type | None = None
The type (class) of the elements of this Domain (page 2584):
Every domain has an associated **dtypes** ("datatype") which is the class of the associated domain elements.

**See also:**

*of_type* (page 2596)

**evalf**(*a*, *prec=None*, **options*)

Returns numerical approximation of *a*.

**exquo**(*a*, *b*)

Exact quotient of *a* and *b*. Analogue of *a / b*.

**Parameters**

*a*: domain element

The dividend

*b*: domain element

The divisor

**Returns**

*q*: domain element

The exact quotient

**Raises**

*ExactQuotientFailed*: if exact division is not possible.

*ZeroDivisionError*: when the divisor is zero.

**Explanation**

This is essentially the same as *a / b* except that an error will be raised if the division is inexact (if there is any remainder) and the result will always be a domain element. When working in a *Domain* (page 2584) that is not a *Field* (page 2600) (e.g. *ZZ* (page 2605) or *K[x]* (page 2627)) `exquo` should be used instead of `/`.

The key invariant is that if *q = K.exquo(a, b)* (and `exquo` does not raise an exception) then *a == b*q.
Examples

We can use K.exquo instead of / for exact division.

```python
>>> from sympy import ZZ
>>> ZZ.exquo(ZZ(4), ZZ(2))
2
>>> ZZ.exquo(ZZ(5), ZZ(2))
Traceback (most recent call last):
... ExactQuotientFailed: 2 does not divide 5 in ZZ
```

Over a Field (page 2600) such as QQ (page 2609), division (with nonzero divisor) is always exact so in that case / can be used instead of exquo() (page 2591).

```python
>>> from sympy import QQ
>>> QQ.exquo(QQ(5), QQ(2))
5/2
>>> QQ(5) / QQ(2)
5/2
```

Notes

Since the default dtype (page 2590) for ZZ (page 2605) is int (or mpz) division as a / b should not be used as it would give a float.

```python
>>> ZZ(4) / ZZ(2)
2.0
>>> ZZ(5) / ZZ(2)
2.5
```

Using / with ZZ (page 2605) will lead to incorrect results so exquo() (page 2591) should be used instead.

See also:

- quo (page 2596)  
  Analogue of a // b
- rem (page 2597)  
  Analogue of a % b
- div (page 2589)  
  Analogue of divmod(a, b)
- frac_field(*symbols, order=LexOrder())  
  Returns a fraction field, i.e. K(X).
- from_AlgebraicField(a, K0)  
  Convert an algebraic number to dtype.
- from_ComplexField(a, K0)  
  Convert a complex element to dtype.
from _ExpressionDomain \((a, K0)\)
Convert a EX object to dtype.

from _ExpressionRawDomain \((a, K0)\)
Convert a EX object to dtype.

from _FF \((a, K0)\)
Convert ModularInteger(int) to dtype.

from _FF_gmpy \((a, K0)\)
Convert ModularInteger(mpz) to dtype.

from _FF_python \((a, K0)\)
Convert ModularInteger(int) to dtype.

from _FractionField \((a, K0)\)
Convert a rational function to dtype.

from _GlobalPolynomialRing \((a, K0)\)
Convert a polynomial to dtype.

from _MonogenicFiniteExtension \((a, K0)\)
Convert an ExtensionElement to dtype.

from _PolynomialRing \((a, K0)\)
Convert a polynomial to dtype.

from _QQ_gmpy \((a, K0)\)
Convert a GMPY mpq object to dtype.

from _QQ_python \((a, K0)\)
Convert a Python Fraction object to dtype.

from _RealField \((a, K0)\)
Convert a real element object to dtype.

from _ZZ_gmpy \((a, K0)\)
Convert a GMPY mpz object to dtype.

from _ZZ_python \((a, K0)\)
Convert a Python int object to dtype.

from _sympy \((a)\)
Convert a SymPy expression to an element of this domain.

Parameters
expr: Expr
A normal SymPy expression of type Expr (page 999).

Returns
a: domain element
An element of this Domain (page 2584).
Explanation

See to_sympy() (page 2597) for explanation and examples.

See also:
to_sympy (page 2597), convert_from (page 2588)

gcd(a, b)
    Returns GCD of a and b.

gcdex(a, b)
    Extended GCD of a and b.

get_exact()
    Returns an exact domain associated with self.

get_field()
    Returns a field associated with self.

get_ring()
    Returns a ring associated with self.

half_gcdex(a, b)
    Half extended GCD of a and b.

has_assoc_Field = False
    Boolean flag indicating if the domain has an associated Field (page 2600).

    >>> from sympy import ZZ
    >>> ZZ.has_assoc_Field
    True
    >>> ZZ.get_field()
    QQ

See also:
is_Field (page 2594), get_field (page 2594)

has_assoc_Ring = False
    Boolean flag indicating if the domain has an associated Ring (page 2601).

    >>> from sympy import QQ
    >>> QQ.has_assoc_Ring
    True
    >>> QQ.get_ring()
    ZZ

See also:
is_Field (page 2594), get_ring (page 2594)

inject(*symbols)
    Inject generators into this domain.

invert(a, b)
    Returns inversion of a mod b, implies something.
is_Field = False
Boolean flag indicating if the domain is a Field (page 2600).

```python
>>> from sympy import ZZ, QQ
>>> ZZ.is_Field
False
>>> QQ.is_Field
True
```

See also:
is_PID (page 2595), is_Ring (page 2595), get_field (page 2594), has_assoc_Field (page 2594)

is_PID = False
Boolean flag indicating if the domain is a principal ideal domain.

```python
>>> from sympy import ZZ
>>> ZZ.has_assoc_Field
True
>>> ZZ.get_field()
QQ
```

See also:
is_Field (page 2594), get_field (page 2594)

is_Ring = False
Boolean flag indicating if the domain is a Ring (page 2601).

```python
>>> from sympy import ZZ
>>> ZZ.is_Ring
True
```

Basically every Domain (page 2584) represents a ring so this flag is not that useful.

See also:
is_PID (page 2595), is_Field (page 2594), get_ring (page 2594), has_assoc_Ring (page 2594)

is_negative(a)
Returns True if a is negative.

is_nonnegative(a)
Returns True if a is non-negative.

is_nonpositive(a)
Returns True if a is non-positive.

is_one(a)
Returns True if a is one.

is_positive(a)
Returns True if a is positive.

is_zero(a)
Returns True if a is zero.
\texttt{lcm}(a, b) \\
Returns LCM of \(a\) and \(b\).

\texttt{log}(a, b) \\
Returns b-base logarithm of \(a\).

\texttt{map}(\text{seq}) \\
Recursively apply self to all elements of \text{seq}.

\texttt{mul}(a, b) \\
Product of \(a\) and \(b\), implies \texttt{__mul__}.

\texttt{n}(a, \text{prec}={\text{None, **options}}) \\
Returns numerical approximation of \(a\).

\texttt{neg}(a) \\
Returns a negated, implies \texttt{__neg__}.

\texttt{numer}(a) \\
Returns numerator of \(a\).

\texttt{of\_type}(\text{element}) \\
Check if \(a\) is of type \texttt{dtype}.

\texttt{old\_frac\_field}(*\text{symbols}, **\text{kwargs}) \\
Returns a fraction field, i.e. \(K(X)\).

\texttt{old\_poly\_ring}(*\text{symbols}, **\text{kwargs}) \\
Returns a polynomial ring, i.e. \(K[X]\).

\texttt{one}: \texttt{Any} = \texttt{None} \\
The one element of the \texttt{Domain} (page 2584):

```python
>>> from sympy import QQ
>>> QQ.one
1
>>> QQ.of_type(QQ.one)
True
```

See also:

\texttt{of\_type} (page 2596), \texttt{zero} (page 2599)

\texttt{poly\_ring}(*\text{symbols, order=LexOrder()}) \\
Returns a polynomial ring, i.e. \(K[X]\).

\texttt{pos}(a) \\
Returns a positive, implies \texttt{__pos__}.

\texttt{pow}(a, b) \\
Raise \(a\) to power \(b\), implies \texttt{__pow__}.

\texttt{quo}(a, b) \\
Quotient of \(a\) and \(b\). Analogue of \(a \div b\).

\(K.quo(a, b)\) is equivalent to \(K.div(a, b)[0]\). See \texttt{div()} (page 2589) for more explanation.

See also:
rem (page 2597)
Analogue of a % b

div (page 2589)
Analogue of divmod(a, b)

exquo (page 2591)
Analogue of a / b

rem(a, b)
Modulo division of a and b. Analogue of a % b.
K.rem(a, b) is equivalent to K.div(a, b)[1]. See div() (page 2589) for more explanation.

See also:

quo (page 2596)
Analogue of a // b

div (page 2589)
Analogue of divmod(a, b)

exquo (page 2591)
Analogue of a / b

revert(a)
Returns a**(-1) if possible.

sqrt(a)
Returns square root of a.

sub(a, b)
Difference of a and b, implies __sub__.

to_sympy(a)
Convert domain element a to a SymPy expression (Expr).

Parameters
a: domain element
An element of this Domain (page 2584).

Returns
expr: Expr
A normal SymPy expression of type Expr (page 999).

Explanation
Convert a Domain (page 2584) element a to Expr (page 999). Most public SymPy functions work with objects of type Expr (page 999). The elements of a Domain (page 2584) have a different internal representation. It is not possible to mix domain elements with Expr (page 999) so each domain has to_sympy() (page 2597) and from_sympy() (page 2593) methods to convert its domain elements to and from Expr (page 999).
Examples

Construct an element of the $QQ$ (page 2609) domain and then convert it to $Expr$ (page 999).

```python
>>> from sympy import QQ, Expr
>>> q_domain = QQ(2)
>>> q_domain
2
>>> q_expr = QQ.to_sympy(q_domain)
>>> q_expr
2
```

Although the printed forms look similar these objects are not of the same type.

```python
>>> isinstance(q_domain, Expr)
False
>>> isinstance(q_expr, Expr)
True
```

Construct an element of $K[x]$ (page 2627) and convert to $Expr$ (page 999).

```python
>>> from sympy import Symbol
>>> x = Symbol('x')
>>> K = QQ[x]
>>> x_domain = K.gens[0]  # generator x as a domain element
>>> p_domain = x_domain**2/3 + 1
>>> p_domain
1/3*x**2 + 1
>>> p_expr = K.to_sympy(p_domain)
>>> p_expr
x**2/3 + 1
```

The $from_sympy()$ (page 2593) method is used for the opposite conversion from a normal SymPy expression to a domain element.

```python
>>> p_domain == p_expr
False
>>> K.from_sympy(p_expr) == p_domain
True
>>> K.to_sympy(p_domain) == p_expr
True
>>> K.from_sympy(K.tosympy(p_domain)) == p_domain
True
>>> K.to_sympy(K.fromsympy(p_expr)) == p_expr
True
```

The $from_sympy()$ (page 2593) method makes it easier to construct domain elements interactively.
from sympy import QQ

>>> QQ.of_type(QQ.zero)
True

See also:

of_type (page 2596), one (page 2596)
Examples

```python
>>> from sympy import ZZ, symbols
>>> x, y = symbols('x, y')
>>> K = ZZ[x,y]
>>> p = K(x)**2 + K(y)**2
>>> p
x**2 + y**2
>>> p.parent()
ZZ[x,y]
```

Notes

This is used by `convert()` (page 2588) to identify the domain associated with a domain element.

```python
class sympy.polys.domains.field.Field
    Represents a field domain.
    div(a, b)
        Division of a and b, implies __truediv__.
    exquo(a, b)
        Exact quotient of a and b, implies __truediv__.
    gcd(a, b)
        Returns GCD of a and b.
        This definition of GCD over fields allows to clear denominators in `primitive()`.
```
\texttt{lcm}(a, b)\\\quad \text{Returns LCM of } a \text{ and } b.

\begin{verbatim}
>>> from sympy.polys.domains import QQ
>>> from sympy import S, lcm

>>> QQ.lcm(QQ(2, 3), QQ(4, 9))
4/3
>>> lcm(S(2)/3, S(4)/9)
4/3
\end{verbatim}

\texttt{quo}(a, b)\\\quad \text{Quotient of } a \text{ and } b, \text{ implies } \_\text{truediv}._

\texttt{rem}(a, b)\\\quad \text{Remainder of } a \text{ and } b, \text{ implies nothing.}

\texttt{revert}(a)\\\quad \text{Returns } a**(-1) \text{ if possible.}

class sympy.polys.domains.ring.Ring\\\quad \text{Represents a ring domain.}

\texttt{denom}(a)\\\quad \text{Returns denominator of } a.

\texttt{div}(a, b)\\\quad \text{Division of } a \text{ and } b, \text{ implies } \_\text{divmod}._

\texttt{exquo}(a, b)\\\quad \text{Exact quotient of } a \text{ and } b, \text{ implies } \_\text{floordiv}._

\texttt{free_module}(rank)\\\quad \text{Generate a free module of rank } rank \text{ over self.}

\begin{verbatim}
>>> from sympy.abc import x
>>> from sympy import QQ
>>> QQ.old_poly_ring(x).free_module(2)
QQ[x]**2
\end{verbatim}

\texttt{get_ring}()\\\quad \text{Returns a ring associated with self.}

\texttt{ideal}(*gens)\\\quad \text{Generate an ideal of self.}

\begin{verbatim}
>>> from sympy.abc import x
>>> from sympy import QQ
>>> QQ.old_poly_ring(x).ideal(x**2)
<x**2>
\end{verbatim}

\texttt{invert}(a, b)\\\quad \text{Returns inversion of } a \text{ mod } b.

\texttt{numer}(a)\\\quad \text{Returns numerator of } a.
\texttt{quo}(a, b)

Quotient of \(a\) and \(b\), implies \texttt{\_floordiv\_}.

\texttt{quotient\_ring}(e)

Form a quotient ring of \texttt{self}.

Here \(e\) can be an ideal or an iterable.

\begin{verbatim}
>>> from sympy.abc import x
>>> from sympy import QQ
>>> QQ.old_poly_ring(x).quotient_ring(QQ.old_poly_ring(x).ideal(x**2))
QQ[x]/<x**2>
>>> QQ.old_poly_ring(x).quotient_ring([x**2])
QQ[x]/<x**2>
\end{verbatim}

The division operator has been overloaded for this:

\begin{verbatim}
>>> QQ.old_poly_ring(x)/[x**2]
QQ[x]/<x**2>
\end{verbatim}

\texttt{rem}(a, b)

Remainder of \(a\) and \(b\), implies \texttt{\_mod\_}.

\texttt{revert}(a)

Returns \(a**(-1)\) if possible.

\texttt{class} \hspace{1em} \texttt{sympy.polys.domains.simpledomain.SimpleDomain}

Base class for simple domains, e.g. \texttt{ZZ}, \texttt{QQ}.

\texttt{inject}(\ast \texttt{gens})

Inject generators into this domain.

\texttt{class} \hspace{1em} \texttt{sympy.polys.domains.compositedomain.CompositeDomain}

Base class for composite domains, e.g. \texttt{ZZ[x]}, \texttt{ZZ(X)}.

\texttt{drop}(\ast \texttt{symbols})

Drop generators from this domain.

\texttt{inject}(\ast \texttt{symbols})

Inject generators into this domain.

\texttt{GF}(p)

\texttt{class} \hspace{1em} \texttt{sympy.polys.domains.FiniteField}(\texttt{mod}, \texttt{symmetric=True})

Finite field of prime order \texttt{GF}(p) (page 2602)

A \texttt{GF}(p) (page 2602) domain represents a \texttt{finite field \ \mathbb{F}_p} of prime order as \texttt{Domain} (page 2584) in the domain system (see \texttt{Introducing the Domains of the poly module} (page 2557)).

A \texttt{Poly} (page 2453) created from an expression with integer coefficients will have the domain \texttt{ZZ} (page 2605). However, if the \texttt{modulus=p} option is given then the domain will be a finite field instead.
It is possible to factorise a polynomial over $GF(p)$ (page 2602) using the modulus argument to `factor()` (page 2447) or by specifying the domain explicitly. The domain can also be given as a string.

It is also possible to use $GF(p)$ (page 2602) with the `cancel()` (page 2451) and `gcd()` (page 2442) functions.

When using the domain directly $GF(p)$ (page 2602) can be used as a constructor to create instances which then support the operations $+,-,\ast,\div,/\,$
Notes

It is also possible to create a $GF(p)$ (page 2602) domain of non-prime order but the resulting ring is not a field: it is just the ring of the integers modulo $n$.

```python
>>> K = GF(9)
>>> z = K(3)
>>> z
3 mod 9
>>> z**2
0 mod 9
```

It would be good to have a proper implementation of prime power fields ($GF(p^{**n})$) but these are not yet implemented in SymPy.

```python
 characteristic()
        return the characteristic of this domain.

 from_FF(a, K0=None)
        Convert ModularInteger(int) to dtype.

 from_FF_gmpy(a, K0=None)
        Convert ModularInteger(mpz) to dtype.

 from_FF_python(a, K0=None)
        Convert ModularInteger(int) to dtype.

 from_QQ(a, K0=None)
        Convert Python's Fraction to dtype.

 from_QQ_gmpy(a, K0=None)
        Convert GMPY's mpq to dtype.

 from_QQ_python(a, K0=None)
        Convert Python's Fraction to dtype.

 from_RealField(a, K0)
        Convert mpmath's mpf to dtype.

 from_ZZ(a, K0=None)
        Convert Python's int to dtype.

 from_ZZ_gmpy(a, K0=None)
        Convert GMPY's mpz to dtype.

 from_ZZ_python(a, K0=None)
        Convert Python's int to dtype.
```
from_sympy(a)
Convert SymPy's Integer to SymPy's Integer.

get_field()
Returns a field associated with self.

to_sympy(a)
Convert a to a SymPy object.

class sympy.polys.domains.PythonFiniteField(mod, symmetric=True)
Finite field based on Python’s integers.

class sympy.polys.domains.GMPYFiniteField(mod, symmetric=True)
Finite field based on GMPY integers.

**ZZ**

The **ZZ** (page 2605) domain represents the integers $\mathbb{Z}$ as a Domain (page 2584) in the domain system (see *Introducing the Domains of the poly module* (page 2557)).

By default a *Poly* (page 2453) created from an expression with integer coefficients will have the domain **ZZ** (page 2605):

```python
>>> from sympy import Poly, Symbol
>>> x = Symbol('x')
>>> p = Poly(x**2 + 1)
>>> p
Poly(x**2 + 1, x, domain='ZZ')
>>> p.domain
ZZ
```

The corresponding field of fractions is the domain of the rationals **QQ** (page 2609). Conversely **ZZ** (page 2605) is the ring of integers of **QQ** (page 2609):

```python
>>> from sympy import ZZ, QQ
>>> ZZ.get_field()
QQ
>>> QQ.get_ring()
ZZ
```

When using the domain directly **ZZ** (page 2605) can be used as a constructor to create instances which then support the operations $+, -, *, **, //, %$ (true division $/$ should not be used with **ZZ** (page 2605) - see the *exquo()* (page 2591) domain method):

```python
>>> x = ZZ(5)
>>> y = ZZ(2)
>>> x // y  # floor division
2
>>> x % y   # modulo division (remainder)
1
```

The *gcd()* (page 2594) method can be used to compute the gcd of any two elements:

```python
>>> ZZ.gcd(ZZ(10), ZZ(2))
2
```
There are two implementations of \texttt{ZZ} (page 2605) in SymPy. If \texttt{gmpy} or \texttt{gmpy2} is installed then \texttt{ZZ} (page 2605) will be implemented by \texttt{GMPYIntegerRing} (page 2608) and the elements will be instances of the \texttt{gmpy.mpz} type. Otherwise if \texttt{gmpy} and \texttt{gmpy2} are not installed then \texttt{ZZ} (page 2605) will be implemented by \texttt{PythonIntegerRing} (page 2608) which uses Python’s standard builtin int type. With larger integers \texttt{gmpy} can be more efficient so it is preferred when available.

\textbf{class} \texttt{sympy.polys.domains.IntegerRing}

The domain \texttt{ZZ} representing the integers \(\mathbb{Z}\).

The \texttt{IntegerRing} (page 2606) class represents the ring of integers as a \texttt{Domain} (page 2584) in the domain system. \texttt{IntegerRing} (page 2606) is a super class of \texttt{PythonIntegerRing} (page 2608) and \texttt{GMPYIntegerRing} (page 2608) one of which will be the implementation for \texttt{ZZ} (page 2605) depending on whether or not \texttt{gmpy} or \texttt{gmpy2} is installed.

\textbf{See also:}

\texttt{Domain} (page 2584)

\textbf{algebraic_field}(*\texttt{extension}, \texttt{alias}=\texttt{None})

Returns an algebraic field, i.e. \(\mathbb{Q}(\alpha,\ldots)\).

\textbf{Parameters}

*\texttt{extension} : One or more \texttt{Expr} (page 999).

Generators of the extension. These should be expressions that are algebraic over \(\mathbb{Q}\).

\texttt{alias} : \texttt{str}, \texttt{Symbol} (page 1028), None, optional (default=\texttt{None})

If provided, this will be used as the alias symbol for the primitive element of the returned \texttt{AlgebraicField} (page 2619).

\textbf{Returns}

\texttt{AlgebraicField} (page 2619)

A \texttt{Domain} (page 2584) representing the algebraic field extension.

\textbf{Examples}

```python
>>> from sympy import ZZ, sqrt
>>> ZZ.algebraic_field(sqrt(2))
QQ<sqrt(2)>
```

\textbf{factorial}(a)

Compute factorial of \(a\).

\textbf{from} \texttt{AlgebraicField}(a, KO)

Convert a \texttt{ANP} (page 2650) object to \texttt{ZZ} (page 2605).

See \texttt{convert()} (page 2588).

\textbf{from} \texttt{FF}(a, KO)

Convert \texttt{ModularInteger(int)} to GMPY’s mpz.

\textbf{from} \texttt{FF_gmpy}(a, KO)

Convert \texttt{ModularInteger(mpz)} to GMPY’s mpz.
from_FF_python(a, K0)
    Convert ModularInteger(int) to GMPY’s mpz.

from_QQ(a, K0)
    Convert Python’s Fraction to GMPY’s mpz.

from_QQ_gmpy(a, K0)
    Convert GMPY mpq to GMPY’s mpz.

from_QQ_python(a, K0)
    Convert Python’s Fraction to GMPY’s mpz.

from_RealField(a, K0)
    Convert mpmath’s mpf to GMPY’s mpz.

from_ZZ(a, K0)
    Convert Python’s int to GMPY’s mpz.

from_ZZ_gmpy(a, K0)
    Convert GMPY’s mpz to GMPY’s mpz.

from_ZZ_python(a, K0)
    Convert Python’s int to GMPY’s mpz.

from_sympy(a)
    Convert SymPy’s Integer to dtype.

gcd(a, b)
    Compute GCD of a and b.

gcdex(a, b)
    Compute extended GCD of a and b.

get_field()
    Return the associated field of fractions QQ (page 2609)
      
      **Returns**
      QQ (page 2609):
          The associated field of fractions QQ (page 2609), a Domain
          (page 2584) representing the rational numbers Q.

Examples

>>> from sympy import ZZ
>>> ZZ.get_field()
QQ

lcm(a, b)
    Compute LCM of a and b.

log(a, b)
    Logarithm of a to the base b.

    **Parameters**
    a: number
    b: number
Returns

$\lfloor \log(a, b) \rfloor$

Floor of the logarithm of $a$ to the base $b$

Examples

```python
>>> from sympy import ZZ
>>> ZZ.log(ZZ(8), ZZ(2))
3
>>> ZZ.log(ZZ(9), ZZ(2))
3
```

Notes

This function uses `math.log` which is based on float so it will fail for large integer arguments.

`sqrt(a)`

Compute square root of $a$.

`to_sympy(a)`

Convert $a$ to a SymPy object.

`class sympy.polys.domains.PythonIntegerRing`

Integer ring based on Python's int type.

This will be used as `ZZ` (page 2605) if gmpy and gmpy2 are not installed. Elements are instances of the standard Python int type.

`class sympy.polys.domains.GMPYIntegerRing`

Integer ring based on GMPY's mpz type.

This will be the implementation of `ZZ` (page 2605) if gmpy or gmpy2 is installed. Elements will be of type `gmpy.mpz`.

`factorial(a)`

Compute factorial of $a$.

`from_FF_gmpy(a, K0)`

Convert ModularInteger(mpz) to GMPY's mpz.

`from_FF_python(a, K0)`

Convert ModularInteger(int) to GMPY's mpz.

`from_QQ(a, K0)`

Convert Python's Fraction to GMPY's mpz.

`from_QQ_gmpy(a, K0)`

Convert GMPY mpq to GMPY's mpz.

`from_QQ_python(a, K0)`

Convert Python's Fraction to GMPY's mpz.
from_RealField\((a, K0)\)

Convert mpmath's \texttt{mpf} to GMPY's \texttt{mpz}.

\texttt{from\_ZZ\_gmpy}\((a, K0)\)

Convert GMPY's \texttt{mpz} to GMPY's \texttt{mpz}.

\texttt{from\_ZZ\_python}\((a, K0)\)

Convert Python's \texttt{int} to GMPY's \texttt{mpz}.

\texttt{from\_sympy}\((a)\)

Convert SymPy's \texttt{Integer} to \texttt{dtype}.

\texttt{gcd}\((a, b)\)

Compute GCD of \(a\) and \(b\).

\texttt{gcdex}\((a, b)\)

Compute extended GCD of \(a\) and \(b\).

\texttt{lcm}\((a, b)\)

Compute LCM of \(a\) and \(b\).

\texttt{sqrt}\((a)\)

Compute square root of \(a\).

\texttt{to\_sympy}\((a)\)

Convert \(a\) to a SymPy object.

**QQ**

The \texttt{QQ} (page 2609) domain represents the rationals \(\mathbb{Q}\) as a \texttt{Domain} (page 2584) in the domain system (see \textit{Introducing the Domains of the \texttt{poly} module} (page 2557)).

By default a \texttt{Poly} (page 2453) created from an expression with rational coefficients will have the domain \texttt{QQ} (page 2609):

```python
>>> from sympy import Poly, Symbol
>>> x = Symbol('x')
>>> p = Poly(x**2 + x/2)
>>> p
Poly(x**2 + 1/2*x, x, domain='QQ')
>>> p.domain
QQ
```

The corresponding ring of integers is the \texttt{Domain} (page 2584) of the integers \texttt{ZZ} (page 2605). Conversely \texttt{QQ} (page 2609) is the field of fractions of \texttt{ZZ} (page 2605):

```python
>>> from sympy import ZZ, QQ
>>> QQ.get_ring()
ZZ
>>> ZZ.get_field()
QQ
```

When using the domain directly \texttt{QQ} (page 2609) can be used as a constructor to create instances which then support the operations \(+,\,-,\,\ast,\,**,\,\div\) (true division \texttt{\div} is always possible for nonzero divisors in \texttt{QQ} (page 2609)):
There are two implementations of `QQ` (page 2609) in SymPy. If gmpy or gmpy2 is installed then `QQ` (page 2609) will be implemented by `GMPYRationalField` (page 2611) and the elements will be instances of the `gmpy.mpq` type. Otherwise if gmpy and gmpy2 are not installed then `QQ` (page 2609) will be implemented by `PythonRationalField` (page 2611) which is a pure Python class as part of sympy. The gmpy implementation is preferred because it is significantly faster.

class sympy.polys.domains.RationalField
    Abstract base class for the domain `QQ` (page 2609).
    The `RationalField` (page 2610) class represents the field of rational numbers \( \mathbb{Q} \) as a `Domain` (page 2584) in the domain system. `RationalField` (page 2610) is a superclass of `PythonRationalField` (page 2611) and `GMPYRationalField` (page 2611) one of which will be the implementation for `QQ` (page 2609) depending on whether either of gmpy or gmpy2 is installed or not.

See also:
`Domain` (page 2584)

`algebraic_field(*extension, alias=None)`
    Returns an algebraic field, i.e. \( \mathbb{Q}(\alpha, \ldots) \).
    Parameters
    *extension : One or more `Expr` (page 999)
        Generators of the extension. These should be expressions that are algebraic over \( \mathbb{Q} \).
    alias : str, `Symbol` (page 1028), None, optional (default=None)
        If provided, this will be used as the alias symbol for the primitive element of the returned `AlgebraicField` (page 2619).
    Returns
    `AlgebraicField` (page 2619)
    A `Domain` (page 2584) representing the algebraic field extension.

Examples

```python
>>> from sympy import QQ, sqrt
>>> QQ.algebraic_field(sqrt(2))
QQ<sqrt(2)>
```

denom(a)
    Returns denominator of a.

div(a, b)
    Division of a and b, implies `__truediv__`. 
exquo(a, b)
    Exact quotient of a and b, implies __truediv__.

from_AlgebraicField(a, K0)
    Convert a ANP (page 2650) object to QQ (page 2609).
    See convert() (page 2588)

from_GaussianRationalField(a, K0)
    Convert a GaussianElement object to dtype.

from_QQ(a, K0)
    Convert a Python Fraction object to dtype.

from_QQ_gmpy(a, K0)
    Convert a GMPY mpq object to dtype.

from_QQ_python(a, K0)
    Convert a Python Fraction object to dtype.

from_RealField(a, K0)
    Convert a mpmath mpf object to dtype.

from_ZZ(a, K0)
    Convert a Python int object to dtype.

from_ZZ_gmpy(a, K0)
    Convert a GMPY mpz object to dtype.

from_ZZ_python(a, K0)
    Convert a Python int object to dtype.

from_sympy(a)
    Convert SymPy’s Integer to dtype.

go_get_ring()
    Returns ring associated with self.

umer(a)
    Returns numerator of a.

quo(a, b)
    Quotient of a and b, implies __truediv__.

rem(a, b)
    Remainder of a and b, implies nothing.

to_sympy(a)
    Convert a to a SymPy object.

class sympy.polys.domains.PythonRationalField
    Rational field based on MPQ (page 2613).
    This will be used as QQ (page 2609) if gmpy and gmpy2 are not installed. Elements are instances of MPQ (page 2613).
class sympy.polys.domains.GMPYRationalField
    Rational field based on GMPY’s mpq type.
    This will be the implementation of QQ (page 2609) if gmpy or gmpy2 is installed. Elements will be of type gmpy.mpq.

denom(a)
    Returns denominator of a.

div(a, b)
    Division of a and b, implies __truediv__.
exquo(a, b)
    Exact quotient of a and b, implies __truediv__.
factorial(a)
    Returns factorial of a.

from_GaussianRationalField(a, K0)
    Convert a GaussianElement object to dtype.

from_QQ_gmpy(a, K0)
    Convert a GMPY mpq object to dtype.

from_QQ_python(a, K0)
    Convert a Python Fraction object to dtype.

from_RealField(a, K0)
    Convert a mpmath mpf object to dtype.

from_ZZ_gmpy(a, K0)
    Convert a GMPY mpz object to dtype.

from_ZZ_python(a, K0)
    Convert a Python int object to dtype.

from_sympy(a)
    Convert SymPy’s Integer to dtype.

get_ring()
    Returns ring associated with self.

numer(a)
    Returns numerator of a.

quo(a, b)
    Quotient of a and b, implies __truediv__.
rem(a, b)
    Remainder of a and b, implies nothing.

to_sympy(a)
    Convert a to a SymPy object.

class sympy.external.pythonmpq.PythonMPQ(numerator, denominator=None)
    Rational number implementation that is intended to be compatible with gmpy2’s mpq.
    Also slightly faster than fractions.Fraction.
    PythonMPQ should be treated as immutable although no effort is made to prevent mutation (since that might slow down calculations).
MPQ

The MPQ type is either PythonMPQ (page 2612) or otherwise the mpq type from gmpy2.

Gaussian domains

The Gaussian domains $\mathbb{Z}_I$ (page 2614) and $\mathbb{Q}_I$ (page 2616) share common superclasses GaussianElement (page 2613) for the domain elements and GaussianDomain (page 2613) for the domains themselves.

```python
class sympy.polys.domains.gaussiandomains.GaussianDomain
    Base class for Gaussian domains.
    
    from_AlgebraicField(a, K0)
        Convert an element from $\mathbb{Z}_I$ or $\mathbb{Q}_I$ to self.dtype.
    from_QQ(a, K0)
        Convert a GMPY mpq to self.dtype.
    from_QQ_gmpy(a, K0)
        Convert a GMPY mpq to self.dtype.
    from_QQ_python(a, K0)
        Convert a QQ_python element to self.dtype.
    from_ZZ(a, K0)
        Convert a ZZ_python element to self.dtype.
    from_ZZ_gmpy(a, K0)
        Convert a GMPY mpz to self.dtype.
    from_ZZ_python(a, K0)
        Convert a ZZ_python element to self.dtype.
    from_sympy(a)
        Convert a to a SymPy object.
    inject(*gens)
        Inject generators into this domain.
    is_negative(element)
        Returns False for any GaussianElement.
    is_nonnegative(element)
        Returns False for any GaussianElement.
    is_nonpositive(element)
        Returns False for any GaussianElement.
    is_positive(element)
        Returns False for any GaussianElement.
    to_sympy(a)
        Convert a to a SymPy object.
```
class sympy.polys.domains.gaussiandomains.GaussianElement(x, y=0)
   Base class for elements of Gaussian type domains.

classmethod new(x, y)
   Create a new GaussianElement of the same domain.

parent()
   The domain that this is an element of (ZZ_I or QQ_I)

quadrant()
   Return quadrant index 0-3.
   0 is included in quadrant 0.

ZZ_I

class sympy.polys.domains.gaussiandomains.GaussianIntegerRing
   Ring of Gaussian integers ZZ_I

The ZZ_I (page 2614) domain represents the Gaussian integers \( \mathbb{Z}[i] \) as a Domain (page 2584) in the domain system (see Introducing the Domains of the poly module (page 2557)).

By default a Poly (page 2453) created from an expression with coefficients that are combinations of integers and \( \sqrt{-1} \) will have the domain ZZ_I (page 2614).

>>> from sympy import Poly, Symbol, I
>>> x = Symbol('x')
>>> p = Poly(x**2 + I)
>>> p
Poly(x**2 + I, x, domain='ZZ_I')
>>> p.domain
ZZ_I

The ZZ_I (page 2614) domain can be used to factorise polynomials that are reducible over the Gaussian integers.

>>> from sympy import factor
>>> factor(x**2 + 1)
\(x^2 + 1\)
>>> factor(x**2 + 1, domain='ZZ_I')
(\(x - \text{i}\))*(\(x + \text{i}\))

The corresponding field of fractions is the domain of the Gaussian rationals QQ_I (page 2616). Conversely ZZ_I (page 2614) is the ring of integers of QQ_I (page 2616).

>>> from sympy import ZZ_I, QQ_I
>>> ZZ_I.get_field()
QQ_I
>>> QQ_I.get_ring()
ZZ_I

When using the domain directly ZZ_I (page 2614) can be used as a constructor.
>>> ZZ_I(3, 4)
(3 + 4*I)
>>> ZZ_I(5)
(5 + 0*I)

The domain elements of \(ZZ_I\) (page 2614) are instances of \(GaussianInteger\) (page 2616) which support the rings operations +, -, *, **.

>>> z1 = ZZ_I(5, 1)
>>> z2 = ZZ_I(2, 3)
>>> z1
(5 + 1*I)
>>> z2
(2 + 3*I)
>>> z1 + z2
(7 + 4*I)
>>> z1 * z2
(7 + 17*I)
>>> z1 ** 2
(24 + 10*I)

Both floor (\(/\)) and modulo (\(\%\)) division work with \(GaussianInteger\) (page 2616) (see the \texttt{div()} (page 2589) method).

>>> z3, z4 = ZZ_I(5), ZZ_I(1, 3)
>>> z3 // z4  # floor division
(1 + -1*I)
>>> z3 % z4  # modulo division (remainder)
(1 + -2*I)
>>> (z3//z4)*z4 + z3%z4 == z3
True

True division (/) in \(ZZ_I\) (page 2614) gives an element of \(QQ_I\) (page 2616). The \texttt{exquo()} (page 2591) method can be used to divide in \(ZZ_I\) (page 2614) when exact division is possible.

>>> z1 / z2
(1 + -1*I)
>>> ZZ_I.exquo(z1, z2)
(1 + -1*I)
>>> z3 / z4
(1/2 + -3/2*I)
>>> ZZ_I.exquo(z3, z4)
Traceback (most recent call last):
...
ExactQuotientFailed: (1 + 3*I) does not divide (5 + 0*I) in ZZ_I

The \texttt{gcd()} (page 2594) method can be used to compute the \texttt{gcd} of any two elements.

>>> ZZ_I.gcd(ZZ_I(10), ZZ_I(2))
(2 + 0*I)
>>> ZZ_I.gcd(ZZ_I(5), ZZ_I(2, 1))
(2 + 1*I)
SymPy Documentation, Release 1.12.1

dtype

    alias of GaussianInteger (page 2616)

from_GaussianIntegerRing(a, K0)
    Convert a ZZ_I element to ZZ_I.

from_GaussianRationalField(a, K0)
    Convert a QQ_I element to ZZ_I.

gcd(a, b)
    Greatest common divisor of a and b over ZZ_I.

get_field()
    Returns a field associated with self.

get_ring()
    Returns a ring associated with self.

lcm(a, b)
    Least common multiple of a and b over ZZ_I.

normalize(d, *args)
    Return first quadrant element associated with d.
    Also multiply the other arguments by the same power of i.

class sympy.polys.domains.gaussiandomains.GaussianInteger(x, y=0)
    Gaussian integer: domain element for ZZ_I (page 2614)

    >>> from sympy import ZZ_I
    >>> z = ZZ_I(2, 3)
    >>> z
    (2 + 3*I)
    >>> type(z)
    <class 'sympy.polys.domains.gaussiandomains.GaussianInteger'>

QQ_I

class sympy.polys.domains.gaussiandomains.GaussianRationalField
    Field of Gaussian rationals QQ_I

    The QQ_I (page 2616) domain represents the Gaussian rationals \( \mathbb{Q}(i) \) as a Domain (page 2584) in the domain system (see Introducing the Domains of the poly module (page 2557)).

    By default a Poly (page 2453) created from an expression with coefficients that are combinations of rationals and I (\( \sqrt{-1} \)) will have the domain QQ_I (page 2616).

    >>> from sympy import Poly, Symbol, I
    >>> x = Symbol('x')
    >>> p = Poly(x**2 + I/2)
    >>> p
    Poly(x**2 + I/2, x, domain='QQ_I')
    >>> p.domain
    QQ_I
The polys option `gaussian=True` can be used to specify that the domain should be \( \text{QQ}\_I \) (page 2616) even if the coefficients do not contain I or are all integers.

```python
>>> Poly(x**2)
Poly(x**2, x, domain='ZZ')
>>> Poly(x**2 + I)
Poly(x**2 + I, x, domain='ZZ\_I')
>>> Poly(x**2/2)
Poly(1/2*x**2, x, domain='QQ')
>>> Poly(x**2, gaussian=True)
Poly(x**2, x, domain='QQ\_I')
>>> Poly(x**2 + I, gaussian=True)
Poly(x**2 + I, x, domain='QQ\_I')
>>> Poly(x**2/2, gaussian=True)
Poly(1/2*x**2, x, domain='QQ\_I')
```

The \( \text{QQ}\_I \) (page 2616) domain can be used to factorise polynomials that are reducible over the Gaussian rationals.

```python
>>> from sympy import factor, QQ_I
>>> factor(x**2/4 + 1)
(x**2 + 4)/4
>>> factor(x**2/4 + 1, domain='QQ\_I')
(x - 2*I)*(x + 2*I)/4
>>> factor(x**2/4 + 1, domain=QQ_I)
(x - 2*I)*(x + 2*I)/4
```

It is also possible to specify the \( \text{QQ}\_I \) (page 2616) domain explicitly with polys functions like `apart()` (page 2522).

```python
>>> from sympy import apart
>>> apart(1/(1 + x**2))
1/(x**2 + 1)
>>> apart(1/(1 + x**2), domain=QQ_I)
I/(2*(x + I)) - I/(2*(x - I))
```

The corresponding ring of integers is the domain of the Gaussian integers \( \text{ZZ}\_I \) (page 2614). Conversely \( \text{QQ}\_I \) (page 2616) is the field of fractions of \( \text{ZZ}\_I \) (page 2614).

```python
>>> from sympy import ZZ_I, QQ_I, QQ
>>> ZZ_I.get_field()
QQ_I
>>> QQ_I.get_ring()
ZZ_I
```

When using the domain directly \( \text{QQ}\_I \) (page 2616) can be used as a constructor.

```python
>>> QQ_I(3, 4)
(3 + 4*I)
>>> QQ_I(5)
(5 + 0*I)
>>> QQ_I(QQ(2, 3), QQ(4, 5))
(2/3 + 4/5*I)
```

The domain elements of \( \text{QQ}\_I \) (page 2616) are instances of `GaussianRational`
which support the field operations +, -, *, **, /.

```python
>>> z1 = QQ_I(5, 1)
>>> z2 = QQ_I(2, QQ(1, 2))
>>> z1
(5 + 1*I)
>>> z2
(2 + 1/2*I)
>>> z1 + z2
(7 + 3/2*I)
>>> z1 * z2
(19/2 + 9/2*I)
>>> z2 ** 2
(15/4 + 2*I)
```

True division (/) in `QQ_I` (page 2616) gives an element of `QQ_I` (page 2616) and is always exact.

```python
>>> z1 / z2
(42/17 + -2/17*I)
>>> QQ_I.exquo(z1, z2)
(42/17 + -2/17*I)
>>> z1 == (z1/z2)*z2
True
```

Both floor (//) and modulo (%) division can be used with `GaussianRational` (page 2619) (see `div()` (page 2589)) but division is always exact so there is no remainder.

```python
>>> z1 // z2
(42/17 + -2/17*I)
>>> z1 % z2
(0 + 0*I)
>>> QQ_I.div(z1, z2)
((42/17 + -2/17*I), (0 + 0*I))
>>> (z1//z2)*z2 + z1%z2 == z1
True
```

**as_AlgebraicField()**
Get equivalent domain as an `AlgebraicField`.

**denom(a)**
Get the denominator of a.

**dtype**
alias of `GaussianRational` (page 2619)

**from_GaussianIntegerRing(a, K0)**
Convert a ZZ_I element to QQ_I.

**from_GaussianRationalField(a, K0)**
Convert a QQ_I element to QQ_I.

**get_field()**
Returns a field associated with self.
get_ring()

Returns a ring associated with self.

numer(a)

Get the numerator of a.

class sympy.polys.domains.gaussiandomains.GaussianRational(x, y=0)

Gaussian rational: domain element for \( QQ_I \) (page 2616)

```
>>> from sympy import QQ_I, QQ
>>> z = QQ_I(QQ(2, 3), QQ(4, 5))
>>> z
(2/3 + 4/5*I)
>>> type(z)
<class 'sympy.polys.domains.gaussiandomains.GaussianRational'>
```

QQ<a>

class sympy.polys.domains.AlgebraicField(dom, *ext, alias=None)

Algebraic number field \( QQ<a> \) (page 2619)

A \( QQ<a> \) (page 2619) domain represents an algebraic number field \( \mathbb{Q}(a) \) as a Domain (page 2584) in the domain system (see Introducing the Domains of the poly module (page 2557)).

A Poly (page 2453) created from an expression involving algebraic numbers will treat the algebraic numbers as generators if the generators argument is not specified.

```
>>> from sympy import Poly, Symbol, sqrt
>>> x = Symbol('x')
>>> Poly(x**2 + sqrt(2))
Poly(x**2 + (sqrt(2)), x, sqrt(2), domain='ZZ')
```

That is a multivariate polynomial with \( \sqrt{2} \) treated as one of the generators (variables). If the generators are explicitly specified then \( \sqrt{2} \) will be considered to be a coefficient but by default the EX (page 2630) domain is used. To make a Poly (page 2453) with a \( QQ<a> \) (page 2619) domain the argument extension=True can be given.

```
>>> Poly(x**2 + sqrt(2), x)
Poly(x**2 + sqrt(2), x, domain='EX')
>>> Poly(x**2 + sqrt(2), x, extension=True)
Poly(x**2 + sqrt(2), x, domain='QQ<sqrt(2)>')
```

A generator of the algebraic field extension can also be specified explicitly which is particularly useful if the coefficients are all rational but an extension field is needed (e.g. to factor the polynomial).

```
>>> Poly(x**2 + 1)
Poly(x**2 + 1, x, domain='ZZ')
>>> Poly(x**2 + 1, extension=sqrt(2))
Poly(x**2 + 1, x, domain='QQ<sqrt(2)>')
```

It is possible to factorise a polynomial over a \( QQ<a> \) (page 2619) domain using the extension argument to \texttt{factor()} (page 2447) or by specifying the domain explicitly.
>>> from sympy import factor, QQ
>>> factor(x**2 - 2)
x**2 - 2
>>> factor(x**2 - 2, extension=sqrt(2))
(x - sqrt(2))*(x + sqrt(2))
>>> factor(x**2 - 2, domain='QQ<sqrt(2)>')
(x - sqrt(2))*(x + sqrt(2))
>>> factor(x**2 - 2, domain=QQ.algebraic_field(sqrt(2)))
(x - sqrt(2))*(x + sqrt(2))

The extension=True argument can be used but will only create an extension that contains the coefficients which is usually not enough to factorise the polynomial.

>>> p = x**3 + sqrt(2)*x**2 - 2*x - 2*sqrt(2)
>>> factor(p)  # treats sqrt(2) as a symbol
(x + sqrt(2))*(x**2 - 2)
>>> factor(p, extension=True)  # all rational coefficients
x**2 - 2

It is also possible to use QQ<a> (page 2619) with the cancel() (page 2451) and gcd() (page 2442) functions.

>>> from sympy import cancel, gcd
>>> cancel((x**2 - 2)/(x - sqrt(2)))
(x**2 - 2)/(x - sqrt(2))
>>> cancel((x**2 - 2)/(x - sqrt(2)), extension=sqrt(2))
x + sqrt(2)
>>> gcd(x**2 - 2, x - sqrt(2))
1
>>> gcd(x**2 - 2, x - sqrt(2), extension=sqrt(2))
x - sqrt(2)

When using the domain directly QQ<a> (page 2619) can be used as a constructor to create instances which then support the operations +,-,*,**,/. The algebraic_field() (page 2588) method is used to construct a particular QQ<a> (page 2619) domain. The from_sympy() (page 2593) method can be used to create domain elements from normal SymPy expressions.

>>> K = QQ.algebraic_field(sqrt(2))
>>> K
QQ<sqrt(2)>
>>> xk = K.from_sympy(3 + 4*sqrt(2))
>>> xk
ANP([4, 3], [1, 0, -2], QQ)

Elements of QQ<a> (page 2619) are instances of ANP (page 2650) which have limited printing support. The raw display shows the internal representation of the element as the list [4, 3] representing the coefficients of 1 and sqrt(2) for this element in the form a * sqrt(2) + b * 1 where a and b are elements of QQ (page 2609). The minimal polynomial for the generator (x**2 - 2) is also shown in the DUP representation (page 2559) as the list [1, 0, -2]. We can use to_sympy() (page 2597) to get a better printed form for the elements and to see the results of operations.
Any expression representing an algebraic number can be used to generate a \texttt{QQ<\textit{a}>} (page 2619) domain provided its \textit{minimal polynomial} can be computed. The function \texttt{minpoly()} (page 2795) function is used for this.

It is also possible to make an algebraic field from multiple extension elements.

Multiple extension elements are always combined together to make a single \textit{primitive element}. In the case of \texttt{[sqrt(2), sqrt(3)]} the primitive element chosen is \texttt{sqrt(2) + sqrt(3)} which is why the domain displays as \texttt{QQ<sqrt(2) + sqrt(3)>}. The minimal polynomial for the primitive element is computed using the \texttt{primitive_element()} (page 2796) function.

The extension elements that generate the domain can be accessed from the do-
main using the `ext` (page 2623) and `orig_ext` (page 2626) attributes as instances of `AlgebraicNumber` (page 1039). The minimal polynomial for the primitive element as a `DMP` (page 2643) instance is available as `mod` (page 2625).

```python
>>> K = QQ.algebraic_field(sqrt(2), sqrt(3))
>>> K
QQ<sqrt(2) + sqrt(3)>
>>> K.ext
sqrt(2) + sqrt(3)
>>> K.orig_ext
(sqrt(2), sqrt(3))
>>> K.mod
DMP([1, 0, -10, 0, 1], QQ, None)
```

The discriminant of the field can be obtained from the `discriminant()` (page 2623) method, and an integral basis from the `integral_basis()` (page 2624) method. The latter returns a list of `ANP` (page 2650) instances by default, but can be made to return instances of `Expr` (page 999) or `AlgebraicNumber` (page 1039) by passing a `fmt` argument. The maximal order, or ring of integers, of the field can also be obtained from the `maximal_order()` (page 2625) method, as a `Submodule` (page 2810).

```python
>>> zeta5 = exp(2*I*pi/5)
>>> K = QQ.algebraic_field(zeta5)
>>> K
QQ<exp(2*I*pi/5)>
>>> K.discriminant()
125
>>> K = QQ.algebraic_field(sqrt(5))
>>> K
QQ<sqrt(5)>
>>> K.integral_basis(fmt='sympy')
[1, 1/2 + sqrt(5)/2]
>>> K.maximal_order()
Submodule([2, 0], [1, 1])/2
```

The factorization of a rational prime into prime ideals of the field is computed by the `primes_above()` (page 2626) method, which returns a list of `PrimeIdeal` (page 2788) instances.

```python
>>> zeta7 = exp(2*I*pi/7)
>>> K = QQ.algebraic_field(zeta7)
>>> K
QQ<exp(2*I*pi/7)>
>>> K.primes_above(11)
[(11, _x**3 + 5*_x**2 + 4*_x - 1), (11, _x**3 - 4*_x**2 - 5*_x - 1)]
```

The Galois group of the Galois closure of the field can be computed (when the minimal polynomial of the field is of sufficiently small degree).

```python
>>> K.galois_group(by_name=True)[0]
S6TransitiveSubgroups.C6
```
Notes

It is not currently possible to generate an algebraic extension over any domain other than \( \mathbb{Q} \) (page 2609). Ideally it would be possible to generate extensions like \( \mathbb{Q}(x)(\sqrt{x^2 - 2}) \). This is equivalent to the quotient ring \( \mathbb{Q}(x)[y]/(y^2 - x^2 + 2) \) and there are two implementations of this kind of quotient ring/extension in the QuotientRing (page 2632) and MonogenicFiniteExtension (page 2555) classes. Each of those implementations needs some work to make them fully usable though.

\[
\text{algebraic_field}(\text{extension}, \text{alias}=\text{None})
\]

Returns an algebraic field, i.e. \( \mathbb{Q}(\alpha, \ldots) \).

\[
\text{denom}(a)
\]

Returns denominator of \( a \).

\[
\text{discriminant}()
\]

Get the discriminant of the field.

\[
\text{dtype}
\]

alias of ANP (page 2650)

\[
\text{ext}
\]

Primitive element used for the extension.

```python
>>> from sympy import QQ, sqrt
>>> K = QQ.algebraic_field(sqrt(2), sqrt(3))
>>> K.ext
sqrt(2) + sqrt(3)
```

\[
\text{from_AlgebraicField}(a, K0)
\]

Convert AlgebraicField element ‘a’ to another AlgebraicField

\[
\text{from_GaussianIntegerRing}(a, K0)
\]

Convert a GaussianInteger element ‘a’ to dtype.

\[
\text{from_GaussianRationalField}(a, K0)
\]

Convert a GaussianRational element ‘a’ to dtype.

\[
\text{from_QQ}(a, K0)
\]

Convert a Python Fraction object to dtype.

\[
\text{from_QQ_gmpy}(a, K0)
\]

Convert a GMPY mpq object to dtype.

\[
\text{from_QQ_python}(a, K0)
\]

Convert a Python Fraction object to dtype.

\[
\text{from_RealField}(a, K0)
\]

Convert a mpmath mpf object to dtype.

\[
\text{from_ZZ}(a, K0)
\]

Convert a Python int object to dtype.

\[
\text{from_ZZ_gmpy}(a, K0)
\]

Convert a GMPY mpz object to dtype.
from ZZ_python(a, K0)
    Convert a Python int object to dtype.

from sympy(a)
    Convert SymPy's expression to dtype.

galois_group(by_name=False, max_tries=30, randomize=False)
    Compute the Galois group of the Galois closure of this field.

**Examples**

If the field is Galois, the order of the group will equal the degree of the field:

```python
>>> from sympy import QQ
>>> from sympy.abc import x
>>> k = QQ.alg_field_from_poly(x**4 + 1)
>>> G, _ = k.galois_group()
>>> G.order()
4
```

If the field is not Galois, then its Galois closure is a proper extension, and the order of the Galois group will be greater than the degree of the field:

```python
>>> k = QQ.alg_field_from_poly(x**4 - 2)
>>> G, _ = k.galois_group()
>>> G.order()
8
```

**See also:**

*sympy.polys.numberfields.galoisgroups.galois_group* (page 2792)

get_ring()
    Returns a ring associated with self.

integral_basis(fmt=\text{None})
    Get an integral basis for the field.

**Parameters**

fmt : str, None, optional (default=None)
    If None, return a list of *ANP* (page 2650) instances. If "sympy", convert each element of the list to an *Expr* (page 999), using self.to_sympy(). If "alg", convert each element of the list to an *AlgebraicNumber* (page 1039), using self.to_alg_num().
Examples

```python
>>> from sympy import QQ, AlgebraicNumber, sqrt
>>> alpha = AlgebraicNumber(sqrt(5), alias='alpha')
>>> k = QQ.algebraic_field(alpha)
>>> B0 = k.integral_basis()
>>> B1 = k.integral_basis(fmt='sympy')
>>> B2 = k.integral_basis(fmt='alg')
>>> print(B0[1])
ANP([mpq(1,2), mpq(1,2)], [mpq(1,1), mpq(0,1), mpq(-5,1)], QQ)
>>> print(B1[1])
1/2 + alpha/2
>>> print(B2[1])
alpha/2 + 1/2
```

In the last two cases we get legible expressions, which print somewhat differently because of the different types involved:

```python
>>> print(type(B1[1]))
<class 'sympy.core.add.Add'>
>>> print(type(B2[1]))
<class 'sympy.core.numbers.AlgebraicNumber'>
```

See also:

- `to_sympy` (page 2626), `to_alg_num` (page 2626), `maximal_order` (page 2625)
- `is_negative(a)`
  Returns True if a is negative.
- `is_nonnegative(a)`
  Returns True if a is non-negative.
- `is_nonpositive(a)`
  Returns True if a is non-positive.
- `is_positive(a)`
  Returns True if a is positive.
- `maximal_order()`
  Compute the maximal order, or ring of integers, of the field.

  Returns
  - `Submodule` (page 2810).

  See also:
  - `integral_basis` (page 2624)

- `mod`
  Minimal polynomial for the primitive element of the extension.

```python
>>> from sympy import QQ, sqrt
>>> K = QQ.algebraic_field(sqrt(2))
>>> K.mod
DMP([1, 0, -2], QQ, None)
```
**SymPy Documentation, Release 1.12.1**

*numer(a)*

Returns numerator of a.

*orig_ext*

Original elements given to generate the extension.

```python
>>> from sympy import QQ, sqrt
>>> K = QQ.algebraic_field(sqrt(2), sqrt(3))
>>> K.orig_ext
(sqrt(2), sqrt(3))
```

*primes_above(p)*

Compute the prime ideals lying above a given rational prime p.

*to_alg_num(a)*

Convert a of dtype to an `AlgebraicNumber` (page 1039).

*to_sympy(a)*

Convert a of dtype to a SymPy object.

**RR**

*class sympy.polys.domains.RealField(prec=53, dps=None, tol=None)*

Real numbers up to the given precision.

*almosteq(a, b, tolerance=None)*

Check if a and b are almost equal.

*from_sympy(expr)*

Convert SymPy’s number to dtype.

*gcd(a, b)*

Returns GCD of a and b.

*get_exact()*

Returns an exact domain associated with self.

*get_ring()*

Returns a ring associated with self.

*lcm(a, b)*

Returns LCM of a and b.

*to_rational(element, limit=True)*

Convert a real number to rational number.

*to_sympy(element)*

Convert element to SymPy number.

*class sympy.polys.domains.mpelements.RealElement(val=(0, 0, 0, 0), **kwargs)*

An element of a real domain.
class sympy.polys.domains.ComplexField(prec=53, dps=None, tol=None)
    Complex numbers up to the given precision.

almosteq(a, b, tolerance=None)
    Check if a and b are almost equal.

from_sympy(expr)
    Convert SymPy's number to dtype.

gcd(a, b)
    Returns GCD of a and b.

gcd(a, b)
    Returns an exact domain associated with self.

gcd(a, b)
    Returns a ring associated with self.

is_negative(element)
    Returns False for any ComplexElement.

is_nonnegative(element)
    Returns False for any ComplexElement.

is_nonpositive(element)
    Returns False for any ComplexElement.

is_positive(element)
    Returns False for any ComplexElement.

lcm(a, b)
    Returns LCM of a and b.

to_sympy(element)
    Convert element to SymPy number.

class sympy.polys.domains.mpelements.ComplexElement(real=0, imag=0)
    An element of a complex domain.

K[x]

class sympy.polys.domains.PolynomialRing(domain_or_ring, symbols=None, order=None)
    A class for representing multivariate polynomial rings.

factorial(a)
    Returns factorial of a.

from_AlgebraicField(a, K0)
    Convert an algebraic number to dtype.

from_ComplexField(a, K0)
    Convert a mpmath mpf object to dtype.
from \texttt{FractionField}(a, K0)
    Convert a rational function to \texttt{dtype}.

from \texttt{GaussianIntegerRing}(a, K0)
    Convert a \texttt{GaussianInteger} object to \texttt{dtype}.

from \texttt{GaussianRationalField}(a, K0)
    Convert a \texttt{GaussianRational} object to \texttt{dtype}.

from \texttt{GlobalPolynomialRing}(a, K0)
    Convert from old poly ring to \texttt{dtype}.

from \texttt{PolynomialRing}(a, K0)
    Convert a polynomial to \texttt{dtype}.

from \texttt{QQ}(a, K0)
    Convert a Python \texttt{Fraction} object to \texttt{dtype}.

from \texttt{QQ\_gmpy}(a, K0)
    Convert a GMPY \texttt{mpq} object to \texttt{dtype}.

from \texttt{QQ\_python}(a, K0)
    Convert a Python \texttt{Fraction} object to \texttt{dtype}.

from \texttt{RealField}(a, K0)
    Convert a \texttt{mpmath} \texttt{mpf} object to \texttt{dtype}.

from \texttt{ZZ}(a, K0)
    Convert a Python \texttt{int} object to \texttt{dtype}.

from \texttt{ZZ\_gmpy}(a, K0)
    Convert a GMPY \texttt{mpz} object to \texttt{dtype}.

from \texttt{ZZ\_python}(a, K0)
    Convert a Python \texttt{int} object to \texttt{dtype}.

from \texttt{sympy}(a)
    Convert SymPy's expression to \texttt{dtype}.

\texttt{gcd}(a, b)
    Returns GCD of \texttt{a} and \texttt{b}.

\texttt{gcdex}(a, b)
    Extended GCD of \texttt{a} and \texttt{b}.

\texttt{get\_field()}
    Returns a field associated with \texttt{self}.

\texttt{is\_negative}(a)
    Returns True if \texttt{LC(a)} is negative.

\texttt{is\_nonnegative}(a)
    Returns True if \texttt{LC(a)} is non-negative.

\texttt{is\_nonpositive}(a)
    Returns True if \texttt{LC(a)} is non-positive.
**is_positive(a)**

Returns True if $LC(a)$ is positive.

**is_unit(a)**

Returns True if $a$ is a unit of self

**lcm(a, b)**

Returns LCM of $a$ and $b$.

**to_sympy(a)**

Convert $a$ to a SymPy object.

---

**K(x)**

```python
class sympy.polys.domains.FractionField(domain_or_field, symbols=None, order=None):
```

A class for representing multivariate rational function fields.

**denom(a)**

Returns denominator of $a$.

**factorial(a)**

Returns factorial of $a$.

**from_AlgebraicField(a, K0)**

Convert an algebraic number to dtype.

**from_ComplexField(a, K0)**

Convert a mpmath mpf object to dtype.

**from_FractionField(a, K0)**

Convert a rational function to dtype.

**from_GaussianIntegerRing(a, K0)**

Convert a GaussianInteger object to dtype.

**from_GaussianRationalField(a, K0)**

Convert a GaussianRational object to dtype.

**from_PolynomialRing(a, K0)**

Convert a polynomial to dtype.

**from QQ(a, K0)**

Convert a Python Fraction object to dtype.

**from QQ_gmpy(a, K0)**

Convert a GMPY mpq object to dtype.

**from QQ_python(a, K0)**

Convert a Python Fraction object to dtype.

**from_RealField(a, K0)**

Convert a mpmath mpf object to dtype.

**from_ZZ(a, K0)**

Convert a Python int object to dtype.
from ZZ_gmpy(a, K0)
    Convert a GMPY mpz object to dtype.
from ZZ_python(a, K0)
    Convert a Python int object to dtype.
from sympy(a)
    Convert SymPy's expression to dtype.
get_ring()
    Returns a field associated with self.
is_negative(a)
    Returns True if LC(a) is negative.
is_nonnegative(a)
    Returns True if LC(a) is non-negative.
is_nonpositive(a)
    Returns True if LC(a) is non-positive.
is_positive(a)
    Returns True if LC(a) is positive.
numer(a)
    Returns numerator of a.
to_sympy(a)
    Convert a to a SymPy object.

EX

class sympy.polys.domains.ExpressionDomain
    A class for arbitrary expressions.
class Expression(ex)
    An arbitrary expression.
denom(a)
    Returns denominator of a.
dtype
    alias of Expression (page 2631)
from ExpressionDomain(a, K0)
    Convert a EX object to dtype.
from FractionField(a, K0)
    Convert a DMF object to dtype.
from GaussianIntegerRing(a, K0)
    Convert a GaussianRational object to dtype.
from GaussianRationalField(a, K0)
    Convert a GaussianRational object to dtype.
from PolynomialRing($a, K0$)
    Convert a DMP object to dtype.
from QQ($a, K0$)
    Convert a Python Fraction object to dtype.
from QQ_gmpy($a, K0$)
    Convert a GMPY mpq object to dtype.
from QQ_python($a, K0$)
    Convert a Python Fraction object to dtype.
from RealField($a, K0$)
    Convert a mpmath mpf object to dtype.
from ZZ($a, K0$)
    Convert a Python int object to dtype.
from ZZ_gmpy($a, K0$)
    Convert a GMPY mpz object to dtype.
from ZZ_python($a, K0$)
    Convert a Python int object to dtype.
from sympy($a$)
    Convert SymPy's expression to dtype.

get_field()
    Returns a field associated with self.
get_ring()
    Returns a ring associated with self.

is_negative($a$)
    Returns True if $a$ is negative.
is_nonnegative($a$)
    Returns True if $a$ is non-negative.
is_nonpositive($a$)
    Returns True if $a$ is non-positive.
is_positive($a$)
    Returns True if $a$ is positive.

numer($a$)
    Returns numerator of $a$.
to_sympy($a$)
    Convert $a$ to a SymPy object.

class ExpressionDomain.Expression(ex)
    An arbitrary expression.
Quotient ring

class sympy.polys.domains.quotientring.QuotientRing(ring, ideal)
Class representing (commutative) quotient rings.

You should not usually instantiate this by hand, instead use the constructor from the base ring in the construction.

```python
>>> from sympy.abc import x
>>> from sympy import QQ
>>> I = QQ.old_poly_ring(x).ideal(x**3 + 1)
>>> QQ.old_poly_ring(x).quotient_ring(I)
QQ[x]/<x**3 + 1>
```

Shorter versions are possible:

```python
>>> QQ.old_poly_ring(x)/I
QQ[x]/<x**3 + 1>
```

```python
>>> QQ.old_poly_ring(x)/[x**3 + 1]
QQ[x]/<x**3 + 1>
```

Attributes:
- ring - the base ring
- base_ideal - the ideal used to form the quotient

Sparse polynomials

Sparse polynomials are represented as dictionaries.

sympy.polys.rings.ring(symbols, domain, order=LexOrder())
Construct a polynomial ring returning (ring, x_1, ..., x_n).

Parameters
- symbols : str
  Symbol/Expr or sequence of str, Symbol/Expr (non-empty)
- domain : Domain (page 2584) or coercible
- order : MonomialOrder (page 2507) or coercible, optional, defaults to lex

Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.orderings import lex

>>> R, x, y, z = ring("x,y,z", ZZ, lex)
>>> R
Polynomial ring in x, y, z over ZZ with lex order
(continues on next page)```
sympy.polys.rings.xring(symbols, domain, order=LexOrder())
Construct a polynomial ring returning (ring, (x_1, ..., x_n)).

Parameters
symbols : str
Symbol/Expr or sequence of str, Symbol/Expr (non-empty)
domain : Domain (page 2584) or coercible
order : MonomialOrder (page 2507) or coercible, optional, defaults to lex

Examples

```python
>>> from sympy.polys.rings import xring
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.orderings import lex

>>> R, (x, y, z) = xring("x,y,z", ZZ, lex)
>>> R
Polynomial ring in x, y, z over ZZ with lex order
>>> x + y + z
x + y + z
>>> type(_)
<class 'sympy.polys.rings.PolyElement'>
```

sympy.polys.rings.vring(symbols, domain, order=LexOrder())
Construct a polynomial ring and inject x_1, ..., x_n into the global namespace.

Parameters
symbols : str
Symbol/Expr or sequence of str, Symbol/Expr (non-empty)
domain : Domain (page 2584) or coercible
order : MonomialOrder (page 2507) or coercible, optional, defaults to lex

Examples

```python
>>> from sympy.polys.rings import vring
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.orderings import lex

>>> vring("x,y,z", ZZ, lex)
Polynomial ring in x, y, z over ZZ with lex order
>>> x + y + z  # noqa:
```

(continues on next page)
sympy.polys.rings.sring(exprs, *symbols, **options)
Construct a ring deriving generators and domain from options and input expressions.

Parameters
- **exprs**: `Expr` (page 999) or sequence of `Expr` (page 999) (sympifiable)
- **symbols**: sequence of `Symbol` (page 1028)/`Expr` (page 999)
- **options**: keyword arguments understood by `Options` (page 2724)

Examples

```python
>>> from sympy import sring, symbols

>>> x, y, z = symbols("x,y,z")
>>> R, f = sring(x + 2*y + 3*z)
>>> R
Polynomial ring in x, y, z over ZZ with lex order
>>> f
x + 2*y + 3*z
>>> type(_)
<class 'sympy.polys.rings.PolyElement'>
```

class sympy.polys.rings.PolyRing(symbols, domain, order=LexOrder())
Multivariate distributed polynomial ring.

**add**(*objs)
Add a sequence of polynomials or containers of polynomials.

Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ

>>> R, x = ring("x", ZZ)
>>> R.add([ x**2 + 2*i + 3 for i in range(4) ])
4*x**2 + 24
>>> _.factor_list()
(4, [(x**2 + 6, 1)])
```

**add_gens**(symbols)
Add the elements of symbols as generators to self

**compose**(other)
Add the generators of other to self
**drop(***gens**)**
Remove specified generators from this ring.

**drop_to_ground(***gens**)**
Remove specified generators from the ring and inject them into its domain.

**index(***gen*)**
Compute index of gen in self.gens.

**monomial_basis(***i*)**
Return the ith-basis element.

**mul(***objs*)**
Multiply a sequence of polynomials or containers of polynomials.

### Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ

>>> R, x = ring("x", ZZ)
>>> R.mul([ x**2 + 2*i + 3 for i in range(4) ])  
x**8 + 24*x**6 + 206*x**4 + 744*x**2 + 945
>>> _.factor_list()
(1, [(x**2 + 3, 1), (x**2 + 5, 1), (x**2 + 7, 1), (x**2 + 9, 1)])
```

**symmetric_poly(***n*)**
Return the elementary symmetric polynomial of degree \( n \) over this ring’s generators.

### class sympy.polys.rings.PolyElement
Element of multivariate distributed polynomial ring.

**almosteq(***p2*, tolerance=None)**
Approximate equality test for polynomials.

**cancel(***g*)**
Cancel common factors in a rational function \( f/g \).

### Examples

```python
>>> from sympy.polys import ring, ZZ

>>> R, x,y = ring("x,y", ZZ)

>>> (2*x**2 - 2).cancel(x**2 - 2*x + 1)
(2*x + 2, x - 1)
```

**coeff(***element*)**
Returns the coefficient that stands next to the given monomial.

### Parameters
- **element**: PolyElement (with is_monomial = True) or 1
Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ

>>> _, x, y, z = ring("x,y,z", ZZ)
>>> f = 3*x**2*y - x*y*z + 7*z**3 + 23

>>> f.coeff(x**2*y)
3
>>> f.coeff(x*y)
0
>>> f.coeff(1)
23
```

`coeffs(order=None)`

Ordered list of polynomial coefficients.

**Parameters**

- `order`: `MonomialOrder` (page 2507) or coercible, optional

**Examples**

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.orderings import lex, grlex

>>> _, x, y = ring("x, y", ZZ, lex)
>>> f = x*y**7 + 2*x**2*y**3

>>> f.coeffs()
[2, 1]
>>> f.coeffs(grlex)
[1, 2]
```

`const()`

Returns the constant coefficient.

`content()`

Returns GCD of polynomial's coefficients.

`copy()`

Return a copy of polynomial self.

Polynomials are mutable; if one is interested in preserving a polynomial, and one plans to use inplace operations, one can copy the polynomial. This method makes a shallow copy.
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.rings import ring

>>> R, x, y = ring('x, y', ZZ)
>>> p = (x + y)**2
>>> p1 = p.copy()
>>> p2 = p
>>> p[R.zero_monom] = 3
>>> p
x**2 + 2*x*y + y**2 + 3
>>> p1
x**2 + 2*x*y + y**2
>>> p2
x**2 + 2*x*y + y**2 + 3
```

degree(x=None)
The leading degree in \(x\) or the main variable.
Note that the degree of 0 is negative infinity (the SymPy object -oo).
degrees()A tuple containing leading degrees in all variables.
Note that the degree of 0 is negative infinity (the SymPy object -oo)
diff(x)Computes partial derivative in \(x\).

Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ

>>> _, x, y = ring("x,y", ZZ)
>>> p = x + x**2*y**3
>>> p.diff(x)
2*x*y**3 + 1
```

div(fv)Division algorithm, see [CLO] p64.

fv array of polynomials

return \(qv, r\) such that self = \(\sum(fv[i]*qv[i]) + r\)
All polynomials are required not to be Laurent polynomials.
Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ

>>> _, x, y = ring('x, y', ZZ)
>>> f = x**3
>>> f0 = x - y**2
>>> f1 = x - y
>>> qv, r = f.div((f0, f1))
>>> qv[0]
x**2 + x*y**2 + y**4
>>> qv[1]
0
>>> r
y**6
```

`imul_num(c)`
multiply inplace the polynomial p by an element in the coefficient ring, provided p is not one of the generators; else multiply not inplace

Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ

>>> _, x, y = ring('x, y', ZZ)
>>> p = x + y**2
>>> p1 = p.imul_num(3)
>>> p1
3*x + 3*y**2
>>> p1 is p
True
>>> p = x
>>> p1 = p.imul_num(3)
>>> p1
3*x
>>> p1 is p
False
```

`itercoeffs()`
Iterator over coefficients of a polynomial.

`itermonoms()`
Iterator over monomials of a polynomial.

`iterterms()`
Iterator over terms of a polynomial.

`leading_expv()`
Leading monomial tuple according to the monomial ordering.
Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ

>>> _, x, y, z = ring('x, y, z', ZZ)
>>> p = x**4 + x**3*y + x**2*z**2 + z**7
>>> p.leading_expv()
(4, 0, 0)
```

`leading_monom()`
Leading monomial as a polynomial element.

Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ

>>> _, x, y = ring('x, y', ZZ)
>>> (3*x*y + y**2).leading_monom()
x*y
```

`leading_term()`
Leading term as a polynomial element.

Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ

>>> _, x, y = ring('x, y', ZZ)
>>> (3*x*y + y**2).leading_term()
3*x*y
```

`listcoeffs()`
Unordered list of polynomial coefficients.

`listmonoms()`
Unordered list of polynomial monomials.

`listterms()`
Unordered list of polynomial terms.

`monic()`
Divides all coefficients by the leading coefficient.

`monoms(order=None)`
Ordered list of polynomial monomials.

Parameters

`order : MonomialOrder` (page 2507) or coercible, optional
Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.orderings import lex, grlex

>>> _, x, y = ring("x, y", ZZ, lex)
>>> f = x*y**7 + 2*x**2*y**3

>>> f.monoms()
[(2, 3), (1, 7)]
>>> f.monoms(grlex)
[(1, 7), (2, 3)]
```

**primitive()**

Returns content and a primitive polynomial.

**square()**

Square of a polynomial

Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ

>>> _, x, y = ring('x, y', ZZ)
>>> p = x + y**2
>>> p.square()
```

**strip_zero()**

Eliminate monomials with zero coefficient.

**symmetrize()**

Rewrite `self` in terms of elementary symmetric polynomials.

Returns

Triple `(p, r, m)`

- `p` is a `PolyElement` (page 2635) that represents our attempt to express `self` as a function of elementary symmetric polynomials. Each variable in `p` stands for one of the elementary symmetric polynomials. The correspondence is given by `m`.
- `r` is the remainder.
- `m` is a list of pairs, giving the mapping from variables in `p` to elementary symmetric polynomials.

The triple satisfies the equation `p.compose(m) + r == self`. If the remainder `r` is zero, `self` is symmetric. If it is nonzero, we were not able to represent `self` as symmetric.
Explanation

If this `PolyElement` (page 2635) belongs to a ring of \(n\) variables, we can try to write it as a function of the elementary symmetric polynomials on \(n\) variables. We compute a symmetric part, and a remainder for any part we were not able to symmetrize.

Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> f = x**2 + y**2
>>> f.symmetrize()
(x**2 - 2*y, 0, [(x, x + y), (y, x*y)])

>>> f = x**2 - y**2
>>> f.symmetrize()
(x**2 - 2*y, -2*y**2, [(x, x + y), (y, x*y)])
```

See also:

`sympy.polys.polyfuncts.symmetrize` (page 2501)

References

[R717]

tail_degree \((x=None)\)
The tail degree in \(x\) or the main variable.

Note that the degree of 0 is negative infinity (the SymPy object -oo)

tail_degrees()
A tuple containing tail degrees in all variables.

Note that the degree of 0 is negative infinity (the SymPy object -oo)

terms \((order=None)\)
Ordered list of polynomial terms.

Parameters

order : `MonomialOrder` (page 2507) or coercible, optional
Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.orderings import lex, grlex

>>> _, x, y = ring("x, y", ZZ, lex)

>>> f = x*y**7 + 2*x**2*y**3

>>> f.terms()
[((2, 3), 2), ((1, 7), 1)]

>>> f.terms(grlex)
[((1, 7), 1), ((2, 3), 2)]
```

Sparse rational functions

Sparse polynomials are represented as dictionaries.

```python
sympy.polys.fields.field(symbols, domain, order=LexOrder())

Construct new rational function field returning (field, x1, ... , xn).

sympy.polys.fields.xfield(symbols, domain, order=LexOrder())

Construct new rational function field returning (field, (x1, ..., xn)).

sympy.polys.fields.vfield(symbols, domain, order=LexOrder())

Construct new rational function field and inject generators into global namespace.

sympy.polys.fields.sfield(exprs, *symbols, **options)

Construct a field deriving generators and domain from options and input expressions.
```

Parameters

- **exprs**: `py:class:Expr` or sequence of `Expr` (page 999) (sympifiable)
- **symbols**: sequence of `Symbol` (page 1028)/`Expr` (page 999)
- **options**: keyword arguments understood by `Options` (page 2724)

Examples

```python
>>> from sympy import exp, log, symbols, sfield

>>> x = symbols("x")

>>> K, f = sfield((x*log(x) + 4*x**2)*exp(1/x + log(x)/3)/x**2)

Rational function field in x, exp(1/x), log(x), x**(1/3) over ZZ with
lex order

>>> f
(4*x**2*(exp(1/x)) + x*(exp(1/x))*(log(x)))/((x**(1/3))**5)
```

```python
class sympy.polys.fields.FracField(symbols, domain, order=LexOrder())

Multivariate distributed rational function field.
```
class sympy.polys.fields.FracElement(numer, denom=None)
Element of multivariate distributed rational function field.

diff(x)
Computes partial derivative in x.

Examples

```python
>>> from sympy.polys.fields import field
>>> from sympy.polys.domains import ZZ

>>> _, x, y, z = field("x,y,z", ZZ)
>>> ((x**2 + y)/(z + 1)).diff(x)
2*x/(z + 1)
```

**Dense polynomials**

class sympy.polys.polyclasses.DMP(rep, dom, lev=None, ring=None)
Dense Multivariate Polynomials over $K$.

LC()
Returns the leading coefficient of $f$.

TC()
Returns the trailing coefficient of $f$.

abs()
Make all coefficients in $f$ positive.

add(g)
Add two multivariate polynomials $f$ and $g$.

add_ground(c)
Add an element of the ground domain to $f$.

all_coeffs()
Returns all coefficients from $f$.

all_monoms()
Returns all monomials from $f$.

all_terms()
Returns all terms from a $f$.

cancel(g, include=True)
Cancel common factors in a rational function $f/g$.

cauych_lower_bound()
Computes the Cauchy lower bound on the nonzero roots of $f$.

cauych_upper_bound()
Computes the Cauchy upper bound on the roots of $f$. 

5.8. Topics
clear_denoms()
    Clear denominators, but keep the ground domain.
coeffs(order=None)
    Returns all non-zero coefficients from f in lex order.
cofactors(g)
    Returns GCD of f and g and their cofactors.
compose(g)
    Computes functional composition of f and g.
content()
    Returns GCD of polynomial coefficients.
convert(dom)
    Convert the ground domain of f.
count_complex_roots(inf=None, sup=None)
    Return the number of complex roots of f in [inf, sup].
count_real_roots(inf=None, sup=None)
    Return the number of real roots of f in [inf, sup].
decompose()
    Computes functional decomposition of f.
deflate()
    Reduce degree of f by mapping $x_i^m$ to $y_i$.
degree(j=0)
    Returns the leading degree of f in x_j.
degree_list()
    Returns a list of degrees of f.
diff(m=1, j=0)
    Computes the m-th order derivative of f in x_j.
discriminant()
    Computes discriminant of f.
div(g)
    Polynomial division with remainder of f and g.
eject(dom, front=False)
    Eject selected generators into the ground domain.
eval(a, j=0)
    Evaluates f at the given point a in x_j.
exclude()
    Remove useless generators from f.
    Returns the removed generators and the new excluded f.
Examples

```python
>>> from sympy.polys.polyclasses import DMP
>>> from sympy.polys.domains import ZZ

>>> DMP([[ZZ(1)]], [[ZZ(1)], [ZZ(2)]], ZZ).exclude()
([2], DMP([[1], [1, 2]], ZZ, None))
```

**exquo**

Computes polynomial exact quotient of \( f \) and \( g \).

**exquo_ground**

Exact quotient of \( f \) by an element of the ground domain.

**factor_list**

Returns a list of irreducible factors of \( f \).

**factor_list_include**

Returns a list of irreducible factors of \( f \).

**classmethod from_dict**

Construct and instance of \( \text{cls} \) from a dict representation.

**classmethod from_list**

Create an instance of \( \text{cls} \) given a list of native coefficients.

**classmethod from_sympy_list**

Create an instance of \( \text{cls} \) given a list of SymPy coefficients.

**gcd**

Returns polynomial GCD of \( f \) and \( g \).

**gcdex**

Extended Euclidean algorithm, if univariate.

**gff_list**

Computes greatest factorial factorization of \( f \).

**half_gcdex**

Half extended Euclidean algorithm, if univariate.

**homogeneous_order**

Returns the homogeneous order of \( f \).

**homogenize**

Return homogeneous polynomial of \( f \)

**inject**

Inject ground domain generators into \( f \).

**integrate**

Computes the \( m \)-th order indefinite integral of \( f \) in \( x_j \).

**intervals**

Compute isolating intervals for roots of \( f \).
invert(g)
    Invert f modulo g, if possible.

property is_cyclotomic
    Returns True if f is a cyclotomic polynomial.

property is_ground
    Returns True if f is an element of the ground domain.

property is_homogeneous
    Returns True if f is a homogeneous polynomial.

property is_irreducible
    Returns True if f has no factors over its domain.

property is_linear
    Returns True if f is linear in all its variables.

property is_monic
    Returns True if the leading coefficient of f is one.

property is_monomial
    Returns True if f is zero or has only one term.

property is_one
    Returns True if f is a unit polynomial.

property is_primitive
    Returns True if the GCD of the coefficients of f is one.

property is_quadratic
    Returns True if f is quadratic in all its variables.

property is_sqf
    Returns True if f is a square-free polynomial.

property is_zero
    Returns True if f is a zero polynomial.

l1_norm()
    Returns l1 norm of f.

l2_norm_squared()
    Return squared l2 norm of f.

lcm(g)
    Returns polynomial LCM of f and g.

lift()
    Convert algebraic coefficients to rationals.

max_norm()
    Returns maximum norm of f.

mignotte_sep_bound_squared()
    Computes the squared Mignotte bound on root separations of f.
monic()
    Divides all coefficients by LC(f).

monoms(order=None)
    Returns all non-zero monomials from f in lex order.

mul(g)
    Multiply two multivariate polynomials f and g.

mul_ground(c)
    Multiply f by a an element of the ground domain.

neg()
    Negate all coefficients in f.

norm()
    Computes Norm(f).

nth(*N)
    Returns the n-th coefficient of f.

pdiv(g)
    Polynomial pseudo-division of f and g.

per(rep, dom=None, kill=False, ring=None)
    Create a DMP out of the given representation.

permute(P)
    Returns a polynomial in K[x_P(1),...,x_P(n)].

Examples

```python
>>> from sympy.polys.polycases import DMP
>>> from sympy.polys.domains import ZZ

>>> DMP([[[ZZ(2)],[ZZ(1), ZZ(0)]],[[]]], ZZ).permute([1, 0, 2])
DMP([[[2], []], [[1, 0], []]], ZZ, None)

>>> DMP([[[ZZ(2)],[ZZ(1), ZZ(0)]],[[]]], ZZ).permute([1, 2, 0])
DMP([[[1], []], [[2, 0], []]], ZZ, None)
```

pexquo(g)
    Polynomial exact pseudo-quotient of f and g.

pow(n)
    Raise f to a non-negative power n.

pquo(g)
    Polynomial pseudo-quotient of f and g.

prem(g)
    Polynomial pseudo-remainder of f and g.

primitive()
    Returns content and a primitive form of f.
quo\( (g) \)
Computes polynomial quotient of \( f \) and \( g \).

quo\_ground\( (c) \)
Quotient of \( f \) by an element of the ground domain.

refine\_root\( (s, t, eps=None, steps=None, fast=False) \)
Refine an isolating interval to the given precision.
\( \text{eps} \) should be a rational number.

rem\( (g) \)
Computes polynomial remainder of \( f \) and \( g \).

resultant\( (g, includePRS=False) \)
Computes resultant of \( f \) and \( g \) via PRS.

revert\( (n) \)
Compute \( f**(-1) \mod x**n \).

shift\( (a) \)
Efficiently compute Taylor shift \( f(x + a) \).

slice\( (m, n, j=0) \)
Take a continuous subsequence of terms of \( f \).

sqf\_list\( (all=False) \)
Returns a list of square-free factors of \( f \).

sqf\_list\_include\( (all=False) \)
Returns a list of square-free factors of \( f \).

sqf\_norm\() \)
Computes square-free norm of \( f \).

sqf\_part() \)
Computes square-free part of \( f \).

sqr() \)
Square a multivariate polynomial \( f \).

sturm() \)
Computes the Sturm sequence of \( f \).

sub\( (g) \)
Subtract two multivariate polynomials \( f \) and \( g \).

sub\_ground\( (c) \)
Subtract an element of the ground domain from \( f \).

subresultants\( (g) \)
Computes subresultant PRS sequence of \( f \) and \( g \).

terms\( (order=\text{None}) \)
Returns all non-zero terms from \( f \) in lex order.

terms\_gcd() \)
Remove GCD of terms from the polynomial \( f \).
to_dict(zero=False)
    Convert f to a dict representation with native coefficients.

to_exact()
    Make the ground domain exact.

to_field()
    Make the ground domain a field.

to_list()
    Convert f to a list representation with native coefficients.

to_ring()
    Make the ground domain a ring.

to_sympy_dict(zero=False)
    Convert f to a dict representation with SymPy coefficients.

to_sympy_list()
    Convert f to a list representation with SymPy coefficients.

to_tuple()
    Convert f to a tuple representation with native coefficients.
    This is needed for hashing.

total_degree()
    Returns the total degree of f.

transform(p, q)
    Evaluate functional transformation q**n * f(p/q).

trunc(p)
    Reduce f modulo a constant p.

unify(g)
    Unify representations of two multivariate polynomials.

class sympy.polys.polyclasses.DMF(rep, dom, lev=None, ring=None)
    Dense Multivariate Fractions over K.

add(g)
    Add two multivariate fractions f and g.

cancel()
    Remove common factors from f.num and f.den.

denom()
    Returns the denominator of f.

exquo(g)
    Computes quotient of fractions f and g.

frac_unify(g)
    Unify representations of two multivariate fractions.

half_per(rep, kill=False)
    Create a DMP out of the given representation.
invert(check=True)
    Computes inverse of a fraction f.

property is_one
    Returns True if f is a unit fraction.

property is_zero
    Returns True if f is a zero fraction.

mul(g)
    Multiply two multivariate fractions f and g.

neg()
    Negate all coefficients in f.

numer()
    Returns the numerator of f.

per(num, den, cancel=True, kill=False, ring=None)
    Create a DMF out of the given representation.

poly_unify(g)
    Unify a multivariate fraction and a polynomial.

pow(n)
    Raise f to a non-negative power n.

quo(g)
    Computes quotient of fractions f and g.

sub(g)
    Subtract two multivariate fractions f and g.

class sympy.polys.polycrlasses.ANP(rep, mod, dom)
    Dense Algebraic Number Polynomials over a field.

LC()
    Returns the leading coefficient of f.

TC()
    Returns the trailing coefficient of f.

property is_ground
    Returns True if f is an element of the ground domain.

property is_one
    Returns True if f is a unit algebraic number.

property is_zero
    Returns True if f is a zero algebraic number.

pow(n)
    Raise f to a non-negative power n.

to_dict()
    Convert f to a dict representation with native coefficients.
to_list()
    Convert f to a list representation with native coefficients.

to_sympy_dict()
    Convert f to a dict representation with SymPy coefficients.

to_sympy_list()
    Convert f to a list representation with SymPy coefficients.

to_tuple()
    Convert f to a tuple representation with native coefficients.
    This is needed for hashing.

unify(g)
    Unify representations of two algebraic numbers.

Internals of the Polynomial Manipulation Module

The implementation of the polynomials module is structured internally in “levels”. There are four levels, called L0, L1, L2 and L3. The levels three and four contain the user-facing functionality and were described in the previous section. This section focuses on levels zero and one.

Level zero provides core polynomial manipulation functionality with C-like, low-level interfaces. Level one wraps this low-level functionality into object oriented structures. These are not the classes seen by the user, but rather classes used internally throughout the polys module.

There is one additional complication in the implementation. This comes from the fact that all polynomial manipulations are relative to a ground domain. For example, when factoring a polynomial like $x^{10} - 1$, one has to decide what ring the coefficients are supposed to belong to, or less trivially, what coefficients are allowed to appear in the factorization. This choice of coefficients is called a ground domain. Typical choices include the integers $\mathbb{Z}$, the rational numbers $\mathbb{Q}$ or various related rings and fields. But it is perfectly legitimate (although in this case uninteresting) to factorize over polynomial rings such as $k[Y]$, where $k$ is some fixed field.

Thus the polynomial manipulation algorithms (both complicated ones like factoring, and simpler ones like addition or multiplication) have to rely on other code to manipulate the coefficients. In the polynomial manipulation module, such code is encapsulated in so-called “domains”. A domain is basically a factory object: it takes various representations of data, and converts them into objects with unified interface. Every object created by a domain has to implement the arithmetic operations $+$, $-$ and $\times$. Other operations are accessed through the domain, e.g. as in $\mathbb{Z}.\text{quo}(\mathbb{Z}(4), \mathbb{Z}(2))$.

Note that there is some amount of circularity: the polynomial ring domains use the level one classes, the level one classes use the level zero functions, and level zero functions use domains. It is possible, in principle, but not in the current implementation, to work in rings like $k[X][Y]$. This would create even more layers. For this reason, working in the isomorphic ring $k[X,Y]$ is preferred.
Level Zero

Level zero contains the bulk code of the polynomial manipulation module.

Manipulation of dense, multivariate polynomials

These functions can be used to manipulate polynomials in $K[X_0, \ldots, X_u]$. Functions for manipulating multivariate polynomials in the dense representation have the prefix `dmp_`. Functions which only apply to univariate polynomials (i.e. $u = 0$) have the prefix `dup__`. The ground domain $K$ has to be passed explicitly. For many multivariate polynomial manipulation functions also the level $u$, i.e. the number of generators minus one, has to be passed. (Note that, in many cases, `dup__` versions of functions are available, which may be slightly more efficient.)

**Basic manipulation:**

```python
sympy.polys.densebasic.dmp_LC(f, K)
```

Return leading coefficient of $f$.

**Examples**

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import poly_LC

>>> poly_LC([], ZZ)
0
>>> poly_LC([ZZ(1), ZZ(2), ZZ(3)], ZZ)
1
```

```python
denmp_TC(f, K)
```

Return trailing coefficient of $f$.

**Examples**

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import poly_TC

>>> poly_TC([], ZZ)
0
>>> poly_TC([ZZ(1), ZZ(2), ZZ(3)], ZZ)
3
```

```python
denmp_ground_LC(f, u, K)
```

Return the ground leading coefficient.
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_ground_LC

>>> f = ZZ.map([[1], [2, 3]])
>>> dmp_ground_LC(f, 2, ZZ)
1
```

```
sympy.polys.densebasic.dmp_ground_TC(f, u, K)
Return the ground trailing coefficient.
```

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_ground_TC

>>> f = ZZ.map([[1], [2, 3]])
>>> dmp_ground_TC(f, 2, ZZ)
3
```

```
sympy.polys.densebasic.dmp_true_LT(f, u, K)
Return the leading term \( c \times x_1^{n_1} \ldots x_k^{n_k} \).
```

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_true_LT

>>> f = ZZ.map([[4], [2, 0], [3, 0, 0]])
>>> dmp_true_LT(f, 1, ZZ)
((2, 0), 4)
```

```
sympy.polys.densebasic.dmp_degree(f, u)
Return the leading degree of \( f \) in \( x_0 \) in \( K[X] \).
Note that the degree of 0 is negative infinity (the SymPy object -oo).
```
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_degree

>>> dmp_degree([[[]]], 2)
-oo

>>> f = ZZ.map([[2], [1, 2, 3]])

>>> dmp_degree(f, 1)
1
```

**sympy.polys.densebasic.dmp_degree_in**

Return the leading degree of \( f \) in \( x_j \) in \( K[X] \).

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_degree_in

>>> f = ZZ.map([[2], [1, 2, 3]])

>>> dmp_degree_in(f, 0, 1)
1
>>> dmp_degree_in(f, 1, 1)
2
```

**sympy.polys.densebasic.dmp_degree_list**

Return a list of degrees of \( f \) in \( K[X] \).

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_degree_list

>>> f = ZZ.map([[1], [1, 2, 3]])

>>> dmp_degree_list(f, 1)
(1, 2)
```

**sympy.polys.densebasic.dmp_strip**

Remove leading zeros from \( f \) in \( K[X] \).
Examples

```python
>>> from sympy.polys.densebasic import dmp_strip

>>> dmp_strip([[], [0, 1, 2], [1]], 1)
[[0, 1, 2], [1]]
```

`sympy.polys.densebasic.dmp_validate(f, K=None)`
Return the number of levels in `f` and recursively strip it.

Examples

```python
>>> from sympy.polys.densebasic import dmp_validate

>>> dmp_validate([[], [0, 1, 2], [1]])
(([[1, 2], [1]], 1)

>>> dmp_validate([[1], 1])
Traceback (most recent call last):
...
ValueError: invalid data structure for a multivariate polynomial
```

`sympy.polys.densebasic.dup_reverse(f)`
Compute \(x^n \cdot f(1/x)\), i.e.: reverse \(f\) in \(K[x]\).

Examples

```python
>>> from sympy.polys.domains import ZZ

>>> from sympy.polys.densebasic import dup_reverse

>>> f = ZZ.map([1, 2, 3, 0])

>>> dup_reverse(f)
[3, 2, 1]
```

`sympy.polys.densebasic.dmp_copy(f, u)`
Create a new copy of a polynomial \(f\) in \(K[X]\).

Examples

```python
>>> from sympy.polys.domains import ZZ

>>> from sympy.polys.densebasic import dmp_copy

>>> f = ZZ.map([[1], [1, 2]])
```
```python
>>> dmp_copy(f, 1)
[[1], [1, 2]]
```

`sympy.polys.densebasic.dmp_to_tuple(f, u)`  
Convert `f` into a nested tuple of tuples.  
This is needed for hashing. This is similar to `dmp_copy()`.

**Examples**

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_to_tuple

>>> f = ZZ.map([[1], [1, 2]])

>>> dmp_to_tuple(f, 1)
((1,), (1, 2))
```

`sympy.polys.densebasic.dmp_normal(f, u, K)`  
Normalize a multivariate polynomial in the given domain.

**Examples**

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_normal

>>> dmp_normal([[], [0, 1.5, 2]], 1, ZZ)
[[[1, 2]]]
```

`sympy.polys.densebasic.dmp_convert(f, u, K0, K1)`  
Convert the ground domain of `f` from `K0` to `K1`.

**Examples**

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_convert

>>> R, x = ring("x", ZZ)

>>> dmp_convert([[R(1)], [R(2)]], 1, R.to_domain(), ZZ)
[[1, 2]]

>>> dmp_convert([[ZZ(1)], [ZZ(2)]], 1, ZZ, R.to_domain())
[[1, 2]]
```

`sympy.polys.densebasic.dmp_from_sympy(f, u, K)`  
Convert the ground domain of `f` from SymPy to `K`.
Examples

```python
>>> from sympy import S
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_from_sympy

>>> dmp_from_sympy([[S(1)], [S(2)]], 1, ZZ) == [[ZZ(1)], [ZZ(2)]]
True
```

dmp_from_sympy([S(1)], [S(2)]), 1, ZZ) == [[ZZ(1)], [ZZ(2)]]

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_nth

>>> f = ZZ.map([[1], [2], [3]])

>>> dmp_nth(f, 0, 1, ZZ)
[3]
>>> dmp_nth(f, 4, 1, ZZ)
[]
```

dmp_nth(f, n, u, K)
Return the n-th coefficient of f in K[x].

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_ground_nth

>>> f = ZZ.map([[1], [2], [3]])

>>> dmp_ground_nth(f, (0, 1), 1, ZZ)
2
```

dmp_ground_nth(f, N, u, K)
Return the ground n-th coefficient of f in K[x].

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_zero_p

>>> dmp_zero_p(f, u)
```

dmp_zero_p(f, u)
Return True if f is zero in K[X].

5.8. Topics
Examples

```python
>>> from sympy.polys.densebasic import dmp_zero_p

>>> dmp_zero_p([[[]]], 4)
True
>>> dmp_zero_p([[[]]], 4)
False
```

`sympy.polys.densebasic.dmp_zero(u)`

Return a multivariate zero.

Examples

```python
>>> from sympy.polys.densebasic import dmp_zero

>>> dmp_zero(4)
[[[[[]]]]]
```

`sympy.polys.densebasic.dmp_one_p(f, u, K)`

Return True if f is one in \( K[X] \).

Examples

```python
>>> from sympy.polys.domains import ZZ

>>> from sympy.polys.densebasic import dmp_one_p

>>> dmp_one_p([[ZZ(1)]], 2, ZZ)
True
```

`sympy.polys.densebasic.dmp_one(u, K)`

Return a multivariate one over \( K \).

Examples

```python
>>> from sympy.polys.domains import ZZ

>>> from sympy.polys.densebasic import dmp_one

>>> dmp_one(2, ZZ)
[[[1]]]
```

`sympy.polys.densebasic.dmp_ground_p(f, c, u)`

Return True if \( f \) is constant in \( K[X] \).
Examples

```python
from sympy.polys.densebasic import dmp_ground_p

>>> dmp_ground_p([[3]], 3, 2)
True
>>> dmp_ground_p([[4]], None, 2)
True
```

`syrpy.polys.densebasic.dmp_ground(c, u)`
Return a multivariate constant.

Examples

```python
from sympy.polys.densebasic import dmp_ground

>>> dmp_ground(3, 5)
[[[[[3]]]]]
>>> dmp_ground(1, -1)
1
```

`syrpy.polys.densebasic.dmp_zeros(n, u, K)`
Return a list of multivariate zeros.

Examples

```python
from sympy.polys.domains import ZZ
from sympy.polys.densebasic import dmp_zeros

>>> dmp_zeros(3, 2, ZZ)
[[[[]]], [[[]]], [[[]]]]
>>> dmp_zeros(3, -1, ZZ)
[0, 0, 0]
```

`syrpy.polys.densebasic.dmp_grounds(c, n, u)`
Return a list of multivariate constants.

Examples

```python
from sympy.polys.domains import ZZ
from sympy.polys.densebasic import dmp_grounds

>>> dmp_grounds(ZZ(4), 3, 2)
[[[[4]]], [[[[4]]]], [[[4]]]]
>>> dmp_grounds(ZZ(4), 3, -1)
[4, 4, 4]
```
SymPy Documentation, Release 1.12.1

sympy.polys.densebasic.dmp_negative_p(f, u, K)

Return True if LC(f) is negative.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_negative_p

>>> dmp_negative_p([[ZZ(1)], [-ZZ(1)]], 1, ZZ)
False
>>> dmp_negative_p([[-ZZ(1)], [ZZ(1)]], 1, ZZ)
True
```

sympy.polys.densebasic.dmp_positive_p(f, u, K)

Return True if LC(f) is positive.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_positive_p

>>> dmp_positive_p([[ZZ(1)], [-ZZ(1)]], 1, ZZ)
True
>>> dmp_positive_p([[-ZZ(1)], [ZZ(1)]], 1, ZZ)
False
```

sympy.polys.densebasic.dmp_from_dict(f, u, K)

Create a K[X] polynomial from a dict.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_from_dict

>>> dmp_from_dict({(0, 0): ZZ(3), (0, 1): ZZ(2), (2, 1): ZZ(1)}, 1, ZZ)
[[1, 0], [], [2, 3]]
>>> dmp_from_dict({}, 0, ZZ)
[]
```

sympy.polys.densebasic.dmp_to_dict(f, u, K=None, zero=False)

Convert a K[X] polynomial to a dict.`"
Examples

```python
>>> from sympy.polys.densebasic import dmp_to_dict

>>> dmp_to_dict([[[1, 0], [1, [2, 3]]], 1])
{(0, 0): 3, (0, 1): 2, (2, 1): 1}
>>> dmp_to_dict([], 0)
{}  
```

sympy.polys.densebasic.dmp_swap(f, i, j, u, K)

Transform $K[x_{i}..x_{j}]$ to $K[x_{j}..x_{i}]$.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_swap

>>> f = ZZ.map([[[2], [1, 0]], []])

>>> dmp_swap(f, 0, 1, 2, ZZ)
[][]
>>> dmp_swap(f, 1, 2, 2, ZZ)
[[], [2, 0]]
>>> dmp_swap(f, 0, 2, 2, ZZ)
[[], [2, 0]]
```

sympy.polys.densebasic.dmp_permute(f, P, u, K)

Return a polynomial in $K[x_{P(1)},..,x_{P(n)}]$.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_permute

>>> f = ZZ.map([[[2], [1, 0]], []])

>>> dmp_permute(f, [1, 0, 2], 2, ZZ)
[][]
>>> dmp_permute(f, [1, 2, 0], 2, ZZ)
[[], [2, 0]]
```

sympy.polys.densebasic.dmp_nest(f, l, K)

Return a multivariate value nested $l$-levels.
sympy.polys.densebasic.dmp_nest(f, l, u, K)
    Return a multivariate polynomial raised l-levels.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_nest

>>> dmp_nest([[ZZ(1)]], 2, ZZ)
[[[[1]]]]
```

sympy.polys.densebasic.dmp_raise(f, l, u, K)
    Map \( x_i^{m_i} \) to \( y_i \) in a polynomial in \( K[X] \).

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_raise

>>> f = ZZ.map([[1, 2]])

>>> dmp_raise(f, 2, 1, ZZ)
[[[[1]], [[1]], [[2]]]]
```

sympy.polys.densebasic.dmp_deflate(f, u, K)
    Map \( x_i^{m_i} \) to \( y_i \) in a polynomial in \( K[X] \).

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_deflate

>>> f = ZZ.map([[1, 2], [], [3, 4]])

>>> dmp_deflate(f, 1, ZZ)
((2, 3), [[1, 2], [3, 4]])
```

sympy.polys.densebasic.dmp_multi_deflate(polys, u, K)
    Map \( x_i^{m_i} \) to \( y_i \) in a set of polynomials in \( K[X] \).

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_multi_deflate

>>> f = ZZ.map([[1, 2], [], [3, 4]])

>>> g = ZZ.map([[1, 2], [], [3, 4]])
```
```python
>>> dmp_multi_deflate((f, g), 1, ZZ)
((2, 1), [[[1, 0, 2], [3, 0, 4]], [[1, 2], [3, 4]]])
```
Examples

```python
>>> from sympy.polys.rings import ring
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_inject

>>> R, x, y = ring(“x,y”, ZZ)

>>> dmp_inject([R(1), x + 2], 0, R.to_domain())
([[1]], [[1], [2]], 2)

>>> dmp_inject([R(1), x + 2], 0, R.to_domain(), front=True)
([[1]], [[1, 2]], 2)
```

sympy.polys.densebasic.dmp_eject(f, u, K, front=False)

Convert f from K[X,Y] to K[X][Y].

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_eject

>>> dmp_eject([[1]], [[1], [2]], 2, ZZ[‘x’, ‘y’])
[1, x + 2]
```

sympy.polys.densebasic.dmp_terms_gcd(f, u, K)

Remove GCD of terms from f in K[X].

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_terms_gcd

>>> f = ZZ.map([[1, 0], [1, 0, 0], [], []])

>>> dmp_terms_gcd(f, 1, ZZ)
((2, 1), [[1], [1, 0]])
```

sympy.polys.densebasic.dmp_list_terms(f, u, K, order=None)

List all non-zero terms from f in the given order order.
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_list_terms

>>> f = ZZ.map([[1, 1], [2, 3]])

>>> dmp_list_terms(f, 1, ZZ)
[((1, 1), 1), ((1, 0), 1), ((0, 1), 2), ((0, 0), 3)]

>>> dmp_list_terms(f, 1, ZZ, order='grevlex')
[((1, 1), 1), ((1, 0), 1), ((0, 1), 2), ((0, 0), 3)]
```

`sympy.polys.densebasic.dmp_apply_pairs(f, g, h, args, u, K)`
Apply h to pairs of coefficients of f and g.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dmp_apply_pairs

>>> h = lambda x, y, z: 2*x + y - z

>>> dmp_apply_pairs([[1], [2, 3]], [[3], [2, 1]], h, (1,), 1, ZZ)
[[4], [5, 6]]
```

`sympy.polys.densebasic.dmp_slice(f, m, n, u, K)`
Take a continuous subsequence of terms of f in K[X].

`sympy.polys.densebasic.dup_random(n, a, b, K)`
Return a polynomial of degree n with coefficients in [a, b].

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.densebasic import dup_random

>>> dup_random(3, -10, 10, ZZ)
[-2, -8, 9, -4]
```

Arithmetic operations:

`sympy.polys.densearith.dmp_add_term(f, c, i, u, K)`
Add c(x_2..x_u)*x_0**i to f in K[X].
### Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_add_term(x*y + 1, 2, 2)
2*x**2 + x*y + 1
```

**sympy.polys.densearith.dmp_sub_term**(*f*, *c*, *i*, *u*, *K*)

Subtract \( c(x_{2..u})x_0^i \) from \( f \) in \( K[X] \).

### Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_sub_term(2*x**2 + x*y + 1, 2, 2)
x*y + 1
```

**sympy.polys.densearith.dmp_mul_term**(*f*, *c*, *i*, *u*, *K*)

Multiply \( f \) by \( c(x_{2..u})x_0^i \) in \( K[X] \).

### Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_mul_term(x**2*y + x, 3*y, 2)
3*x**4*y**2 + 3*x**3*y
```

**sympy.polys.densearith.dmp_add_ground**(*f*, *c*, *u*, *K*)

Add an element of the ground domain to \( f \).

### Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_add_ground(x**3 + 2*x**2 + 3*x + 4, ZZ(4))
x**3 + 2*x**2 + 3*x + 8
```

**sympy.polys.densearith.dmp_sub_ground**(*f*, *c*, *u*, *K*)

Subtract an element of the ground domain from \( f \).
Examples

```python
>>> from sympy.polys import ring, ZZ

>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_sub_ground(x**3 + 2*x**2 + 3*x + 4, ZZ(4))

x**3 + 2*x**2 + 3*x
```

`sympy.polys.densearith.dmp_mul_ground(f, c, u, K)`

Multiply `f` by a constant value in `K[X]`.

Examples

```python
>>> from sympy.polys import ring, ZZ

>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_mul_ground(2*x + 2*y, ZZ(3))

6*x + 6*y
```

`sympy.polys.densearith.dmp_quo_ground(f, c, u, K)`

Quotient by a constant in `K[X]`.

Examples

```python
>>> from sympy.polys import ring, ZZ, QQ

>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_quo_ground(2*x**2*y + 3*x, ZZ(2))

x**2*y + x
```

```python
>>> R, x, y = ring("x,y", QQ)

>>> R.dmp_quo_ground(2*x**2*y + 3*x, QQ(2))

x**2*y + 3/2*x
```

`sympy.polys.densearith.dmp_exquo_ground(f, c, u, K)`

Exact quotient by a constant in `K[X]`.

Examples

```python
>>> from sympy.polys import ring, QQ

>>> R, x, y = ring("x,y", QQ)

>>> R.dmp_exquo_ground(x**2*y + 2*x, QQ(2))

1/2*x**2*y + x
```

`sympy.polys.densearith.dup_lshift(f, n, K)`

Efficiently multiply `f` by `x**n` in `K[x]`.

5.8. Topics 2667
**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x = ring("x", ZZ)

>>> R.dup_lshift(x**2 + 1, 2)
x**4 + x**2
```

`sympy.polys.densearith.dup_rshift(f, n, K)`

Efficiently divide \( f \) by \( x^n \) in \( K[x] \).

**Examples**

```python
>>> from sympy.polys import ring, ZZ

>>> R, x = ring("x", ZZ)

>>> R.dup_rshift(x**4 + x**2, 2)
x**2 + 1
>>> R.dup_rshift(x**4 + x**2 + 2, 2)
x**2 + 1
```

`sympy.polys.densearith.dmp_abs(f, u, K)`

Make all coefficients positive in \( K[X] \).

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_abs(x**2*y - x)
x**2*y + x
```

`sympy.polys.densearith.dmp_neg(f, u, K)`

Negate a polynomial in \( K[X] \).

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_neg(x**2*y - x)
-x**2*y + x
```

`sympy.polys.densearith.dmp_add(f, g, u, K)`

Add dense polynomials in \( K[X] \).
Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> R.dmp_add(x**2 + y, x**2*y + x)
2*x**2*y + x**2 + x + y
```

sympy.polys.densearith.dmp_sub(f, g, u, K)
Subtract dense polynomials in K[X].

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> R.dmp_sub(x**2 + y, x**2*y + x)
-x**2*y + x**2 - x + y
```

sympy.polys.densearith.dmp_add_mul(f, g, h, u, K)
Returns $f + g \cdot h$ where $f$, $g$, $h$ are in $K[X]$.

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> R.dmp_add_mul(x**2 + y, x, x + 2)
2*x**2 + 2*x + y
```

sympy.polys.densearith.dmp_sub_mul(f, g, h, u, K)
Returns $f - g \cdot h$ where $f$, $g$, $h$ are in $K[X]$.

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> R.dmp_sub_mul(x**2 + y, x, x + 2)
-2*x + y
```

sympy.polys.densearith.dmp_mul(f, g, u, K)
Multiply dense polynomials in $K[X]$. 2669
**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_mul(x*y + 1, x)
x**2*y + x
```

`sympy.polys.densearith.dmp_sqr(f, u, K)`

Square dense polynomials in $K[X]$.

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_sqr(x**2 + x*y + y**2)
x**4 + 2*x**3*y + 3*x**2*y**2 + 2*x*y**3 + y**4
```

`sympy.polys.densearith.dmp_pow(f, n, u, K)`

Raise $f$ to the $n$-th power in $K[X]$.

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_pow(x*y + 1, 3)
x**3*y**3 + 3*x**2*y**2 + 3*x*y + 1
```

`sympy.polys.densearith.dmp_pdiv(f, g, u, K)`

Polynomial pseudo-division in $K[X]$.

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_pdiv(x**2 + x*y, 2*x + 2)
(2*x + 2*y - 2, -4*y + 4)
```

`sympy.polys.densearith.dmp_prem(f, g, u, K)`

Polynomial pseudo-remainder in $K[X]$.
Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> R.dmp_prem(x**2 + x*y, 2*x + 2)
-4*y + 4
```

sympy.polys.densearith.dmp_pquo(f, g, u, K)
Polynomial exact pseudo-quotient in K[X].

Examples

```python
>>> from sympy.polys import ring, ZZ

>>> f = x**2 + x*y
>>> g = 2*x + 2*y
>>> h = 2*x + 2

>>> R.dmp_pquo(f, g)
2*x

>>> R.dmp_pquo(f, h)
2*x + 2*y - 2
```

sympy.polys.densearith.dmp_pexquo(f, g, u, K)
Polynomial pseudo-quotient in K[X].

Examples

```python
>>> from sympy.polys import ring, ZZ

>>> f = x**2 + x*y
>>> g = 2*x + 2*y
>>> h = 2*x + 2

>>> R.dmp_pexquo(f, g)
2*x

>>> R.dmp_pexquo(f, h)
Traceback (most recent call last):
...
ExactQuotientFailed: [[2], [2]] does not divide [[1], [1, 0], []]
```

sympy.polys.densearith.dmp_rr_div(f, g, u, K)
Multivariate division with remainder over a ring.
SymPy Documentation, Release 1.12.1

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> R.dmp_rr_div(x**2+x*y, 2*x + 2)
(0, x**2 + x*y)
```

sympy.polys.densearith.dmp_ff_div(f, g, u, K)
Polynomial division with remainder over a field.

Examples

```python
>>> from sympy.polys import ring, QQ
>>> R, x,y = ring("x,y", QQ)

>>> R.dmp_ff_div(x**2 + x*y, 2*x + 2)
(1/2*x + 1/2*y - 1/2, -y + 1)
```

sympy.polys.densearith.dmp_div(f, g, u, K)
Polynomial division with remainder in K[X].

Examples

```python
>>> from sympy.polys import ring, ZZ, QQ
>>> R, x,y = ring("x,y", ZZ)

>>> R.dmp_div(x**2 + x*y, 2*x + 2)
(0, x**2 + x*y)

>>> R, x,y = ring("x,y", QQ)

>>> R.dmp_div(x**2 + x*y, 2*x + 2)
(1/2*x + 1/2*y - 1/2, -y + 1)
```

sympy.polys.densearith.dmp_rem(f, g, u, K)
Returns polynomial remainder in K[X].

Examples

```python
>>> from sympy.polys import ring, ZZ, QQ
>>> R, x,y = ring("x,y", ZZ)

>>> R.dmp_rem(x**2 + x*y, 2*x + 2)
x**2 + x*y
```
```python
>>> R, x, y = ring("x,y", QQ)
>>> R.dmp_rem(x**2 + x*y, 2*x + 2)
-y + 1
```

sympy.polys.densearith.dmp_quo(f, g, u, K)

Returns exact polynomial quotient in K[X].

**Examples**

```python
>>> from sympy.polys import ring, ZZ, QQ

>>> R, x, y = ring("x,y", ZZ)
>>> R.dmp_quo(x**2 + x*y, 2*x + 2)
0

>>> R, x, y = ring("x,y", QQ)
>>> R.dmp_quo(x**2 + x*y, 2*x + 2)
1/2*x + 1/2*y - 1/2
```

sympy.polys.densearith.dmp_exquo(f, g, u, K)

Returns polynomial quotient in K[X].

**Examples**

```python
>>> from sympy.polys import ring, ZZ

>>> R, x, y = ring("x,y", ZZ)

>>> f = x**2 + x*y
>>> g = x + y
>>> h = 2*x + 2

>>> R.dmp_exquo(f, g)
x

>>> R.dmp_exquo(f, h)
Traceback (most recent call last):
...  
ExactQuotientFailed: [[2], [2]] does not divide [[1], [1, 0], []]
```

sympy.polys.densearith.dmp_max_norm(f, u, K)

Returns maximum norm of a polynomial in K[X].
Examples

```python
from sympy.polys import ring, ZZ

R, x, y = ring("x,y", ZZ)

R.dmp_max_norm(2*x*y - x - 3)
```

SymPy.polys.densearith.dmp_l1_norm(f, u, K)

Returns l1 norm of a polynomial in K[X].

Examples

```python
from sympy.polys import ring, ZZ

R, x, y = ring("x,y", ZZ)

R.dmp_l1_norm(2*x*y - x - 3)
```

SymPy.polys.densearith.dmp_expand(polys, u, K)

Multiply together several polynomials in K[X].

Examples

```python
from sympy.polys import ring, ZZ

R, x, y = ring("x,y", ZZ)

R.dmp_expand([x**2 + y**2, x + 1])
x**3 + x**2 + x*y**2 + y**2
```

Further tools:

SymPy.polys.densetools.dmp_integrate(f, m, u, K)

Computes the indefinite integral of f in x_0 in K[X].

Examples

```python
from sympy.polys import ring, QQ

R, x, y = ring("x,y", QQ)

R.dmp_integrate(x + 2*y, 1)
1/2*x**2 + 2*x*y
R.dmp_integrate(x + 2*y, 2)
1/6*x**3 + x**2*y
```

SymPy.polys.densetools.dmp_integrate_in(f, m, j, u, K)

Computes the indefinite integral of f in x_j in K[X].
Examples

```python
>>> from sympy.polys import ring, QQ
>>> R, x,y = ring("x,y", QQ)

>>> R.dmp_integrate_in(x + 2*y, 1, 0)
1/2*x**2 + 2*x*y
>>> R.dmp_integrate_in(x + 2*y, 1, 1)
x*y + y**2
```

`sympy.polys.densetools.dmp_diff(f, m, u, K)`

m-th order derivative in x_0 of a polynomial in K[X].

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> f = x*y**2 + 2*x*y + 3*x + 2*y**2 + 3*y + 1

>>> R.dmp_diff(f, 1)
y**2 + 2*y + 3
>>> R.dmp_diff(f, 2)
0
```

`sympy.polys.densetools.dmp_diff_in(f, m, j, u, K)`

m-th order derivative in x_j of a polynomial in K[X].

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> f = x*y**2 + 2*x*y + 3*x + 2*y**2 + 3*y + 1

>>> R.dmp_diff_in(f, 1, 0)
y**2 + 2*y + 3
>>> R.dmp_diff_in(f, 1, 1)
2*x*y + 2*x + 4*y + 3
```

`sympy.polys.densetools.dmp_eval(f, a, u, K)`

Evaluate a polynomial at x_0 = a in K[X] using the Horner scheme.
SymPy Documentation, Release 1.12.1

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> R.dmp_eval(2*x*y + 3*x + y + 2, 2)
5*y + 8
```

sympy.polys.densetools.dmp_eval_in(f, a, j, u, K)

Evaluate a polynomial at x_j = a in K[X] using the Horner scheme.

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> f = 2*x*y + 3*x + y + 2

>>> R.dmp_eval_in(f, 2, 0)
5*y + 8
>>> R.dmp_eval_in(f, 2, 1)
7*x + 4
```

sympy.polys.densetools.dmp_eval_tail(f, A, u, K)

Evaluate a polynomial at x_j = a_j, ... in K[X].

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> f = 2*x*y + 3*x + y + 2

>>> R.dmp_eval_tail(f, [2])
7*x + 4
>>> R.dmp_eval_tail(f, [2, 2])
18
```

sympy.polys.densetools.dmp_diff_eval_in(f, m, a, j, u, K)

Differentiate and evaluate a polynomial in x_j at a in K[X].
Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> f = x*y**2 + 2*x*y + 3*x + 2*y**2 + 3*y + 1

>>> R.dmp_diff_eval_in(f, 1, 2, 0)
y**2 + 2*y + 3
>>> R.dmp_diff_eval_in(f, 1, 2, 1)
6*x + 11
```

`sympy.polys.densetools.dmp_trunc(f, p, u, K)`
Reduce a $K[X]$ polynomial modulo a polynomial $p$ in $K[Y]$.

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> f = 3*x**2*y + 8*x**2 + 5*x*y + 6*x + 2*y + 3
>>> g = (y - 1).drop(x)

>>> R.dmp_trunc(f, g)
11*x**2 + 11*x + 5
```

`sympy.polys.densetools.dmp_ground_trunc(f, p, u, K)`
Reduce a $K[X]$ polynomial modulo a constant $p$ in $K$.

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> f = 3*x**2*y + 8*x**2 + 5*x*y + 6*x + 2*y + 3

>>> R.dup_ground_trunc(f, ZZ(3))
-x**2 - x*y - y
```

`sympy.polys.densetools.dup_monic(f, K)`
Divide all coefficients by $LC(f)$ in $K[x]$.

5.8. Topics 2677
Examples

>>> from sympy.polys import ring, ZZ, QQ

```python
>>> R, x = ring("x", ZZ)
>>> R.dup_monic(3*x**2 + 6*x + 9)
x**2 + 2*x + 3
```

```python
>>> R, x = ring("x", QQ)
>>> R.dup_monic(3*x**2 + 4*x + 2)
x**2 + 4/3*x + 2/3
```

```python
sympy.polys.densetools.dmp_ground_monic(f, u, K)
Divide all coefficients by LC(f) in K[X].
```

Examples

```python
>>> from sympy.polys import ring, ZZ, QQ

>>> R, x, y = ring("x,y", ZZ)
>>> f = 3*x**2*y + 6*x**2 + 3*x*y + 9*y + 3
```

```python
>>> R.dmp_ground_monic(f)
x**2*y + 2*x**2 + x*y + 3*y + 1
```

```python
>>> R, x, y = ring("x,y", QQ)
>>> f = 3*x**2*y + 8*x**2 + 5*x*y + 6*x + 2*y + 3
```

```python
>>> R.dmp_ground_monic(f)
x**2*y + 2/3*x**2 + 5/3*x*y + 2*x + 2/3*y + 1
```

```python
sympy.polys.densetools.dup_content(f, K)
Compute the GCD of coefficients of f in K[x].
```

Examples

```python
>>> from sympy.polys import ring, ZZ, QQ

```python
>>> R, x = ring("x", ZZ)
>>> f = 6*x**2 + 8*x + 12
```

```python
>>> R.dup_content(f)
2
```

```python
>>> R, x = ring("x", QQ)
>>> f = 6*x**2 + 8*x + 12
```
sympy.polys.densetools.dmp_ground_content(f, u, K)
Compute the GCD of coefficients of f in K[X].

Examples

```python
>>> from sympy.polys import ring, ZZ, QQ

>>> R, x,y = ring("x,y", ZZ)
>>> f = 2*x*y + 6*x + 4*y + 12
>>> R.dmp_ground_content(f)
2

>>> R, x,y = ring("x,y", QQ)
>>> f = 2*x*y + 6*x + 4*y + 12
>>> R.dmp_ground_content(f)
2
```

sympy.polys.densetools.dup_primitive(f, K)
Compute content and the primitive form of f in K[x].

Examples

```python
>>> from sympy.polys import ring, ZZ, QQ

>>> R, x = ring("x", ZZ)
>>> f = 6*x**2 + 8*x + 12
>>> R.dup_primitive(f)
(2, 3*x**2 + 4*x + 6)

>>> R, x = ring("x", QQ)
>>> f = 6*x**2 + 8*x + 12
>>> R.dup_primitive(f)
(2, 3*x**2 + 4*x + 6)
```

sympy.polys.densetools.dmp_ground_primitive(f, u, K)
Compute content and the primitive form of f in K[X].
Examples

```python
>>> from sympy import ring, ZZ, QQ

>>> R, x, y = ring("x, y", ZZ)
>>> f = 2*x*y + 6*x + 4*y + 12

>>> R.dmp_ground_primitive(f)
(2, x*y + 3*x + 2*y + 6)

>>> R, x, y = ring("x, y", QQ)
>>> f = 2*x*y + 6*x + 4*y + 12

>>> R.dmp_ground_primitive(f)
(2, x*y + 3*x + 2*y + 6)
```

`sympy.polys.densetools.dup_extract(f, g, K)`

Extract common content from a pair of polynomials in `K[x]`.

Examples

```python
>>> from sympy import ring, ZZ

>>> R, x = ring("x", ZZ)

>>> R.dup_extract(6*x**2 + 12*x + 18, 4*x**2 + 8*x + 12)
(2, 3*x**2 + 6*x + 9, 2*x**2 + 4*x + 6)
```

`sympy.polys.densetools.dmp_ground_extract(f, g, u, K)`

Extract common content from a pair of polynomials in `K[X]`.

Examples

```python
>>> from sympy import ring, ZZ

>>> R, x, y = ring("x, y", ZZ)

>>> R.dmp_ground_extract(6*x*y + 12*x + 18, 4*x*y + 8*x + 12)
(2, 3*x*y + 6*x + 9, 2*x*y + 4*x + 6)
```

`sympy.polys.densetools.dup_real_imag(f, K)`

Return bivariate polynomials f1 and f2, such that f = f1 + f2*I.
Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x, y", ZZ)

>>> R.dup_real_imag(x**3 + x**2 + x + 1)
(x**3 + x**2 - 3*x*y**2 + x - y**2 + 1, 3*x**2*y + 2*x*y - y**3 + y)
```

`sympy.polys.densetools.dup_mirror(f, K)`
Evaluate efficiently the composition \( f(-x) \) in \( K[x] \).

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x = ring("x", ZZ)

>>> R.dup_mirror(x**3 + 2*x**2 - 4*x + 2)
-x**3 + 2*x**2 + 4*x + 2
```

`sympy.polys.densetools.dup_scale(f, a, K)`
Evaluate efficiently composition \( f(a*x) \) in \( K[x] \).

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x = ring("x", ZZ)

>>> R.dup_scale(x**2 - 2*x + 1, ZZ(2))
4*x**2 - 4*x + 1
```

`sympy.polys.densetools.dup_shift(f, a, K)`
Evaluate efficiently Taylor shift \( f(x + a) \) in \( K[x] \).

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x = ring("x", ZZ)

>>> R.dup_shift(x**2 - 2*x + 1, ZZ(2))
x**2 + 2*x + 1
```

`sympy.polys.densetools.dup_transform(f, p, q, K)`
Evaluate functional transformation \( q^n \cdot f(p/q) \) in \( K[x] \).
symy.polys.densetools.dmp_compose(f, g, u, K)
Evaluate functional composition f(g) in K[X].

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)
>>> R.dmp_compose(x*y + 2*x + y, y)
y**2 + 3*y
```

symy.polys.densetools.dup_decompose(f, K)
Computes functional decomposition of f in K[x].

Given a univariate polynomial f with coefficients in a field of characteristic zero, returns list \([f_1, f_2, \ldots, f_n]\), where:

\[
f = f_1 \circ f_2 \circ \ldots \circ f_n = f_1(f_2(\ldots f_n))
\]

and \(f_2, \ldots, f_n\) are monic and homogeneous polynomials of at least second degree. Unlike factorization, complete functional decompositions of polynomials are not unique, consider examples:

1. \(f \circ g = f(x + b) \circ (g - b)\)
2. \(x^{**n} \circ x^{**m} = x^{**m} \circ x^{**n}\)
3. \(T_n \circ T_m = T_m \circ T_n\)

where \(T_n\) and \(T_m\) are Chebyshev polynomials.

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x = ring("x", ZZ)
>>> R.dup_decompose(x**4 - 2*x**3 + x**2)
[x**2, x**2 - x]
```
References

[R718]
sympy.polys.densetools.dmp_lift(f, u, K)
Convert algebraic coefficients to integers in K[X].

Examples

```python
>>> from sympy.polys import ring, QQ
>>> from sympy import I

>>> K = QQ.algebraic_field(I)
>>> R, x = ring("x", K)

>>> f = x**2 + K([QQ(1), QQ(0)])*x + K([QQ(2), QQ(0)])

>>> R.dmp_lift(f)
x**8 + 2*x**6 + 9*x**4 - 8*x**2 + 16
```

sympy.polys.densetools.dup_sign_variations(f, K)
Compute the number of sign variations of f in K[x].

Examples

```python
>>> from sympy.polys import ring, ZZ

>>> R, x = ring("x", ZZ)

>>> R.dup_sign_variations(x**4 - x**2 - x + 1)
2
```

sympy.polys.densetools.dmp_clear_denoms(f, u, K0, K1=None, convert=False)
Clear denominators, i.e. transform K_0 to K_1.

Examples

```python
>>> from sympy.polys import ring, QQ

>>> R, x,y = ring("x,y", QQ)

>>> f = QQ(1,2)*x + QQ(1,3)*y + 1

>>> R.dmp_clear_denoms(f, convert=False)
(6, 3*x + 2*y + 6)
```

sympy.polys.densetools.dmp_revert(f, g, u, K)
Compute f**(-1) mod x**n using Newton iteration.
Examples

```python
>>> from sympy.polys import ring, QQ
>>> R, x,y = ring("x,y", QQ)
```

Manipulation of dense, univariate polynomials with finite field coefficients

Functions in this module carry the prefix `gf_`, referring to the classical name “Galois Fields” for finite fields. Note that many polynomial factorization algorithms work by reduction to the finite field case, so having special implementations for this case is justified both by performance, and by the necessity of certain methods which do not even make sense over general fields.

```python
sympy.polys.galoistools.gf_crt(U, M, K=None)
```
Chinese Remainder Theorem.

Given a set of integer residues \( u_0,\ldots,u_n \) and a set of co-prime integer moduli \( m_0,\ldots,m_n \), returns an integer \( u \), such that \( u = u_i \mod m_i \) for \( i = 0,\ldots,n \).

Examples

Consider a set of residues \( U = [49, 76, 65] \) and a set of moduli \( M = [99, 97, 95] \). Then we have:

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_crt

>>> gf_crt([49, 76, 65], [99, 97, 95], ZZ)
639985
```

This is the correct result because:

```python
>>> [639985 % m for m in [99, 97, 95]]
[49, 76, 65]
```

Note: this is a low-level routine with no error checking.

See also:

* `sympy.ntheory.modular.crt` (page 1554)
  a higher level crt routine

* `sympy.ntheory.modular.solve_congruence` (page 1556)

* `sympy.polys.galoistools.gf_crt1(M, K)`
  First part of the Chinese Remainder Theorem.
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_crt1

>>> gf_crt1([99, 97, 95], ZZ)
(912285, [9215, 9405, 9603], [62, 24, 12])
```

```
sympy.polys.galoistools.gf_crt2(U, M, p, E, S, K)
Second part of the Chinese Remainder Theorem.
```

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_crt2

>>> U = [49, 76, 65]
>>> M = [99, 97, 95]
>>> p = 912285
>>> E = [9215, 9405, 9603]
>>> S = [62, 24, 12]

>>> gf_crt2(U, M, p, E, S, ZZ)
639985
```

```
sympy.polys.galoistools.gf_int(a, p)
Coerce a mod p to an integer in the range [-p/2, p/2].
```

```python
>>> from sympy.polys.galoistools import gf_int

>>> gf_int(2, 7)
2
>>> gf_int(5, 7)
-2
```

```
sympy.polys.galoistools.gf_degree(f)
Return the leading degree of f.
```
Examples

```python
>>> from sympy.polys.galoistools import gf_degree

>>> gf_degree([1, 1, 2, 0])
3
>>> gf_degree([])
-1
```

`sympy.polys.galoistools.gf_LC(f, K)`
Return the leading coefficient of \( f \).

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_LC

>>> gf_LC([3, 0, 1], ZZ)
3
```

`sympy.polys.galoistools.gf_TC(f, K)`
Return the trailing coefficient of \( f \).

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_TC

>>> gf_TC([3, 0, 1], ZZ)
1
```

`sympy.polys.galoistools.gf_strip(f)`
Remove leading zeros from \( f \).

Examples

```python
>>> from sympy.polys.galoistools import gf_strip

>>> gf_strip([0, 0, 0, 3, 0, 1])
[3, 0, 1]
```

`sympy.polys.galoistools.gf_trunc(f, p)`
Reduce all coefficients modulo \( p \).
Examples

```python
>>> from sympy.polys.galoistools import gf_trunc

>>> gf_trunc([7, -2, 3], 5)
[2, 3, 3]
```

```python
sympy.polys.galoistools.gf_normal(f, p, K)
Normalize all coefficients in K.
```

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_normal

>>> gf_normal([5, 10, 21, -3], 5, ZZ)
[1, 2]
```

```python
sympy.polys.galoistools.gf_from_dict(f, p, K)
Create a GF(p)[x] polynomial from a dict.
```

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_from_dict

>>> gf_from_dict({10: ZZ(4), 4: ZZ(33), 0: ZZ(-1)}, 5, ZZ)
[4, 0, 0, 0, 0, 0, 3, 0, 0, 0, 4]
```

```python
sympy.polys.galoistools.gf_to_dict(f, p, symmetric=True)
Convert a GF(p)[x] polynomial to a dict.
```

Examples

```python
>>> from sympy.polys.galoistools import gf_to_dict

>>> gf_to_dict([4, 0, 0, 0, 0, 0, 3, 0, 0, 0, 4], 5)
{0: -1, 4: -2, 10: -1}
>>> gf_to_dict([4, 0, 0, 0, 0, 0, 3, 0, 0, 0, 4], 5, symmetric=False)
{0: 4, 4: 3, 10: 4}
```

```python
sympy.polys.galoistools.gf_from_int_poly(f, p)
Create a GF(p)[x] polynomial from Z[x].
```
Examples

```python
>>> from sympy.polys.galoistools import gf_from_int_poly

>>> gf_from_int_poly([7, -2, 3], 5)
[2, 3, 3]
```

`sympy.polys.galoistools.gf_to_int_poly(f, p, symmetric=True)`

Convert a GF(p)[x] polynomial to Z[x].

Examples

```python
>>> from sympy.polys.galoistools import gf_to_int_poly

>>> gf_to_int_poly([2, 3, 3], 5)
[2, -2, -2]

>>> gf_to_int_poly([2, 3, 3], 5, symmetric=False)
[2, 3, 3]
```

`sympy.polys.galoistools.gf_neg(f, p, K)`

Negate a polynomial in GF(p)[x].

Examples

```python
>>> from sympy.polys.domains import ZZ

>>> from sympy.polys.galoistools import gf_neg

>>> gf_neg([3, 2, 1, 0], 5, ZZ)
[2, 3, 4, 0]
```

`sympy.polys.galoistools.gf_add_ground(f, a, p, K)`

Compute \( f + a \) where \( f \) in GF(p)[x] and \( a \) in GF(p).

Examples

```python
>>> from sympy.polys.domains import ZZ

>>> from sympy.polys.galoistools import gf_add_ground

>>> gf_add_ground([3, 2, 4], 2, 5, ZZ)
[3, 2, 1]
```

`sympy.polys.galoistools.gf_sub_ground(f, a, p, K)`

Compute \( f - a \) where \( f \) in GF(p)[x] and \( a \) in GF(p).
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_sub_ground

>>> gf_sub_ground([3, 2, 4], 2, 5, ZZ)
[3, 2, 2]
```

`sympy.polys.galoistools.gf_sub_ground(f, a, p, K)`
Compute `f * a` where `f` in `GF(p)[x]` and `a` in `GF(p)`.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_sub

>>> gf_sub([3, 2, 4], [2, 2, 2], 5, ZZ)
[4, 1]
```

`sympy.polys.galoistools.gf_add(f, g, p, K)`
Add polynomials in `GF(p)[x]`.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_add

>>> gf_add([3, 2, 4], [2, 2, 2], 5, ZZ)
[4, 1]
```

`sympy.polys.galoistools.gf_sub(f, g, p, K)`
Subtract polynomials in `GF(p)[x]`.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_sub

>>> gf_sub([3, 2, 4], [2, 2, 2], 5, ZZ)
[4, 1]
```
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_sub

```

```python
>>> gf_sub([3, 2, 4], [2, 2, 2], 5, ZZ)
[1, 0, 2]
```

```
sympy.polys.galoistools.gf_mul(f, g, p, K)
Multiply polynomials in GF(p)[x].

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_mul

```

```python
>>> gf_mul([3, 2, 4], [2, 2, 2], 5, ZZ)
[1, 0, 3, 2, 3]
```

```
sympy.polys.galoistools.gf_sqr(f, p, K)
Square polynomials in GF(p)[x].

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_sqr

```

```python
>>> gf_sqr([3, 2, 4], 5, ZZ)
[4, 2, 3, 1, 1]
```

```
sympy.polys.galoistools.gf_add_mul(f, g, h, p, K)
Returns f + g*h where f, g, h in GF(p)[x].

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_add_mul

```

```python
>>> gf_add_mul([3, 2, 4], [2, 2, 2], [1, 4], 5, ZZ)
[2, 3, 2, 2]
```

```
sympy.polys.galoistools.gf_sub_mul(f, g, h, p, K)
Compute f - g*h where f, g, h in GF(p)[x].

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_sub_mul

```

```python
>>> gf_sub_mul([3, 2, 4], [2, 2, 2], [1, 4], 5, ZZ)
[2, 3, 2, 2]
```
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_sub_mul

>>> gf_sub_mul([3, 2, 4], [2, 2, 2], [1, 4], 5, ZZ)
[3, 3, -2, 1]
```

`sympy.polys.galoistools.gf_expand(F, p, K)`
Expand results of `factor()` (page 2447) in GF(p)[x].

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_expand

>>> gf_expand([[3, 2, 4], [2, 2], [1, 4]], 5, ZZ)
[4, 3, 0, 3, 0, 1, 4, 1]
```

`sympy.polys.galoistools.gf_div(f, g, p, K)`
Division with remainder in GF(p)[x].

Given univariate polynomials f and g with coefficients in a finite field with p elements, returns polynomials q and r (quotient and remainder) such that \( f = q \cdot g + r \).

Consider polynomials \( x^3 + x + 1 \) and \( x^2 + x \) in GF(2):

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_div, gf_add_mul

>>> gf_div(ZZ.map([1, 0, 1, 1]), ZZ.map([1, 1, 0]), 2, ZZ)
([1, 1], [1])
```

As result we obtained quotient \( x + 1 \) and remainder 1, thus:

```python
>>> gf_add_mul(ZZ.map([1]), ZZ.map([1]), ZZ.map([1, 1, 0]), 2, ZZ)
[1, 0, 1, 1]
```

References

[R719], [R720]

`sympy.polys.galoistools.gf_rem(f, g, p, K)`
Compute polynomial remainder in GF(p)[x].
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_rem

>>> gf_rem(ZZ.map([1, 0, 1, 1]), ZZ.map([1, 1, 0]), 2, ZZ)
[1]
```

sympy.polys.galoistools.gf_quo(f, g, p, K)
Compute exact quotient in GF(p)[x].

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_quo

>>> gf_quo(ZZ.map([1, 0, 1, 1]), ZZ.map([1, 1, 0]), 2, ZZ)
[1, 1]
>>> gf_quo(ZZ.map([1, 0, 3, 2, 3]), ZZ.map([2, 2, 2]), 5, ZZ)
[3, 2, 4]
```

sympy.polys.galoistools.gf_exquo(f, g, p, K)
Compute polynomial quotient in GF(p)[x].

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_exquo

>>> gf_exquo(ZZ.map([1, 0, 3, 2, 3]), ZZ.map([2, 2, 2]), 5, ZZ)
[3, 2, 4]
>>> gf_exquo(ZZ.map([1, 0, 1, 1]), ZZ.map([1, 1, 0]), 2, ZZ)
Traceback (most recent call last):
...
ExactQuotientFailed: [1, 1, 0] does not divide [1, 0, 1, 1]
```

sympy.polys.galoistools.gf_lshift(f, n, K)
Efficiently multiply f by x**n.
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_lshift

>>> gf_lshift([3, 2, 4], 4, ZZ)
[3, 2, 4, 0, 0, 0, 0]
```

sympy.polys.galoistools.gf_rshift(f, n, K)
Efficiently divide f by x**n.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_rshift

>>> gf_rshift([1, 2, 3, 4, 0], 3, ZZ)
([1, 2], [3, 4, 0])
```

sympy.polys.galoistools.gf_pow(f, n, p, K)
Compute f**n in GF(p)[x] using repeated squaring.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_pow

>>> gf_pow([3, 2, 4], 3, 5, ZZ)
[2, 4, 4, 2, 2, 1, 4]
```

sympy.polys.galoistools.gf_pow_mod(f, n, g, p, K)
Compute f**n in GF(p)[x]/(g) using repeated squaring.
Given polynomials f and g in GF(p)[x] and a non-negative integer n, efficiently computes f**n (mod g) i.e. the remainder of f**n from division by g, using the repeated squaring algorithm.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_pow_mod

>>> gf_pow_mod(ZZ.map([3, 2, 4]), 3, ZZ.map([1, 1]), 5, ZZ)
[]
```
References

[R721]
sympy.polys.galoistools.gf_gcd(f, g, p, K)
  Euclidean Algorithm in GF(p)[x].

Examples

```python
gf_gcd(ZZ.map([3, 2, 4]), ZZ.map([2, 2, 3]), 5, ZZ)
[1, 3]
```

sympy.polys.galoistools.gf_lcm(f, g, p, K)
  Compute polynomial LCM in GF(p)[x].

Examples

```python
gf_lcm(ZZ.map([3, 2, 4]), ZZ.map([2, 2, 3]), 5, ZZ)
[1, 2, 0, 4]
```

sympy.polys.galoistools.gf_cofactors(f, g, p, K)
  Compute polynomial GCD and cofactors in GF(p)[x].

Examples

```python
gf_cofactors(ZZ.map([3, 2, 4]), ZZ.map([2, 2, 3]), 5, ZZ)
(([1, 3], [3, 3], [2, 1])
```

sympy.polys.galoistools.gf_gcdex(f, g, p, K)
  Extended Euclidean Algorithm in GF(p)[x].
  Given polynomials f and g in GF(p)[x], computes polynomials s, t and h, such that h = gcd(f, g) and s*f + t*g = h. The typical application of EEA is solving polynomial diophantine equations.
  Consider polynomials f = (x + 7) (x + 1), g = (x + 7) (x**2 + 1) in GF(11)[x]. Application of Extended Euclidean Algorithm gives:
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_gcdex, gf_mul, gf_add

>>> s, t, g = gf_gcdex(ZZ.map([1, 8, 7]), ZZ.map([1, 7, 1, 7]), 11, ZZ)
>>> s, t, g
([5, 6], [6], [1, 7])

As result we obtained polynomials \( s = 5x + 6 \) and \( t = 6 \), and additionally \( \text{gcd}(f, g) = x + 7 \). This is correct because:

>>> S = gf_mul(s, ZZ.map([1, 8, 7]), 11, ZZ)
>>> T = gf_mul(t, ZZ.map([1, 7, 1, 7]), 11, ZZ)

>>> gf_add(S, T, 11, ZZ) == [1, 7]
True

**References**

[R722]
sympy.polys.galoistools.gf_monic\((f, p, K)\)
Compute LC and a monic polynomial in \( \mathbb{F}_p[x] \).

**Examples**

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_monic

>>> gf_monic(ZZ.map([3, 2, 4]), 5, ZZ)
(3, [1, 4, 3])
```

sympy.polys.galoistools.gf_diff\((f, p, K)\)
Differentiate polynomial in \( \mathbb{F}_p[x] \).

**Examples**

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_diff

>>> gf_diff([3, 2, 4], 5, ZZ)
[1, 2]
```

sympy.polys.galoistools.gf_eval\((f, a, p, K)\)
Evaluate \( f(a) \) in \( \mathbb{F}_p \) using Horner scheme.

5.8. Topics
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_eval

>>> gf_eval([3, 2, 4], 2, 5, ZZ)
0
```

sympy.polys.galoistools.gf_multi_eval(f, A, p, K)
Evaluate \( f(a) \) for \( a \) in \([a_1, \ldots, a_n]\).

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_multi_eval

>>> gf_multi_eval([3, 2, 4], [0, 1, 2, 3, 4], 5, ZZ)
[4, 4, 0, 2, 0]
```

sympy.polys.galoistools.gf_compose(f, g, p, K)
Compute polynomial composition \( f(g) \) in \( GF(p)[x] \).

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_compose

>>> gf_compose([3, 2, 4], [2, 2, 2], 5, ZZ)
[2, 4, 0, 3, 0]
```

sympy.polys.galoistools.gf_compose_mod(g, h, f, p, K)
Compute polynomial composition \( g(h) \) in \( GF(p)[x]/(f) \).

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_compose_mod

>>> gf_compose_mod(ZZ.map([3, 2, 4]), ZZ.map([2, 2, 2]), ZZ.map([4, 3]), ZZ)
[4]
```

sympy.polys.galoistools.gf_trace_map(a, b, c, n, f, p, K)
Compute polynomial trace map in \( GF(p)[x]/(f) \).
Given a polynomial \( f \) in \( GF(p)[x] \), polynomials \( a, b, c \) in the quotient ring \( GF(p)[x]/(f) \) such that \( b = c^{**t} \pmod{f} \) for some positive power \( t \) of \( p \), and a positive integer \( n \), returns a mapping:
In factorization context, \(b = x^p \mod f\) and \(c = x \mod f\). This way we can efficiently compute trace polynomials in equal degree factorization routine, much faster than with other methods, like iterated Frobenius algorithm, for large degrees.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_trace_map

>>> gf_trace_map([1, 2], [4, 4], [1, 1], 4, [3, 2, 4], 5, ZZ)
((1, 3), (1, 3))
```

References

[R723]

sympy.polys.galoistools.gf_random\((n, p, K)\)
Generate a random polynomial in \(GF(p)[x]\) of degree \(n\).

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_random

>>> gf_random(10, 5, ZZ)
[1, 2, 3, 2, 1, 1, 1, 2, 0, 4, 2]
```

sympy.polys.galoistools.gf_irreducible\((n, p, K)\)
Generate random irreducible polynomial of degree \(n\) in \(GF(p)[x]\).

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_irreducible

>>> gf_irreducible(10, 5, ZZ)
[1, 4, 2, 2, 3, 2, 1, 4, 0, 4]
```

sympy.polys.galoistools.gf_irreducible_p\((f, p, K)\)
Test irreducibility of a polynomial \(f\) in \(GF(p)[x]\).
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_irreducible_p

>>> gf_irreducible_p(ZZ.map([1, 4, 2, 2, 3, 2, 4, 1, 4, 0, 4]), 5, ZZ)
True
>>> gf_irreducible_p(ZZ.map([3, 2, 4]), 5, ZZ)
False
```

`sympy.polys.galoistools.gf_sqf_p(f, p, K)`
Return True if f is square-free in GF(p)[x].

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_sqf_p

>>> gf_sqf_p(ZZ.map([3, 2, 4]), 5, ZZ)
True
>>> gf_sqf_p(ZZ.map([2, 4, 4, 2, 2, 1, 4]), 5, ZZ)
False
```

`sympy.polys.galoistools.gf_sqf_part(f, p, K)`
Return square-free part of a GF(p)[x] polynomial.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_sqf_part

>>> gf_sqf_part(ZZ.map([1, 1, 3, 0, 1, 0, 2, 2, 1]), 5, ZZ)
[1, 4, 3]
```

`sympy.polys.galoistools.gf_sqf_list(f, p, K, all=False)`
Return the square-free decomposition of a GF(p)[x] polynomial.

Given a polynomial f in GF(p)[x], returns the leading coefficient of f and a square-free decomposition f_1*e_1 f_2*e_2 ... f_k*e_k such that all f_i are monic polynomials and (f_i, f_j) for i != j are co-prime and e_1 ... e_k are given in increasing order. All trivial terms (i.e. f_i = 1) are not included in the output.

Consider polynomial f = x**11 + 1 over GF(11)[x]:

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import (...
gf_from_dict, gf_diff, gf_sqf_list, gf_pow,
...
)  # (continues on next page)
```
Note that $f'(x) = 0$:

```python
>>> gf_diff(f, 11, ZZ)
[]
```

This phenomenon does not happen in characteristic zero. However we can still compute square-free decomposition of $f$ using `gf_sqf()`:

```python
>>> gf_sqf_list(f, 11, ZZ)
(1, [(1, [1], 11)])
```

We obtained factorization $f = (x + 1)^{11}$. This is correct because:

```python
>>> gf_pow([1, 1], 11, 11, ZZ) == f
True
```

**References**

[R724]

`sympy.polys.galoistools.gf_Qmatrix(f, p, K)`

Calculate Berlekamp's $Q$ matrix.

**Examples**

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_Qmatrix

>>> gf_Qmatrix([3, 2, 4], 5, ZZ)
[[1, 0],
 [3, 4]]

>>> gf_Qmatrix([1, 0, 0, 0, 1], 5, ZZ)
[[1, 0, 0, 0, 0],
 [0, 4, 0, 0],
 [0, 0, 1, 0],
 [0, 0, 0, 4]]
```

`sympy.polys.galoistools.gf_Qbasis(Q, p, K)`

Compute a basis of the kernel of $Q$. 5.8. Topics 2699
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_Qmatrix, gf_Qbasis

>>> gf_Qbasis(gf_Qmatrix([[1, 0, 0, 0, 1], 5, ZZ], 5, ZZ))
[[1, 0, 0, 0], [0, 0, 1, 0]]

>>> gf_Qbasis(gf_Qmatrix([[3, 2, 4], 5, ZZ], 5, ZZ))
[[1, 0]]
```

`sympy.polys.galoistools.gf_berlekamp(f, p, K)`
Factor a square-free `f` in `GF(p)[x]` for small `p`.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_berlekamp

>>> gf_berlekamp([[1, 0, 0, 0, 1], 5, ZZ])
[[1, 0, 2], [1, 0, 3]]
```

`sympy.polys.galoistools.gf_zassenhaus(f, p, K)`
Factor a square-free `f` in `GF(p)[x]` for medium `p`.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_zassenhaus

>>> gf_zassenhaus(ZZ.map([1, 4, 3]), 5, ZZ)
[[1, 1], [1, 3]]
```

`sympy.polys.galoistools.gf_shoup(f, p, K)`
Factor a square-free `f` in `GF(p)[x]` for large `p`.

Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_shoup

>>> gf_shoup(ZZ.map([1, 4, 3]), 5, ZZ)
[[1, 1], [1, 3]]
```

`sympy.polys.galoistools.gf_factor_sqf(f, p, K, method=None)`
Factor a square-free polynomial `f` in `GF(p)[x]`.

Examples
Examples

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_factor_sqf

>>> gf_factor_sqf(ZZ.map([3, 2, 4]), 5, ZZ)
(3, [[[1, 1], [1, 3]]])
```

`sympy.polys.galoistools.gf_factor(f, p, K)`

Factor (non square-free) polynomials in GF(p)[x].

Given a possibly non square-free polynomial `f` in GF(p)[x], returns its complete factorization into irreducibles:

```
f_1(x)**e_1 f_2(x)**e_2 ... f_d(x)**e_d
```

where each `f_i` is a monic polynomial and gcd(`f_i`, `f_j`) == 1, for `i` != `j`. The result is given as a tuple consisting of the leading coefficient of `f` and a list of factors of `f` with their multiplicities.

The algorithm proceeds by first computing square-free decomposition of `f` and then iteratively factoring each of square-free factors.

Consider a non square-free polynomial `f = (7*x + 1) (x + 2)**2` in GF(11)[x]. We obtain its factorization into irreducibles as follows:

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.galoistools import gf_factor

>>> gf_factor(ZZ.map([5, 2, 7, 2]), 11, ZZ)
(5, [[1, 2], [1, 8], 2])
```

We arrived with factorization `f = 5 (x + 2) (x + 8)**2`. We did not recover the exact form of the input polynomial because we requested to get monic factors of `f` and its leading coefficient separately.

Square-free factors of `f` can be factored into irreducibles over GF(p) using three very different methods:

**Berlekamp**

  efficient for very small values of `p` (usually `p < 25`)

**Cantor-Zassenhaus**

  efficient on average input and with “typical” `p`

**Shoup-Kaltofen-Gathen**

  efficient with very large inputs and modulus

If you want to use a specific factorization method, instead of the default one, set `GF_FACTOR_METHOD` with one of berlekamp, zassenhaus or shoup values.
**References**

[R725] sympy.polys.galoistools.gf_value(f, a)
Value of polynomial ‘f’ at ‘a’ in field R.

**Examples**

```python
>>> from sympy.polys.galoistools import gf_value

>>> gf_value([1, 7, 2, 4], 11)
2204
```

sympy.polys.galoistools.gf_csolve(f, n)
To solve f(x) congruent 0 mod(n).

n is divided into canonical factors and f(x) cong 0 mod(p**e) will be solved for each factor. Applying the Chinese Remainder Theorem to the results returns the final answers.

**Examples**

Solve [1, 1, 7] congruent 0 mod(189):

```python
>>> from sympy.polys.galoistools import gf_csolve

>>> gf_csolve([1, 1, 7], 189)
[13, 49, 76, 112, 139, 175]
```

[R726]

**Manipulation of sparse, distributed polynomials and vectors**

Dense representations quickly require infeasible amounts of storage and computation time if the number of variables increases. For this reason, there is code to manipulate polynomials in a *sparse* representation. The Ring object and elements are implemented by the classes `PolyRing` (page 2634) and `PolyElement` (page 2635).

In commutative algebra, one often studies not only polynomials, but also *modules* over polynomial rings. The polynomial manipulation module provides rudimentary low-level support for finitely generated free modules. This is mainly used for Groebner basis computations (see there), so manipulation functions are only provided to the extend needed. They carry the prefix sdm_. Note that in examples, the generators of the free module are called $f_1, f_2, ...$

sympy.polys.distributedmodules.sdm_monomial_mul(M, X)
Multiply tuple X representing a monomial of $K[X]$ into the tuple M representing a monomial of $F$. 

2702 Chapter 5. API Reference
Examples

Multiplying $xy^3$ into $xf_1$ yields $x^2y^3f_1$:

```python
>>> from sympy.polys.distributedmodules import sdm_monomial_mul
>>> sdm_monomial_mul((1, 1, 0), (1, 3))
(1, 2, 3)
```

Examples

sympy.polys.distributedmodules.sdm_monomial_deg($M$)
Return the total degree of $M$

Examples

For example, the total degree of $x^2yf_5$ is 3:

```python
>>> from sympy.polys.distributedmodules import sdm_monomial_deg
>>> sdm_monomial_deg((5, 2, 1))
3
```

Examples

sympy.polys.distributedmodules.sdm_monomial_divides($A$, $B$)
Does there exist a (polynomial) monomial $X$ such that $XA = B$?

Examples

Positive examples:
In the following examples, the monomial is given in terms of $x$, $y$ and the generator(s), $f_1,f_2$ etc. The tuple form of that monomial is used in the call to sdm_monomial_divides. Note: the generator appears last in the expression but first in the tuple and other factors appear in the same order that they appear in the monomial expression.

$A = f_1$ divides $B = f_1$

```python
>>> from sympy.polys.distributedmodules import sdm_monomial_divides
>>> sdm_monomial_divides((1, 0, 0), (1, 0, 0))
True
```

$A = f_1$ divides $B = x^2yf_1$

```python
>>> sdm_monomial_divides((1, 0, 0), (1, 2, 1))
True
```

$A = xyf_5$ divides $B = x^2yf_5$

```python
>>> sdm_monomial_divides((5, 1, 1), (5, 2, 1))
True
```

Negative examples:

$A = f_1$ does not divide $B = f_2$

```python
>>> sdm_monomial_divides((1, 0, 0), (2, 0, 0))
False
```
\[ A = x f_1 \text{ does not divide } B = f_1 \]

```python
>>> sdm_monomial_divides((1, 1, 0), (1, 0, 0))
False
```

\[ A = x y^2 f_5 \text{ does not divide } B = y f_5 \]

```python
>>> sdm_monomial_divides((5, 1, 2), (5, 0, 1))
False
```

`sympy.polys.distributedmodules.sdm_LC(f, K)`

Returns the leading coefficient of \( f \).

`sympy.polys.distributedmodules.sdm_to_dict(f)`

Make a dictionary from a distributed polynomial.

`sympy.polys.distributedmodules.sdm_from_dict(d, O)`

Create an sdm from a dictionary.

Here \( O \) is the monomial order to use.

### Examples

```python
>>> from sympy.polys.distributedmodules import sdm_from_dict
>>> from sympy.polys import QQ, lex

>>> dic = {(1, 1, 0): QQ(1), (1, 0, 0): QQ(2), (0, 1, 0): QQ(0)}
>>> sdm_from_dict(dic, lex)
[((1, 1, 0), 1), ((1, 0, 0), 2)]
```

`sympy.polys.distributedmodules.sdm_add(f, g, O, K)`

Add two module elements \( f, g \).

Addition is done over the ground field \( K \), monomials are ordered according to \( O \).

### Examples

All examples use lexicographic order.

\[ (x y f_1) + (f_2) = f_2 + x y f_1 \]

```python
>>> from sympy.polys.distributedmodules import sdm_add
>>> from sympy.polys import lex, QQ

>>> sdm_add(((1, 1, 1), QQ(1)), ((2, 0, 0), QQ(2)), lex, QQ)
[((2, 0, 0), 1), ((1, 1, 1), 1)]
```

\[ (x y f_1) + (-x y f_1) = 0 \]

```python
>>> sdm_add(((1, 1, 1), QQ(1)), [(1, 1, 1), QQ(-1)], lex, QQ)
[]
```

\[ (f_1) + (2 f_1) = 3 f_1 \]

```python
>>> sdm_add(((1, 0, 0), QQ(1)), [(1, 0, 0), QQ(2)], lex, QQ)
[((1, 0, 0), 3)]
```
\[(y f_1) + (x f_1) = x f_1 + y f_1\]

```python
>>> sdm.add([[(1, 0, 1), QQ(1)]], [((1, 1, 0), QQ(1))], lex, QQ)
[((1, 1, 0), 1), ((1, 0, 1), 1)]
```

```  
sympy.polys.distributedmodules.sdm_zero()  
Return the zero module element.

sympy.polys.distributedmodules.sdm_deg(f)  
Degree of f.
This is the maximum of the degrees of all its monomials. Invalid if f is zero.

**Examples**

```python
>>> from sympy.polys.distributedmodules import sdm_deg
>>> sdm_deg([[(1, 2, 3), 1], ((10, 0, 1), 1), ((2, 3, 4), 4)]

```

```python
7
```  
sympy.polys.distributedmodules.sdm_from_vector(vec, O, K, **opts)  
Create an sdm from an iterable of expressions.

Coefficients are created in the ground field K, and terms are ordered according to monomial order O. Named arguments are passed on to the polys conversion code and can be used to specify for example generators.

**Examples**

```python
>>> from sympy.polys.distributedmodules import sdm_from_vector
>>> from sympy.abc import x, y, z
>>> from sympy.polys import QQ, lex
>>>
```  
```python
[sdm_from_vector([x**2+y**2, 2*z], lex, QQ

```

```python
[[(1, 0, 0, 1), 2), ((0, 2, 0, 0), 1), ((0, 0, 2, 0), 1)
```  
sympy.polys.distributedmodules.sdm_to_vector(f, gens, K, n=None)  
Convert sdm f into a list of polynomial expressions.

The generators for the polynomial ring are specified via gens. The rank of the module is guessed, or passed via n. The ground field is assumed to be K.
Examples

```python
>>> from sympy.polys.distributedmodules import sdm_to_vector
>>> from sympy.abc import x, y, z
>>> from sympy.polys import QQ
>>> f = [((1, 0, 0, 1), QQ(2)), ((0, 2, 0, 0), QQ(1)), ((0, 0, 2, 0), QQ(1))]
>>> sdm_to_vector(f, [x, y, z], QQ)
[x**2 + y**2, 2*z]
```

Polynomial factorization algorithms

Many variants of Euclid’s algorithm:

Classical remainder sequence

Let $K$ be a field, and consider the ring $K[X]$ of polynomials in a single indeterminate $X$ with coefficients in $K$. Given two elements $f$ and $g$ of $K[X]$ with $g \neq 0$ there are unique polynomials $q$ and $r$ such that $f = qg + r$ and $\deg(r) < \deg(g)$ or $r = 0$. They are denoted by $\text{quo}(f, g)$ (quotient) and $\text{rem}(f, g)$ (remainder), so we have the division identity

$$f = \text{quo}(f, g)g + \text{rem}(f, g).$$

It follows that every ideal $I$ of $K[X]$ is a principal ideal, generated by any element $\neq 0$ of minimum degree (assuming $I$ non-zero). In fact, if $g$ is such a polynomial and $f$ is any element of $I$, $\text{rem}(f, g)$ belongs to $I$ as a linear combination of $f$ and $g$, hence must be zero; therefore $f$ is a multiple of $g$.

Using this result it is possible to find a greatest common divisor (gcd) of any polynomials $f, g, \ldots$ in $K[X]$. If $I$ is the ideal formed by all linear combinations of the given polynomials with coefficients in $K[X]$, and $d$ is its generator, then every common divisor of the polynomials also divides $d$. On the other hand, the given polynomials are multiples of the generator $d$; hence $d$ is a gcd of the polynomials, denoted $\gcd(f, g, \ldots)$.

An algorithm for the gcd of two polynomials $f$ and $g$ in $K[X]$ can now be obtained as follows. By the division identity, $r = \text{rem}(f, g)$ is in the ideal generated by $f$ and $g$, as well as $f$ is in the ideal generated by $g$ and $r$. Hence the ideals generated by the pairs $(f, g)$ and $(g, r)$ are the same. Set $f_0 = f$, $f_1 = g$, and define recursively $f_i = \text{rem}(f_{i-2}, f_{i-1})$ for $i \geq 2$. The recursion ends after a finite number of steps with $f_{k+1} = 0$, since the degrees of the polynomials are strictly decreasing. By the above remark, all the pairs $(f_{i-1}, f_i)$ generate the same ideal. In particular, the ideal generated by $f$ and $g$ is generated by $f_k$ alone as $f_{k+1} = 0$. Hence $d = f_k$ is a gcd of $f$ and $g$.

The sequence of polynomials $f_0, f_1, \ldots, f_k$ is called the Euclidean polynomial remainder sequence determined by $(f, g)$ because of the analogy with the classical Euclidean algorithm for the gcd of natural numbers.

The algorithm may be extended to obtain an expression for $d$ in terms of $f$ and $g$ by using the full division identities to write recursively each $f_i$ as a linear combination of $f$ and $g$. This leads to an equation

$$d = uf + vg \quad (u, v \in K[X])$$

analogous to Bézout’s identity in the case of integers.
sympy.polys.euclidtools.dmp_half_gcdex(f, g, u, K)

Half extended Euclidean algorithm in \( F[X] \).

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)
```

sympy.polys.euclidtools.dmp_gcdex(f, g, u, K)

Extended Euclidean algorithm in \( F[X] \).

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)
```

sympy.polys.euclidtools.dmp_invert(f, g, u, K)

Compute multiplicative inverse of \( f \) modulo \( g \) in \( F[X] \).

**Examples**

```python
>>> from sympy.polys import ring, QQ
>>> R, x = ring("x", QQ)
```

sympy.polys.euclidtools.dmp_euclidean_prs(f, g, u, K)

Euclidean polynomial remainder sequence (PRS) in \( K[X] \).

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)
```

**Simplified remainder sequences**

Assume, as is usual, that the coefficient field \( K \) is the field of fractions of an integral domain \( A \). In this case the coefficients (numerators and denominators) of the polynomials in the Euclidean remainder sequence tend to grow very fast.

If \( A \) is a unique factorization domain, the coefficients may be reduced by cancelling common factors of numerators and denominators. Further reduction is possible noting that a gcd of polynomials in \( K[X] \) is not unique: it may be multiplied by any (non-zero) constant factor.

Any polynomial \( f \) in \( K[X] \) can be simplified by extracting the denominators and common factors of the numerators of its coefficients. This yields the representation \( f = cF \) where \( c \in K \) is the content of \( f \) and \( F \) is a primitive polynomial, i.e., a polynomial in \( A[X] \) with coprime coefficients.
It is possible to start the algorithm by replacing the given polynomials \( f \) and \( g \) with their primitive parts. This will only modify \( \text{rem}(f, g) \) by a constant factor. Replacing it with its primitive part and continuing recursively we obtain all the primitive parts of the polynomials in the Euclidean remainder sequence, including the primitive \( \text{gcd}(f, g) \).

This sequence is the **primitive polynomial remainder sequence**. It is an example of **general polynomial remainder sequences** where the computed remainders are modified by constant multipliers (or divisors) in order to simplify the results.

```python
sympy.polys.euclidtools.dmp_primitive_prs(f, g, u, K)
```

Primitive polynomial remainder sequence (PRS) in \( K[X] \).

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)
```

**Subresultant sequence**

The coefficients of the primitive polynomial sequence do not grow excessively, but the computation of the primitive parts requires extra processing effort. Besides, the method only works with fraction fields of unique factorization domains, excluding, for example, the general number fields.

Collins [Collins67] realized that the so-called **subresultant polynomials** of a pair of polynomials also form a generalized remainder sequence. The coefficients of these polynomials are expressible as determinants in the coefficients of the given polynomials. Hence (the logarithm of) their size only grows linearly. In addition, if the coefficients of the given polynomials are in the subdomain \( A \), so are those of the subresultant polynomials. This means that the subresultant sequence is comparable to the primitive remainder sequence without relying on unique factorization in \( A \).

To see how subresultants are associated with remainder sequences recall that all polynomials \( h \) in the sequence are linear combinations of the given polynomials \( f \) and \( g \)

\[
h = uf + vg
\]

with polynomials \( u \) and \( v \) in \( K[X] \). Moreover, as is seen from the extended Euclidean algorithm, the degrees of \( u \) and \( v \) are relatively low, with limited growth from step to step.

Let \( n = \text{deg}(f) \), and \( m = \text{deg}(g) \), and assume \( n \geq m \). If \( \text{deg}(h) = j < m \), the coefficients of the powers \( X^k \) \((k > j)\) in the products \( uf \) and \( vg \) cancel each other. In particular, the products must have the same degree, say, \( l \). Then \( \text{deg}(u) = l - n \) and \( \text{deg}(v) = l - m \) with a total of \( 2l - n - m + 2 \) coefficients to be determined.

On the other hand, the equality \( h = uf + vg \) implies that \( l - j \) linear combinations of the coefficients are zero, those associated with the powers \( X^i \) \((j < i \leq l)\), and one has a given non-zero value, namely the leading coefficient of \( h \).

To satisfy these \( l - j + 1 \) linear equations the total number of coefficients to be determined cannot be lower than \( l - j + 1 \), in general. This leads to the inequality \( l \geq n + m - j - 1 \). Taking \( l = n + m - j - 1 \), we obtain \( \text{deg}(u) = m - j - 1 \) and \( \text{deg}(v) = n - j - 1 \).

In the case \( j = 0 \) the matrix of the resulting system of linear equations is the **Sylvester matrix** \( S(f, g) \) associated to \( f \) and \( g \), an \((n + m) \times (n + m)\) matrix with coefficients of \( f \) and \( g \) as entries.
Its determinant is the resultant \( \text{res}(f, g) \) of the pair \((f, g)\). It is non-zero if and only if \( f \) and \( g \) are relatively prime.

For any \( j \) in the interval from 0 to \( m \) the matrix of the linear system is an \((n+m-2j) \times (n+m-2j)\) submatrix of the Sylvester matrix. Its determinant \( s_j(f, g) \) is called the \( j \) th \emph{scalar subresultant} of \( f \) and \( g \).

If \( s_j(f, g) \) is not zero, the associated equation \( h = uf + vg \) has a unique solution where \( \deg(h) = j \) and the leading coefficient of \( h \) has any given value; the one with leading coefficient \( s_j(f, g) \) is the \( j \) th \emph{subresultant polynomial} or, briefly, \emph{subresultant} of the pair \((f, g)\), and denoted \( S_j(f, g) \). This choice guarantees that the remaining coefficients are also certain subdeterminants of the Sylvester matrix. In particular, if \( f \) and \( g \) are in \( A[X] \), so is \( S_j(f, g) \) as well. This construction of subresultants applies to any \( j \) between 0 and \( m \) regardless of the value of \( s_j(f, g) \); if it is zero, then \( \deg(S_j(f, g)) < j \).

The properties of subresultants are as follows. Let \( n_0 = \deg(f) \), \( n_1 = \deg(g) \), \( n_2, \ldots, n_k \) be the decreasing sequence of degrees of polynomials in a remainder sequence. Let \( 0 \leq j \leq n_1 \); then

\begin{itemize}
  \item \( s_j(f, g) \neq 0 \) if and only if \( j = n_i \) for some \( i \).
  \item \( S_j(f, g) \neq 0 \) if and only if \( j = n_i \) or \( j = n_i - 1 \) for some \( i \).
\end{itemize}

Normally, \( n_{i-1} - n_i = 1 \) for \( 1 < i \leq k \). If \( n_{i-1} - n_i > 1 \) for some \( i \) (the abnormal case), then \( S_{n_{i-1}}(f, g) \) and \( S_{n_i}(f, g) \) are constant multiples of each other. Hence either one could be included in the polynomial remainder sequence. The former is given by smaller determinants, so it is expected to have smaller coefficients.

Collins defined the \emph{subresultant remainder sequence} by setting

\[ f_i = S_{n_{i-1}}(f, g) \quad (2 \leq i \leq k). \]

In the normal case, these are the same as the \( S_{n_i}(f, g) \). He also derived expressions for the constants \( \gamma_i \) in the remainder formulas

\[ \gamma_i f_i = \text{rem}(f_{i-2}, f_{i-1}) \]

in terms of the leading coefficients of \( f_1, \ldots, f_{i-1} \), working in the field \( K \).

Brown and Traub [BrownTraub71] later developed a recursive procedure for computing the coefficients \( \gamma_i \). Their algorithm deals with elements of the domain \( A \) exclusively (assuming \( f, g \in A[X] \)). However, in the abnormal case there was a problem, a division in \( A \) which could only be conjectured to be exact.

This was subsequently justified by Brown [Brown78] who showed that the result of the division is, in fact, a scalar subresultant. More specifically, the constant appearing in the computation of \( f_i \) is \( s_{n_{i-2}}(f, g) \) (Theorem 3). The implication of this discovery is that the scalar subresultants are computed as by-products of the algorithm, all but \( s_{n_k}(f, g) \) which is not needed after finding \( f_{k+1} = 0 \). Completing the last step we obtain all non-zero scalar subresultants, including the last one which is the resultant if this does not vanish.

```python
sympy.polys.euclidtools.dmp_inner_subresultants(f, g, u, K)
```

Subresultant PRS algorithm in \( K[X] \).
Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> f = 3*x**2*y - y**3 - 4
>>> g = x**2 + x*y**3 - 9

>>> a = 3*x*y**4 + y**3 - 27*y + 4
>>> b = -3*y**10 - 12*y**7 + y**6 - 54*y**4 + 8*y**3 + 729*y**2 - 216*y + 16

>>> prs = [f, g, a, b]
>>> sres = [[1], [1], [3, 0, 0, 0, 0], [-3, 0, 0, -12, 1, 0, -54, 8, 729, -216, 16]]

>>> R.dmp_inner_subresultants(f, g) == (prs, sres)
True
```

`sympy.polys.euclidtools.dmp_subresultants(f, g, u, K)`
Computes subresultant PRS of two polynomials in \( K[X] \).

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> f = 3*x**2*y - y**3 - 4
>>> g = x**2 + x*y**3 - 9

>>> a = 3*x*y**4 + y**3 - 27*y + 4
>>> b = -3*y**10 - 12*y**7 + y**6 - 54*y**4 + 8*y**3 + 729*y**2 - 216*y + 16

>>> R.dmp_subresultants(f, g) == [f, g, a, b]
True
```

`sympy.polys.euclidtools.dmp_prs_resultant(f, g, u, K)`
Resultant algorithm in \( K[X] \) using subresultant PRS.

5.8. Topics
Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> f = 3*x**2*y - y**3 - 4
>>> g = x**2 + x*y**3 - 9

>>> a = 3*x*y**4 + y**3 - 27*y + 4
>>> b = -3*y**10 - 12*y**7 + y**6 - 54*y**4 + 8*y**3 + 729*y**2 - 216*y
+ 16

>>> res, prs = R.dmp_prs_resultant(f, g)

>>> res == b # resultant has n-1 variables
False
>>> res == b.drop(x)
True
>>> prs == [f, g, a, b]
True
```

dmp_zz_modular_resultant(f, g, p, u, K)

Compute resultant of f and g modulo a prime p.

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> f = x + y + 2
>>> g = 2*x*y + x + 3

>>> R.dmp_zz_modular_resultant(f, g, 5)
-2*y**2 + 1
```

dmp_zz_collins_resultant(f, g, u, K)

Collins’s modular resultant algorithm in Z[X].

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y = ring("x,y", ZZ)

>>> f = x + y + 2
>>> g = 2*x*y + x + 3

>>> R.dmp_zz_collins_resultant(f, g)
-2*y**2 - 5*y + 1
```
**sympy.polys.euclidtools.dmp_qq_collins_resultant**\( (f, g, u, K0) \)
Collins’s modular resultant algorithm in \( Q[X] \).

**Examples**

```python
>>> from sympy.polys import ring, QQ
>>> R, x, y = ring("x,y", QQ)

>>> f = QQ(1,2)*x + y + QQ(2,3)
>>> g = 2*x*y + x + 3

>>> R.dmp_qq_collins_resultant(f, g)
-2*y**2 - 7/3*y + 5/6
```

**sympy.polys.euclidtools.dmp_resultant**\( (f, g, u, K, \text{includePRS}=False) \)
Computes resultant of two polynomials in \( K[X] \).

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> f = 3*x**2*y - y**3 - 4
>>> g = x**2 + x*y**3 - 9

>>> R.dmp_resultant(f, g)
-3*y**10 - 12*y**7 + y**6 - 54*y**4 + 8*y**3 + 729*y**2 - 216*y + 16
```

**sympy.polys.euclidtools.dmp_discriminant**\( (f, u, K) \)
Computes discriminant of a polynomial in \( K[X] \).

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y, z, t = ring("x,y,z,t", ZZ)

>>> R.dmp_discriminant(x**2*y + x*z + t)
-4*y*t + z**2
```

**sympy.polys.euclidtools.dmp_rr_prs_gcd**\( (f, g, u, K) \)
Computes polynomial GCD using subresultants over a ring.
Returns \( (h, \text{cff}, \text{cfg}) \) such that \( a = \gcd(f, g), \text{cff} = \text{quo}(f, h), \text{and} \text{cfg} = \text{quo}(g, h) \).
Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y, = ring("x,y", ZZ)

>>> f = x**2 + 2*x*y + y**2
>>> g = x**2 + x*y

>>> R.dmp_rr_prs_gcd(f, g)
(x + y, x + y, x)
```

SymPy.polys.euclidtools.dmp_ff_prs_gcd(f, g, u, K)
Computes polynomial GCD using subresultants over a field.
Returns (h, cff, cfg) such that \(a = \gcd(f, g), cff = \text{quo}(f, h), \text{and} \ cfg = \text{quo}(g, h)\).

Examples

```python
>>> from sympy.polys import ring, QQ
>>> R, x, y, = ring("x,y", QQ)

>>> f = QQ(1,2)*x**2 + x*y + QQ(1,2)*y**2
>>> g = x**2 + x*y

>>> R.dmp_ff_prs_gcd(f, g)
(x + y, 1/2*x + 1/2*y, x)
```

SymPy.polys.euclidtools.dmp_zz_heu_gcd(f, g, u, K)
Heuristic polynomial GCD in \(\mathbb{Z}[X]\).
Given univariate polynomials \(f\) and \(g\) in \(\mathbb{Z}[X]\), returns their GCD and cofactors, i.e. polynomials \(h, cff\) and \(cfg\) such that:

\[ h = \gcd(f, g), cff = \text{quo}(f, h) \text{ and } cfg = \text{quo}(g, h) \]

The algorithm is purely heuristic which means it may fail to compute the GCD. This will be signaled by raising an exception. In this case you will need to switch to another GCD method.

The algorithm computes the polynomial GCD by evaluating polynomials \(f\) and \(g\) at certain points and computing (fast) integer GCD of those evaluations. The polynomial GCD is recovered from the integer image by interpolation. The evaluation process reduces \(f\) and \(g\) variable by variable into a large integer. The final step is to verify if the interpolated polynomial is the correct GCD. This gives cofactors of the input polynomials as a side effect.
Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y, = ring("x,y", ZZ)

>>> f = x**2 + 2*x*y + y**2
>>> g = x**2 + x*y

>>> R.dmp ZZ heu gcd(f, g)
(x + y, x + y, x)
```

References

[R727] sympy.polys.euclidtools.dmp_qq_heu_gcd(f, g, u, K0)
Heuristic polynomial GCD in \( \mathbb{Q}[X] \).

Returns \((h, \text{cff}, \text{cfg})\) such that \(a = \gcd(f, g)\), \(\text{cff} = \text{quo}(f, h)\), and \(\text{cfg} = \text{quo}(g, h)\).

Examples

```python
>>> from sympy.polys import ring, QQ
>>> R, x,y, = ring("x,y", QQ)

>>> f = QQ(1,4)*x**2 + x*y + y**2
>>> g = QQ(1,2)*x**2 + x*y

>>> R.dmp qq heu gcd(f, g)
(x + 2*y, 1/4*x + 1/2*y, 1/2*x)
```

sympy.polys.euclidtools.dmp_inner_gcd(f, g, u, K)
Computes polynomial GCD and cofactors of \(f\) and \(g\) in \(K[X]\).

Returns \((h, \text{cff}, \text{cfg})\) such that \(a = \gcd(f, g)\), \(\text{cff} = \text{quo}(f, h)\), and \(\text{cfg} = \text{quo}(g, h)\).

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x,y, = ring("x,y", ZZ)

>>> f = x**2 + 2*x*y + y**2
>>> g = x**2 + x*y

>>> R.dmp inner gcd(f, g)
(x + y, x + y, x)
```
sympy.polys.euclidtools.dmp_gcd(f, g, u, K)
Computes polynomial GCD of \( f \) and \( g \) in \( K[X] \).

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y, = ring("x,y", ZZ)

>>> f = x**2 + 2*x*y + y**2
>>> g = x**2 + x*y

>>> R.dmp_gcd(f, g)
x + y
```

sympy.polys.euclidtools.dmp_lcm(f, g, u, K)
Computes polynomial LCM of \( f \) and \( g \) in \( K[X] \).

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y, = ring("x,y", ZZ)

>>> f = x**2 + 2*x*y + y**2
>>> g = x**2 + x*y

>>> R.dmp_lcm(f, g)
x**3 + 2*x**2*y + x*y**2
```

sympy.polys.euclidtools.dmp_content(f, u, K)
Returns GCD of multivariate coefficients.

**Examples**

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y, = ring("x,y", ZZ)

>>> R.dmp_content(2*x*y + 6*x + 4*y + 12)
2*y + 6
```

sympy.polys.euclidtools.dmp_primitive(f, u, K)
Returns multivariate content and a primitive polynomial.
Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y, = ring("x,y", ZZ)

>>> R.dmp_primitive(2*x*y + 6*x + 4*y + 12)
(2*y + 6, x + 2)
```

`sympy.polys.euclidtools.dmp_cancel(f, g, u, K, include=True)`
Cancel common factors in a rational function \( f/g \).

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)

>>> R.dmp_cancel(2*x**2 - 2, x**2 - 2*x + 1)
(2*x + 2, x - 1)
```

Polynomial factorization in characteristic zero:

`sympy.polys.factortools.dmp_trial_division(f, factors, u, K)`
Determine multiplicities of factors for a multivariate polynomial using trial division.

`sympy.polys.factortools.dmp_zz_mignotte_bound(f, u, K)`
Mignotte bound for multivariate polynomials in \( K[X] \).

`sympy.polys.factortools.dup_zz_hensel_step(m, f, g, h, s, t, K)`
One step in Hensel lifting in \( Z[x] \).
Given positive integer \( m \) and \( Z[x] \) polynomials \( f, g, h, s \) and \( t \) such that:

\[
\begin{align*}
f &= g*h \pmod{m} \\
sg + th &= 1 \pmod{m} \\
lc(f) & \text{ is not a zero divisor } \pmod{m} \\
lc(h) &= 1 \\
deg(f) &= \deg(g) + \deg(h) \\
deg(s) &< \deg(h) \\
deg(t) &< \deg(g)
\end{align*}
\]

returns polynomials \( G, H, S \) and \( T \), such that:

\[
\begin{align*}
f &= G*H \pmod{m**2} \\
S*G + T*H &= 1 \pmod{m**2}
\end{align*}
\]
References

[R728]
sympy.polys.factortools.dup_zz_hensel_lift(p, f, f_list, l, K)
Multifactor Hensel lifting in \( Z[x] \).
Given a prime \( p \), polynomial \( f \) over \( Z[x] \) such that \( lc(f) \) is a unit modulo \( p \), monic pair-wise coprime polynomials \( f_i \) over \( Z[x] \) satisfying:

\[
f = lc(f) \ f_1 \ldots \ f_r \pmod{p} \]

and a positive integer \( l \), returns a list of monic polynomials \( F_1, F_2, \ldots, F_r \) satisfying:

\[
f = lc(f) \ F_1 \ldots \ F_r \pmod{p^l} \]
\[
F_i = f_i \pmod{p}, \quad i = 1 \ldots r
\]

sympy.polys.factortools.dup_zz_zassenhaus(f, K)
Factor primitive square-free polynomials in \( Z[x] \).
sympy.polys.factortools.dup_zz_irreducible_p(f, K)
Test irreducibility using Eisenstein’s criterion.
sympy.polys.factortools.dup_cyclotomic_p(f, K, irreducible=False)
Efficiently test if \( f \) is a cyclotomic polynomial.

Examples

```python
>>> from sympy.polys import ring, ZZ
>>> R, x = ring("x", ZZ)

>>> f = x**16 + x**14 - x**10 + x**8 - x**6 + x**2 + 1
>>> R.dup_cyclotomic_p(f)
False

>>> g = x**16 + x**14 - x**10 - x**8 - x**6 + x**2 + 1
>>> R.dup_cyclotomic_p(g)
True
```
References

sympy.polys.factortools.dup_zz_cyclotomic_poly(n, K)
Efficiently generate n-th cyclotomic polynomial.

sympy.polys.factortools.dup_zz_cyclotomic_factor(f, K)
Efficiently factor polynomials $x^n - 1$ and $x^n + 1$ in $\mathbb{Z}[x]$.

Given a univariate polynomial $f$ in $\mathbb{Z}[x]$ returns a list of factors of $f$, provided that $f$ is in the form $x^n - 1$ or $x^n + 1$ for $n \geq 1$. Otherwise returns None.

Factorization is performed using cyclotomic decomposition of $f$, which makes this method much faster than any other direct factorization approach (e.g. Zassenhaus’s).

References

[R730]

sympy.polys.factortools.dup_zz_factor_sqf(f, K)
Factor square-free (non-primitive) polynomials in $\mathbb{Z}[x]$.

sympy.polys.factortools.dup_zz_factor(f, K)
Factor (non square-free) polynomials in $\mathbb{Z}[x]$.

Given a univariate polynomial $f$ in $\mathbb{Z}[x]$ computes its complete factorization $f_1, ..., f_n$ into irreducibles over integers:

$$f = \text{content}(f) \cdot f_1^{**k_1} \ldots f_n^{**k_n}$$

The factorization is computed by reducing the input polynomial into a primitive square-free polynomial and factoring it using Zassenhaus algorithm. Trial division is used to recover the multiplicities of factors.

The result is returned as a tuple consisting of:

$$(\text{content}(f), [(f_1, k_1), \ldots, (f_n, k_n))]$$

Examples

Consider the polynomial $f = 2 \cdot x^4 - 2$:

```python
>>> from sympy.polys import ring, ZZ
>>> R, x = ring("x", ZZ)
>>> R.dup_zz_factor(2*x**4 - 2)
(2, [(x - 1, 1), (x + 1, 1), (x**2 + 1, 1)])
```

In result we got the following factorization:

$$f = 2 \cdot (x - 1) \cdot (x + 1) \cdot (x^2 + 1)$$
Note that this is a complete factorization over integers, however over Gaussian integers we can factor the last term.

By default, polynomials \( x^{2n} - 1 \) and \( x^{2n} + 1 \) are factored using cyclotomic decomposition to speedup computations. To disable this behaviour set cyclotomic=False.

sympy.polys.factortools.dmp_zz_wang\((f, u, K, mod=None, seed=None)\)
Factor primitive square-free polynomials in \( \mathbb{Z}[X] \).
Given a multivariate polynomial \( f \) in \( \mathbb{Z}[x_1, ..., x_n] \), which is primitive and square-free in \( x_1 \), computes factorization of \( f \) into irreducibles over integers.
The procedure is based on Wang’s Enhanced Extended Zassenhaus algorithm. The algorithm works by viewing \( f \) as a univariate polynomial in \( \mathbb{Z}[x_2, ..., x_n][x_1] \), for which an evaluation mapping is computed:

\[
\begin{align*}
x_2 & \rightarrow a_2, \ldots, x_n & \rightarrow a_n
\end{align*}
\]

where \( a_i \), for \( i = 2, \ldots, n \), are carefully chosen integers. The mapping is used to transform \( f \) into a univariate polynomial in \( \mathbb{Z}[x_1] \), which can be factored efficiently using Zassenhaus algorithm. The last step is to lift univariate factors to obtain true multivariate factors. For this purpose a parallel Hensel lifting procedure is used.
The parameter seed is passed to _randint and can be used to seed randint (when an integer) or (for testing purposes) can be a sequence of numbers.

sympy.polys.factortools.dmp_zz_factor\((f, u, K)\)
Factor (non square-free) polynomials in \( \mathbb{Z}[X] \).
Given a multivariate polynomial \( f \) in \( \mathbb{Z}[x] \) computes its complete factorization \( f_1, \ldots, f_n \) into irreducibles over integers:
The factorization is computed by reducing the input polynomial into a primitive square-free polynomial and factoring it using Enhanced Extended Zassenhaus (EEZ) algorithm. Trial division is used to recover the multiplicities of factors.

The result is returned as a tuple consisting of:

```
(content(f), [(f_1, k_1), ..., (f_n, k_n))
```

Consider polynomial \( f = 2(x^2 - y^2) \):

```python
>>> from sympy.polys import ring, ZZ
>>> R, x, y = ring("x,y", ZZ)
>>> R.dmp_zz_factor(2*x**2 - 2*y**2)
(2, [(x - y, 1), (x + y, 1)])
```

In result we got the following factorization:

```
f = 2 (x - y) (x + y)
```

**Groebner basis algorithms**

Groebner bases can be used to answer many problems in computational commutative algebra. Their computation in rather complicated, and very performance-sensitive. We present here various low-level implementations of Groebner basis computation algorithms; please see the previous section of the manual for usage.

sympy.polys.groebnertools.groebner(seq, ring, method=None)

Computes Groebner basis for a set of polynomials in \( K[X] \).
Wrapper around the (default) improved Buchberger and the other algorithms for computing Groebner bases. The choice of algorithm can be changed via method argument or `sympy.polys.polyconfig.setup()` (page 2725), where method can be either `buchberger` or `f5b`.

```python
sympy.polys.groebnertools.spoly(p1, p2, ring)
```
Compute LCM(LM(p1), LM(p2))/LM(p1)*p1 - LCM(LM(p1), LM(p2))/LM(p2)*p2 This is the S-poly provided p1 and p2 are monic

```python
sympy.polys.groebnertools.red_groebner(G, ring)
```
Compute reduced Groebner basis, from BeckerWeispfenning93, p. 216
Selects a subset of generators, that already generate the ideal and computes a reduced Groebner basis for them.

```python
sympy.polys.groebnertools.is_groebner(G, ring)
```
Check if G is a Groebner basis.

```python
sympy.polys.groebnertools.is_minimal(G, ring)
```
Checks if G is a minimal Groebner basis.

```python
sympy.polys.groebnertools.is_reduced(G, ring)
```
Checks if G is a reduced Groebner basis.

```python
sympy.polys.fglmtools.matrix_fglm(F, ring, O_to)
```
Converts the reduced Groebner basis F of a zero-dimensional ideal w.r.t. 0_from to a reduced Groebner basis w.r.t. 0_to.

**References**

[R735] Groebner basis algorithms for modules are also provided:

```python
sympy.polys.distributedmodules.sdm_spoly(f, g, O, K, phantom=None)
```
Compute the generalized s-polynomial of f and g.
The ground field is assumed to be K, and monomials ordered according to O.
This is invalid if either of f or g is zero.
If the leading terms of f and g involve different basis elements of F, their s-poly is defined to be zero. Otherwise it is a certain linear combination of f and g in which the leading terms cancel. See [SCA, defn 2.3.6] for details.
If phantom is not None, it should be a pair of module elements on which to perform the same operation(s) as on f and g. The in this case both results are returned.
Examples

```python
>>> from sympy.polys.distributedmodules import sdm_spoly
>>> from sympy.polys import QQ, lex
>>> f = [(2, 1, 1), (1, 0, 1)]
>>> g = [(2, 3, 0), (1, 1)]
>>> h = [(1, 2, 3), (1)]
>>> sdm_spoly(f, h, lex, QQ)
[]
>>> sdm_spoly(f, g, lex, QQ)
[[(1, 2, 1), 1]]
```

`sympy.polys.distributedmodules.sdm_ecart(f)`
Compute the ecart of f.

This is defined to be the difference of the total degree of f and the total degree of the leading monomial of f [SCA, defn 2.3.7].

Invalid if f is zero.

Examples

```python
>>> from sympy.polys.distributedmodules import sdm_ecart
>>> sdm_ecart([(1, 2, 1), (1, 0, 1)])
0
>>> sdm_ecart([(2, 2, 1), (1, 5, 1)])
3
```

`sympy.polys.distributedmodules.sdm_nf_mora(f, G, O, K, phantom=None)`
Compute a weak normal form of f with respect to G and order O.

The ground field is assumed to be K, and monomials ordered according to O.

Weak normal forms are defined in [SCA, defn 2.3.3]. They are not unique. This function deterministically computes a weak normal form, depending on the order of G.

The most important property of a weak normal form is the following: if R is the ring associated with the monomial ordering (if the ordering is global, we just have \( R = K[x_1, \ldots, x_n] \), otherwise it is a certain localization thereof), I any ideal of R and G a standard basis for I, then for any \( f \in R \), we have \( f \in I \) if and only if \( NF(f|G) = 0 \).

This is the generalized Mora algorithm for computing weak normal forms with respect to arbitrary monomial orders [SCA, algorithm 2.3.9].

If phantom is not None, it should be a pair of “phantom” arguments on which to perform the same computations as on f, G, both results are then returned.

`sympy.polys.distributedmodules.sdm_groebner(G, NF, O, K, extended=False)`
Compute a minimal standard basis of G with respect to order O.

The algorithm uses a normal form NF, for example sdm_nf_mora. The ground field is assumed to be K, and monomials ordered according to O.

Let N denote the submodule generated by elements of G. A standard basis for N is a subset S of N, such that \( \text{in}(S) = \text{in}(N) \), where for any subset X of F, \( \text{in}(X) \) denotes the submodule generated by the initial forms of elements of X. [SCA, defn 2.3.2]
A standard basis is called minimal if no subset of it is a standard basis.

One may show that standard bases are always generating sets.

Minimal standard bases are not unique. This algorithm computes a deterministic result, depending on the particular order of $G$.

If extended=True, also compute the transition matrix from the initial generators to the groebner basis. That is, return a list of coefficient vectors, expressing the elements of the groebner basis in terms of the elements of $G$.

This functions implements the “sugar” strategy, see

**Options**

Options manager for Poly (page 2453) and public API functions.

```python
class sympy.polys.polyoptions.Options(gens, args, flags=None, strict=False)
```

Options manager for polynomial manipulation module.

**Examples**

```python
>>> from sympy.polys.polyoptions import Options
>>> from sympy.polys.polyoptions import build_options

>>> from sympy.abc import x, y, z

>>> Options((x, y, z), {'domain': 'ZZ'})
{'auto': False, 'domain': ZZ, 'gens': (x, y, z)}

>>> build_options((x, y, z), {'domain': 'ZZ'})
{'auto': False, 'domain': ZZ, 'gens': (x, y, z)}
```

**Options**

Modular GCD

sympy.polys.modulargcd.modgcd_univariate(f, g)
Computes the GCD of two polynomials in \(\mathbb{Z}[x]\) using a modular algorithm.

The algorithm computes the GCD of two univariate integer polynomials \(f\) and \(g\) by computing the GCD in \(\mathbb{Z}_p[x]\) for suitable primes \(p\) and then reconstructing the coefficients with the Chinese Remainder Theorem. Trial division is only made for candidates which are very likely the desired GCD.

Parameters
- **f**: PolyElement
  - univariate integer polynomial
- **g**: PolyElement
  - univariate integer polynomial

Returns
- **h**: PolyElement
  - GCD of the polynomials \(f\) and \(g\)
- **cfr**: PolyElement
cofactor of \( f \), i.e. \( \frac{f}{h} \)

**cfg** : PolyElement
cofactor of \( g \), i.e. \( \frac{g}{h} \)

### Examples

```python
>> from sympy.polys.modulargcd import modgcd_univariate
>> from sympy.polys import ring, ZZ

>> R, x = ring("x", ZZ)

>> f = x**5 - 1
>> g = x - 1

>> h, cff, cfg = modgcd_univariate(f, g)
>> h, cff, cfg
(x - 1, x**4 + x**3 + x**2 + x + 1, 1)

>> cff * h == f
True
>> cfg * h == g
True

>> f = 6*x**2 - 6
>> g = 2*x**2 + 4*x + 2

>> h, cff, cfg = modgcd_univariate(f, g)
>> h, cff, cfg
(2*x + 2, 3*x - 3, x + 1)

>> cff * h == f
True
>> cfg * h == g
True
```

sympy.polys.modulargcd.modgcd_multivariate(f, g)

Compute the GCD of two polynomials in \(\mathbb{Z}[x_0, \ldots, x_{k-1}]\) using a modular algorithm.

The algorithm computes the GCD of two multivariate integer polynomials \(f\) and \(g\) by calculating the GCD in \(\mathbb{Z}_p[x_0, \ldots, x_{k-1}]\) for suitable primes \(p\) and then reconstructing the coefficients with the Chinese Remainder Theorem. To compute the multivariate GCD over \(\mathbb{Z}_p\), the recursive subroutine \_modgcd_multivariate_p() (page 2730) is used. To verify the result in \(\mathbb{Z}[x_0, \ldots, x_{k-1}]\), trial division is done, but only for candidates which are very likely the desired GCD.

Parameters

\(f\) : PolyElement
  multivariate integer polynomial

\(g\) : PolyElement
  multivariate integer polynomial

Returns

\(h\) : PolyElement
  GCD of the polynomials \(f\) and \(g\)

\(\text{cff}\) : PolyElement
  cofactor of \(f\), i.e. \(\frac{f}{h}\)

\(\text{cfg}\) : PolyElement
  cofactor of \(g\), i.e. \(\frac{g}{h}\)

Examples

```python
>>> from sympy.polys.modulargcd import modgcd_multivariate
>>> from sympy.polys import ring, ZZ

>>> R, x, y = ring("x, y", ZZ)

>>> f = x**2 - y**2
>>> g = x**2 + 2*x*y + y**2

>>> h, cff, cfg = modgcd_multivariate(f, g)
>>> h, cff, cfg
(x + y, x - y, x + y)

>>> cff * h == f
True
>>> cfg * h == g
True
```
```python
>>> R, x, y, z = ring("x, y, z", ZZ)

>>> f = x*z**2 - y*z**2
>>> g = x**2*z + z

>>> h, cff, cfg = modgcd_multivariate(f, g)
>>> h, cff, cfg
(z, x*z - y*z, x**2 + 1)

>>> cff * h == f
True
>>> cfg * h == g
True
```

_modgcd_multivariate_p (page 2730)

References

1. [Monagan00]
2. [Brown71]

[Monagan00], [Brown71]
sympy.polys.modulargcd._modgcd_multivariate_p(f, g, p, degbound, contbound)
Compute the GCD of two polynomials in \( \mathbb{Z}_p[x_0, \ldots, x_{k-1}] \).
The algorithm reduces the problem step by step by evaluating the polynomials \( f \) and \( g \) at \( x_{k-1} = a \) for suitable \( a \in \mathbb{Z}_p \) and then calls itself recursively to compute the GCD in \( \mathbb{Z}_p[x_0, \ldots, x_{k-2}] \). If these recursive calls are successful for enough evaluation points, the GCD in \( k \) variables is interpolated, otherwise the algorithm returns None. Every time a GCD or a content is computed, their degrees are compared with the bounds. If a degree greater then the bound is encountered, then the current call returns None and a new evaluation point has to be chosen. If at some point the degree is smaller, the correspondent bound is updated and the algorithm fails.

Parameters

- **f**: PolyElement
  multivariate integer polynomial with coefficients in \( \mathbb{Z}_p \)
- **g**: PolyElement
  multivariate integer polynomial with coefficients in \( \mathbb{Z}_p \)
- **p**: Integer
  prime number, modulus of \( f \) and \( g \)
- **degbound**: list of Integer objects
  degbound[i] is an upper bound for the degree of the GCD of \( f \) and \( g \)
  in the variable \( x_i \)
- **contbound**: list of Integer objects
contbound[i] is an upper bound for the degree of the content of the GCD in \( \mathbb{Z}_p[x_1, x_0, \ldots, x_{n-1}] \), contbound[0] is not used can therefore be chosen arbitrarily.

**Returns**

- \( h : \text{PolyElement} \)
  - GCD of the polynomials \( f \) and \( g \) or None

**References**

1. [Monagan00]
2. [Brown71]

[Monagan00], [Brown71]

```python
sympy.polys.modulargcd.func_field_modgcd(f, g)
```

Compute the GCD of two polynomials \( f \) and \( g \) in \( \mathbb{Q}(\alpha)[x_0, \ldots, x_{n-1}] \) using a modular algorithm.

The algorithm first computes the primitive associate \( \tilde{m}_\alpha(z) \) of the minimal polynomial \( m_\alpha \) in \( \mathbb{Z}[z] \) and the primitive associates of \( f \) and \( g \) in \( \mathbb{Z}[x_1, \ldots, x_{n-1}][z]/(\tilde{m}_\alpha)[x_0] \). Then it computes the GCD in \( \mathbb{Q}(x_1, \ldots, x_{n-1})[z]/(m_\alpha(z))[x_0] \). This is done by calculating the GCD in \( \mathbb{Z}_p[x_1, \ldots, x_{n-1}][z]/(\tilde{m}_\alpha(z))[x_0] \) for suitable primes \( p \) and then reconstructing the coefficients with the Chinese Remainder Theorem and Rational Reconstruction. The GCD over \( \mathbb{Z}_p[x_1, \ldots, x_{n-1}][z]/(\tilde{m}_\alpha(z))[x_0] \) is computed with a recursive subroutine, which evaluates the polynomials at \( x_{n-1} = a \) for suitable evaluation points \( a \in \mathbb{Z}_p \) and then calls itself recursively until the ground domain does no longer contain any parameters. For \( \mathbb{Z}_p[z]/(\tilde{m}_\alpha(z))[x_0] \) the Euclidean Algorithm is used. The results of those recursive calls are then interpolated and Rational Function Reconstruction is used to obtain the correct coefficients. The results, both in \( \mathbb{Q}(x_1, \ldots, x_{n-1})[z]/(m_\alpha(z))[x_0] \) and \( \mathbb{Z}_p[x_1, \ldots, x_{n-1}][z]/(\tilde{m}_\alpha(z))[x_0] \), are verified by a fraction free trial division.

Apart from the above GCD computation some GCDs in \( \mathbb{Q}(\alpha)[x_0, \ldots, x_{n-1}] \) have to be calculated, because treating the polynomials as univariate ones can result in a spurious content of the GCD. For this `func_field_modgcd` is called recursively.

**Parameters**

- \( f, g : \text{PolyElement} \)
  - polynomials in \( \mathbb{Q}(\alpha)[x_0, \ldots, x_{n-1}] \)

**Returns**

- \( h : \text{PolyElement} \)
  - monic GCD of the polynomials \( f \) and \( g \)
- \( \text{cff} : \text{PolyElement} \)
  - cofactor of \( f \), i.e. \( \frac{f}{h} \)
- \( \text{cfg} : \text{PolyElement} \)
  - cofactor of \( g \), i.e. \( \frac{g}{h} \)

5.8. Topics 2731

```python
>>> from sympy.polys.modulargcd import func_field_modgcd
>>> from sympy.polys import AlgebraicField, QQ, ring
>>> from sympy import sqrt

>>> A = AlgebraicField(QQ, sqrt(2))
>>> R, x = ring('x', A)

>>> f = x**2 - 2
>>> g = x + sqrt(2)

>>> h, cff, cfg = func_field_modgcd(f, g)

>>> h == x + sqrt(2)
True
>>> cff * h == f
True
>>> cfg * h == g
True

>>> R, x, y = ring('x, y', A)

>>> f = x**2 + 2*sqrt(2)*x*y + 2*y**2
>>> g = x + sqrt(2)*y

>>> h, cff, cfg = func_field_modgcd(f, g)

>>> h == x + sqrt(2)*y
True
>>> cff * h == f
True
>>> cfg * h == g
True

>>> f = x + sqrt(2)*y
>>> g = x + y

>>> h, cff, cfg = func_field_modgcd(f, g)

>>> h == R.one
True
>>> cff * h == f
True
>>> cfg * h == g
True
```
Undocumented

Many parts of the polys module are still undocumented, and even where there is documentation it is scarce. Please contribute!

Series Manipulation using Polynomials

Any finite Taylor series, for all practical purposes is, in fact a polynomial. This module makes use of the efficient representation and operations of sparse polynomials for very fast multivariate series manipulations. Typical speedups compared to SymPy’s `series` method are in the range 20-100, with the gap widening as the series being handled gets larger.

All the functions expand any given series on some ring specified by the user. Thus, the coefficients of the calculated series depend on the ring being used. For example:

```python
>>> from sympy.polys import ring, QQ, RR
>>> from sympy.polys.ring_series import rs_sin
>>> R, x, y = ring('x, y', QQ)
>>> rs_sin(x*y, x, 5)
-1/6*x**3*y**3 + x*y
```

QQ stands for the Rational domain. Here all coefficients are rationals. It is recommended to use QQ with ring series as it automatically chooses the fastest Rational type.

Similarly, if a Real domain is used:

```python
>>> R, x, y = ring('x, y', RR)
>>> rs_sin(x*y, x, 5)
-0.166666666666667*x**3*y**3 + x*y
```

Though the definition of a polynomial limits the use of Polynomial module to Taylor series, we extend it to allow Laurent and even Puiseux series (with fractional exponents):

```python
>>> from sympy.polys.ring_series import rs_cos, rs_tan
>>> R, x, y = ring('x, y', QQ)
>>> rs_cos(x + x*y, x, 3)/x**3
-1/2*x**(-1)*y**2 - x**(-1)*y - 1/2*x**(-1) + x**(-3)
>>> rs_tan(x**QQ(2, 5)*y**QQ(1, 2), x, 2)
1/3*x**(6/5)*y**(3/2) + x**(2/5)*y**(1/2)
```

By default, PolyElement did not allow non-natural numbers as exponents. It converted a fraction to an integer and raised an error on getting negative exponents. The goal of the ring series module is fast series expansion, and not to use the polys module. The reason we use it as our backend is simply because it implements a sparse representation and most of the

5.8. Topics
basic functions that we need. However, this default behaviour of polys was limiting for ring series.

Note that there is no such constraint (in having rational exponents) in the data-structure used by polys- dict. Sparse polynomials (PolyElement) use the Python dict to store a polynomial term by term, where a tuple of exponents is the key and the coefficient of that term is the value. There is no reason why we can’t have rational values in the dict so as to support rational exponents.

So the approach we took was to modify sparse polys to allow non-natural exponents. And it turned out to be quite simple. We only had to delete the conversion to int of exponents in the __pow__ method of PolyElement. So:

```python
>>> x**QQ(3, 4)
x**(3/4)
```

and not 1 as was the case earlier.

Though this change violates the definition of a polynomial, it doesn’t break anything yet. Ideally, we shouldn’t modify polys in any way. But to have all the series capabilities we want, no other simple way was found. If need be, we can separate the modified part of polys from core polys. It would be great if any other elegant solution is found.

All series returned by the functions of this module are instances of the PolyElement class. To use them with other SymPy types, convert them to Expr:

```python
>>> from sympy.polys.ring_series import rs_exp
>>> from sympy.abc import a, b, c
>>> series = rs_exp(x, x, 5)
>>> a + series.as_expr()
a + x**4/24 + x**3/6 + x**2/2 + x + 1
```

### rs_series

Direct use of elementary ring series functions does give more control, but is limiting at the same time. Creating an appropriate ring for the desired series expansion and knowing which ring series function to call, are things not everyone might be familiar with.

*rs_series* is a function that takes an arbitrary Expr and returns its expansion by calling the appropriate ring series functions. The returned series is a polynomial over the simplest (almost) possible ring that does the job. It recursively builds the ring as it parses the given expression, adding generators to the ring when it needs them. Some examples:

```python
>>> from sympy.polys.ring_series import rs_series
>>> from sympy.functions.elementary.trigonometric import sin
>>> rs_series(sin(a + b), a, 5)
1/24*sin(b)*a**4 - 1/2*sin(b)*a**2 + sin(b) - 1/6*cos(b)*a**3 + cos(b)*a

>>> rs_series(sin(exp(a*b) + cos(a + c)), a, 2)
-sin(c)*cos(cos(c) + 1)*a + cos(cos(c) + 1)*a*b + sin(cos(c) + 1)

>>> rs_series(sin(a + b)*cos(a + c)*tan(a**2 + b), a, 2)
cos(b)*cos(c)*tan(b)*a - sin(b)*sin(c)*tan(b)*a + sin(b)*cos(c)*tan(b)
```

It can expand complicated multivariate expressions involving multiple functions and most importantly, it does so blazingly fast:
rs_series is over 300 times faster. Given an expression to expand, there is some fixed overhead to parse it. Thus, for larger orders, the speed improvement becomes more prominent:

To figure out the right ring for a given expression, rs_series uses the sring function, which in turn uses other functions of polys. As explained above, non-natural exponents are not allowed. But the restriction is on exponents and not generators. So, polys allows all sorts of symbolic terms as generators to make sure that the exponent is a natural number:

rs_series is not fully implemented yet. As of now, it supports only multivariate Taylor expansions of expressions involving sin, cos, exp and tan. Adding the remaining functions is not at all difficult and they will be gradually added. If you are interested in helping, read the comments in ring_series.py. Currently, it does not support Puiseux series (though the elementary functions do). This is expected to be fixed soon.

You can also add more functions to ring_series.py. Only elementary functions are supported currently. The long term goal is to replace SymPy’s current series method with rs_series.
Reference

Functions in this module carry the prefix `rs_`, standing for “ring series”. They manipulate finite power series in the sparse representation provided by `polys.ring.ring`.

Elementary functions

`sympy.polys.ring_series.rs_log(p, x, prec)`

The Logarithm of $p$ modulo $O(x**prec)$.

**Notes**

Truncation of integral $dx \ p**-1 \cdot d \ p/dx$ is used.

**Examples**

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_log
>>> R, x = ring('x', QQ)
>>> rs_log(1 + x, x, 8)
1/7*x**7 - 1/6*x**6 + 1/5*x**5 - 1/4*x**4 + 1/3*x**3 - 1/2*x**2 + x
```

`sympy.polys.ring_series.rs_LambertW(p, x, prec)`

Calculate the series expansion of the principal branch of the Lambert W function.

**Examples**

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_LambertW
>>> R, x, y = ring('x, y', QQ)
>>> rs_LambertW(x + x*y, x, 3)
-x**2*y**2 - 2*x**2*y - x*y**2 + x*y + x
```

See also:

`LambertW` (page 469)

`sympy.polys.ring_series.rs_exp(p, x, prec)`

Exponentiation of a series modulo $O(x**prec)$
Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_exp
>>> R, x = ring('x', QQ)
>>> rs_exp(x**2, x, 7)
1/6*x**6 + 1/2*x**4 + x**2 + 1
```

`sympy.polys.ring_series.rs_atan(p, x, prec)`

The arctangent of a series

Return the series expansion of the atan of p, about 0.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_atan
>>> R, x, y = ring('x, y', QQ)
>>> rs_atan(x + x*y, x, 4)
-1/3*x**3*y**3 - x**3*y**2 - x**3*y - 1/3*x**3 + x*y + x
```

See also:

`atan` (page 455)

`sympy.polys.ring_series.rs_asin(p, x, prec)`

Arcsine of a series

Return the series expansion of the asin of p, about 0.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_asin
>>> R, x, y = ring('x, y', QQ)
>>> rs_asin(x, x, 8)
5/112*x**7 + 3/40*x**5 + 1/6*x**3 + x
```

See also:

`asin` (page 454)

`sympy.polys.ring_series.rs_tan(p, x, prec)`

Tangent of a series.

Return the series expansion of the tan of p, about 0.
Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_tan
>>> R, x, y = ring('x, y', QQ)
>>> rs_tan(x + x*y, x, 4)
1/3*x**3*y**3 + x**3*y**2 + x**3*y + 1/3*x**3 + x*y + x
```

See also:

- `tan` (page 450)

```
sympy.polys.ring_series._tan1(p, x, prec)
```

Helper function of `rs_tan()` (page 2737).

Return the series expansion of tan of a univariate series using Newton’s method. It takes advantage of the fact that series expansion of atan is easier than that of tan.

Consider \( f(x) = y - \arctan(x) \) Let \( r \) be a root of \( f(x) \) found using Newton’s method. Then \( f(r) = 0 \) or \( y = \arctan(x) \) where \( x = \tan(y) \) as required.

```
sympy.polys.ring_series.rs_cot(p, x, prec)
```

Cotangent of a series

Return the series expansion of the cot of \( p \), about 0.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_cot
>>> R, x, y = ring('x, y', QQ)
>>> rs_cot(x, x, 6)
-2/945*x**5 - 1/45*x**3 - 1/3*x + x**(-1)
```

See also:

- `cot` (page 451)

```
sympy.polys.ring_series.rs_sin(p, x, prec)
```

Sine of a series

Return the series expansion of the sin of \( p \), about 0.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_sin
>>> R, x, y = ring('x, y', QQ)
>>> rs_sin(x + x*y, x, 4)
-1/6*x**3*y**3 - 1/2*x**3*y**2 - 1/2*x**3*y - 1/6*x**3 + x*y + x
```

(continues on next page)
(continued from previous page)

```python
>>> rs_sin(x**QQ(3, 2) + x*y**QQ(7, 5), x, 4)
-1/2*x**(7/2)*y**(14/5) - 1/6*x**3*y**(21/5) + x**(3/2) + x*y**(7/5)
```

See also:

sin (page 449)

sympy.polys.ring_series.rs_cos(p, x, prec)

Cosine of a series

Return the series expansion of the cos of p, about 0.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_cos
>>> R, x, y = ring('x, y', QQ)
>>> rs_cos(x + x*y, x, 4)
-1/2*x**2*y**2 - x**2*y - 1/2*x**2 + 1
>>> rs_cos(x + x*y, x, 4)/x**QQ(7, 5)
-1/2*x**(3/5)*y**2 - x**(3/5)*y - 1/2*x**(3/5) + x**(-7/5)
```

See also:

cos (page 450)

sympy.polys.ring_series.rs_cos_sin(p, x, prec)

Return the tuple (rs_cos(p, x, prec), `rs_sin(p, x, prec)`).

Is faster than calling rs_cos and rs_sin separately

sympy.polys.ring_series.rs_atanh(p, x, prec)

Hyperbolic arctangent of a series

Return the series expansion of the atanh of p, about 0.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_atanh
>>> R, x, y = ring('x, y', QQ)
>>> rs_atanh(x + x*y, x, 4)
1/3*x**3*y**3 + x**3*y**2 + x**3*y + 1/3*x**3 + x*y + x
```

See also:

atanh (page 464)

sympy.polys.ring_series.rs_sinh(p, x, prec)

Hyperbolic sine of a series

Return the series expansion of the sinh of p, about 0.

5.8. Topics 2739
Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_sinh
>>> R, x, y = ring('x, y', QQ)
>>> rs_sinh(x + x*y, x, 4)
1/6*x**3*y**3 + 1/2*x**3*y**2 + 1/2*x**3*y + 1/6*x**3 + x*y + x
```

See also:

`sinh` (page 461)

sympy.polys.ring_series.rs_cosh(p, x, prec)

Hyperbolic cosine of a series

Return the series expansion of the cosh of p, about 0.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_cosh
>>> R, x, y = ring('x, y', QQ)
>>> rs_cosh(x + x*y, x, 4)
1/2*x**2*y**2 + x**2*y + 1/2*x**2 + 1
```

See also:

`cosh` (page 461)

sympy.polys.ring_series.rs_tanh(p, x, prec)

Hyperbolic tangent of a series

Return the series expansion of the tanh of p, about 0.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_tanh
>>> R, x, y = ring('x, y', QQ)
>>> rs_tanh(x + x*y, x, 4)
-1/3*x**3*y**3 - x**3*y**2 - x**3*y - 1/3*x**3 + x*y + x
```

See also:

`tanh` (page 462)

sympy.polys.ring_series.rs_hadamard_exp(p1, inverse=False)

Return sum \( f_i/i!*x**i \) from sum \( f_i*x**i \), where \( x \) is the first variable.

If \( \text{inverse} = \text{True} \) return sum \( f_i*i!*x**i \)
Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_hadamard_exp
>>> R, x = ring('x', QQ)
>>> p = 1 + x + x**2 + x**3
>>> rs_hadamard_exp(p)
1/6*x**3 + 1/2*x**2 + x + 1
```

Operations

sympy.polys.ring_series.rs_mul(p1, p2, x, prec)
Return the product of the given two series, modulo $O(x^{\text{prec}})$.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_mul
>>> R, x = ring('x', QQ)
>>> p1 = x**2 + 2*x + 1
>>> p2 = x + 1
>>> rs_mul(p1, p2, x, 3)
3*x**2 + 3*x + 1
```

sympy.polys.ring_series.rs_square(p1, x, prec)
Square the series modulo $O(x^{\text{prec}})$

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_square
>>> R, x = ring('x', QQ)
>>> p = x**2 + 2*x + 1
>>> rs_square(p, x, 3)
6*x**2 + 4*x + 1
```

sympy.polys.ring_series.rs_pow(p1, n, x, prec)
Return $p1^{n}$ modulo $O(x^{\text{prec}})$
Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_pow

>>> R, x = ring('x', QQ)
>>> p = x + 1
>>> rs_pow(p, 4, x, 3)
6*x**2 + 4*x + 1
```

sympy.polys.ring_series.rs_series_inversion(p, x, prec)

Multivariate series inversion $1/p$ modulo $O(x^{\text{prec}})$.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_series_inversion

>>> R, x, y = ring('x, y', QQ)
>>> rs_series_inversion(1 + x*y**2, x, 4)
-x**3*y**6 + x**2*y**4 - x*y**2 + 1
>>> rs_series_inversion(1 + x*y**2, y, 4)
-x*y**2 + 1
>>> rs_series_inversion(x + x**2, x, 4)
x**3 - x**2 + x - 1 + x**(-1)
```

sympy.polys.ring_series.rs_series_reversion(p, x, n, y)

Reversion of a series.

$p$ is a series with $O(x^n)$ of the form $p = ax + f(x)$ where $a$ is a number different from 0.

$f(x) = \sum_{k=2}^{n-1} a_k x_k$

**Parameters**

- $a_k$: Can depend polynomially on other variables, not indicated.
  - $x$: Variable with name x.
  - $y$: Variable with name y.

**Returns**

Solve $p = y$, that is, given $ax + f(x) - y = 0$,

find the solution $x = r(y)$ up to $O(y^n)$.

**Algorithm**

If $r_i$ is the solution at order $i$, then: $ar_i + f(r_i) - y = O(y^{i+1})$

and if $r_{i+1}$ is the solution at order $i + 1$, then: $ar_{i+1} + f(r_{i+1}) - y = O(y^{i+2})$

We have, $r_{i+1} = r_i + e$, such that, $ae + f(r_i) = O(y^{i+2})$ or $e = -f(r_i)/a$

So we use the recursion relation: $r_{i+1} = r_i - f(r_i)/a$ with the boundary condition: $r_1 = y$
Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_series_reversion, rs_trunc
>>> R, x, y, a, b = ring('x, y, a, b', QQ)
>>> p = x - x**2 - 2*b*x**2 + 2*a*b*x**2
>>> p1 = rs_series_reversion(p, x, 3, y); p1
-2*y**2*a*b + 2*y**2*b + y**2 + y
>>> rs_trunc(p.compose(x, p1), y, 3)
```

sympy.polys.ring_series.rs_nth_root(p, n, x, prec)
Multivariate series expansion of the nth root of p.

**Parameters**

- **p**: Expr
  The polynomial to computer the root of.
- **n**: integer
  The order of the root to be computed.
- **x**: PolyElement (page 2635)
- **prec**: integer
  Order of the expanded series.

**Notes**

The result of this function is dependent on the ring over which the polynomial has been defined. If the answer involves a root of a constant, make sure that the polynomial is over a real field. It cannot yet handle roots of symbols.

Examples

```python
>>> from sympy.polys.domains import QQ, RR
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_nth_root
>>> R, x, y = ring('x, y', QQ)
>>> rs_nth_root(1 + x + x*y, -3, x, 3)
2/9*x**2*y**2 + 4/9*x**2*y + 2/9*x**2 - 1/3*x*y - 1/3*x + 1
>>> R, x, y = ring('x, y', RR)
>>> rs_nth_root(3 + x + x*y, 3, x, 2)
0.160249952256379*x*y + 0.160249952256379*x + 1.44224957030741
```

sympy.polys.ring_series.rs_trunc(p1, x, prec)
Truncate the series in the x variable with precision prec, that is, modulo \(O(x^{**\text{prec}})\)
Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_trunc
>>> R, x = ring('x', QQ)
>>> p = x**10 + x**5 + x + 1
>>> rs_trunc(p, x, 12)
\xrightarrow{x^{10} + x^{5} + x + 1}
>>> rs_trunc(p, x, 10)
\xrightarrow{x^{5} + x + 1}
```

`sympy.polys.ring_series.rs_subs(p, rules, x, prec)`
Substitution with truncation according to the mapping in rules.
Return a series with precision prec in the generator x
Note that substitutions are not done one after the other

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_subs
>>> R, x, y = ring('x, y', QQ)
>>> p = x**2 + y**2
>>> rs_subs(p, {x: x+y, y: x+2*y}, x, 3)
6*x**2*y**2 + x**2 + 4*x*y**3 + y**4
>>> rs_subs(rs_subs(p, {x: x+y}, x, 3), {y: x+2*y}, x, 3)
5*x**2 + 12*x*y + 8*y**2
```

**Parameters**
- `p`: `PolyElement` (page 2635) Input series.
- `rules`: dict with substitution mappings.
- `x`: `PolyElement` (page 2635) in which the series truncation is to be done.
- `prec`: `Integer` (page 1038) order of the series after truncation.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_subs
>>> R, x, y = ring('x, y', QQ)
>>> rs_subs(x**2+y**2, {y: (x+y)**2}, x, 3)
6*x**2*y**2 + x**2 + 4*x*y**3 + y**4
```

`sympy.polys.ring_series.rs_diff(p, x)`
Return partial derivative of p with respect to x.
Parameters

\(x: PolyElement\) (page 2635) with respect to which \(p\) is differentiated.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_diff
>>> R, x, y = ring('x, y', QQ)
>>> p = x + x**2*y**3
>>> rs_diff(p, x)
2*x*y**3 + 1
```

```
sympy.polys.ring_series.rs_integrate(p, x)
Integrate \(p\) with respect to \(x\).

Parameters

\(x: PolyElement\) (page 2635) with respect to which \(p\) is integrated.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_integrate
>>> R, x, y = ring('x, y', QQ)
>>> p = x + x**2*y**3
>>> rs_integrate(p, x)
1/3*x**3*y**3 + 1/2*x**2
```

```
sympy.polys.ring_series.rs_newton(p, x, prec)
Compute the truncated Newton sum of the polynomial \(p\)

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_newton
>>> R, x = ring('x', QQ)
>>> p = x**2 - 2
>>> rs_newton(p, x, 5)
8*x**4 + 4*x**2 + 2
```

```
sympy.polys.ring_series.rs_compose_add(p1, p2)
compute the composed sum \(\prod(p2(x - \text{beta})\) for beta root of \(p1\)

5.8. Topics
Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_compose_add
>>> R, x = ring('x', QQ)
>>> f = x**2 - 2
>>> g = x**2 - 3
>>> rs_compose_add(f, g)
```
```
x**4 - 10*x**2 + 1
```

References

[R755]

Utility functions

sympy.polys.ring_series.rs_is_puiseux(p, x)

Test if p is Puiseux series in x.

Raise an exception if it has a negative power in x.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_is_puiseux
>>> R, x = ring('x', QQ)
>>> p = x**QQ(2,5) + x**QQ(2,3) + x
>>> rs_is_puiseux(p, x)
```
```
True
```

sympy.polys.ring_series.rs_puiseux(f, p, x, prec)

Return the puiseux series for \(f(p, x, \text{prec})\).

To be used when function f is implemented only for regular series.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_puiseux, rs_exp
>>> R, x = ring('x', QQ)
>>> p = x**QQ(2,5) + x**QQ(2,3) + x
>>> rs_puiseux(rs_exp, p, x, 1)
```
```
1/2*x**(4/5) + x**(2/3) + x**(2/5) + 1
```

sympy.polys.ring_series.rs_puiseux2(f, p, q, x, prec)

Return the puiseux series for \(f(p, q, x, \text{prec})\).

To be used when function f is implemented only for regular series.
sympy.polys.ring_series.rs_series_from_list(p, c, x, prec, concur=1)

Return a series \( \text{sunc}[n] \ast p \ast n \) modulo \( O(x \ast prec) \).

It reduces the number of multiplications by summing concurrently.

\[
ax = [1, p, p \ast 2, \ldots, p \ast (J - 1)] \quad s = \sum(c[i] \ast ax[i] \text{ for } i \text{ in } \text{range}(r, (r + 1) \ast J)) \ast p \ast ((K - 1) \ast J)
\]

with \( K >= (n + 1)/J \)

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_series_from_list, rs_trunc
>>> R, x = ring('x', QQ)
>>> p = x**2 + x + 1
>>> c = [1, 2, 3]
>>> rs_series_from_list(p, c, x, 4)
6*x**3 + 11*x**2 + 8*x + 6
>>> rs_trunc(1 + 2*p + 3*p**2, x, 4)
6*x**3 + 11*x**2 + 8*x + 6
>>> pc = R.from_list(list(reversed(c)))
>>> rs_trunc(pc.compose(x, p), x, 4)
6*x**3 + 11*x**2 + 8*x + 6
```

defined as an attributes access.

sympy.polys.ring_series.rs_fun(p, f, *args)

Function of a multivariate series computed by substitution.

The case with f method name is used to compute \( rs\_tan \) and \( rs\_nth\_root \) of a multivariate series:

\[
rs\_fun(p, tan, iv, prec)
\]

tan series is first computed for a dummy variable \( x \), i.e, \( rs\_tan(x, iv, prec) \). Then we substitute \( x \) with \( p \) to get the desired series

Parameters

- **p**: `PolyElement` (page 2635) The multivariate series to be expanded.
- **f**: `ring_series` function to be applied on \( p \).
- **args[-2]**: `PolyElement` (page 2635) with respect to which, the series is to be expanded.
- **args[-1]**: Required order of the expanded series.

Examples

```python
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import rs_fun, _tan1
>>> R, x, y = ring('x, y', QQ)
>>> p = x + x*y + x**2*y + x**3*y**2
>>> rs_fun(p, _tan1, x, 4)
1/3*x**3*y**3 + 2*x**3*y**2 + x**3*y + 1/3*x**3 + x**2*y + x*y + x
```
SymPy Documentation, Release 1.12.1

sympy.polys.ring_series.mul_xin(p, i, n)

Return $p \times x_i \times n$.

$x_i$ is the $i$th variable in $p$.

sympy.polys.ring_series.pow_xin(p, i, n)

```
>>> from sympy.polys.domains import QQ
>>> from sympy.polys.rings import ring
>>> from sympy.polys.ring_series import pow_xin
>>> R, x, y = ring('x, y', QQ)
>>> p = x**QQ(2,5) + x + x**QQ(2,3)
>>> index = p.ring.gens.index(x)
>>> pow_xin(p, index, 15)
x**15 + x**10 + x**6
```

Literature

The following is a non-comprehensive list of publications that were used as a theoretical foundation for implementing polynomials manipulation module.

Poly solvers

This module provides functions for solving systems of linear equations that are used internally in sympy. Low-level linear systems solver.

sympy.polys.solvers.solve_lin_sys(eqs, ring, _raw=True)

Solve a system of linear equations from a PolynomialRing

Parameters

  eqs: list[PolyElement]

  The linear equations to be solved as elements of a PolynomialRing (assumed equal to zero).

  ring: PolynomialRing

  The polynomial ring from which eqs are drawn. The generators of this ring are the unknowns to be solved for and the domain of the ring is the domain of the coefficients of the system of equations.

  _raw: bool

  If _raw is False, the keys and values in the returned dictionary will be of type Expr (and the unit of the field will be removed from the keys) otherwise the low-level polys types will be returned, e.g. PolyElement: PythonRational.

Returns

None if the system has no solution.

dict[Symbol, Expr] if _raw=False

dict[Symbol, DomainElement] if _raw=True.
**Explanation**

Solves a system of linear equations given as PolyElement instances of a PolynomialRing. The basic arithmetic is carried out using instance of DomainElement which is more efficient than Expr (page 999) for the most common inputs.

While this is a public function it is intended primarily for internal use so its interface is not necessarily convenient. Users are suggested to use the sympy.solvers.solveset.linsolve() (page 919) function (which uses this function internally) instead.

**Examples**

```python
>>> from sympy import symbols
>>> from sympy.polys.solvers import solve_lin_sys, sympy_eqs_to_ring
>>> x, y = symbols('x, y')
>>> eqs = [x - y, x + y - 2]
>>> eqs_ring, ring = sympy_eqs_to_ring(eqs, [x, y])
>>> solve_lin_sys(eqs_ring, ring)
{y: 1, x: 1}
```

Passing `_raw=False` returns the same result except that the keys are Expr rather than low-level poly types.

```python
>>> solve_lin_sys(eqs_ring, ring, _raw=False)
{x: 1, y: 1}
```

**See also:**

sympy_eqs_to_ring (page 2750)
preparstheinputs to solve_lin_sys.

linsolve (page 919)
linsolve uses solve_lin_sys internally.

sympy.solvers.solvers.solve (page 882)
solve uses solve_lin_sys internally.

sympy.polys.solvers.eqs_to_matrix(eqs_coeffs, eqs_rhs, gens, domain)
Get matrix from linear equations in dict format.

**Parameters**

eqs_coeffs: list[dict[Symbol, DomainElement]]
The left hand sides of the equations as dicts mapping from symbols to coefficients where the coefficients are instances of DomainElement.

eqs_rhs: list[DomainElements]
The right hand sides of the equations as instances of DomainElement.

gens: list[Symbol]
The unknowns in the system of equations.

domain: Domain
The domain for coefficients of both lhs and rhs.
**Returns**

The augmented matrix representation of the system as a DomainMatrix.

**Explanation**

Get the matrix representation of a system of linear equations represented as dicts with low-level DomainElement coefficients. This is an *internal* function that is used by solve_lin_sys.

**Examples**

```python
>>> from sympy import symbols, ZZ
>>> from sympy.polys.solvers import eqs_to_matrix
>>> x, y = symbols('x, y')
>>> eqs_coeff = [{x: ZZ(1), y: ZZ(1)}, {x: ZZ(1), y: ZZ(-1)}]
>>> eqs_rhs = [ZZ(0), ZZ(-1)]
>>> eqs_to_matrix(eqs_coeff, eqs_rhs, [x, y], ZZ)
DomainMatrix([[1, 1, 0], [1, -1, 1]], (2, 3), ZZ)
```

**See also:**

`solve_lin_sys` (page 2748)

Uses `eqs_to_matrix()` (page 2749) internally

sympy.polys.solvers.**sympy_eqs_to_ring**(eqs, symbols)

Convert a system of equations from Expr to a PolyRing

**Parameters**

- **eqs**: List of Expr
  A list of equations as Expr instances

- **symbols**: List of Symbol
  A list of the symbols that are the unknowns in the system of equations.

**Returns**

Tuple[List[PolyElement], Ring]: The equations as PolyElement instances and the ring of polynomials within which each equation is represented.

**Explanation**

High-level functions like solve expect Expr as inputs but can use solve_lin_sys internally. This function converts equations from Expr to the low-level poly types used by the solve_lin_sys function.
Examples

```python
>>> from sympy import symbols
>>> from sympy.polys.solvers import sympy_eqs_to_ring
>>> a, x, y = symbols('a, x, y')
>>> eqs = [x-y, x+a*y]
>>> eqs_ring, ring = sympy_eqs_to_ring(eqs, [x, y])
>>> eqs_ring
[x - y, x + a*y]
>>> type(eqs_ring[0])
<class 'sympy.polys.rings.PolyElement'>
>>> ring
ZZ(a)[x,y]
```

With the equations in this form they can be passed to `solve_lin_sys`:

```python
>>> from sympy.polys.solvers import solve_lin_sys
>>> solve_lin_sys(eqs_ring, ring)
{y: 0, x: 0}
```

`sympy.polys.solvers._solve_lin_sys(eqs_coeffs, eqs_rhs, ring)`
Solve a linear system from dict of PolynomialRing coefficients

Explanation

This is an internal function used by `solve_lin_sys()` (page 2748) after the equations have been preprocessed. The role of this function is to split the system into connected components and pass those to `_solve_lin_sys_component()` (page 2751).

Examples

Setup a system for $x - y = 0$ and $x + y = 2$ and solve:

```python
>>> from sympy import symbols, sring
>>> from sympy.polys.solvers import _solve_lin_sys
>>> x, y = symbols('x, y')
>>> R, (xr, yr) = sring([x, y], [x, y])
>>> eqs = [{xr:R.one, yr:-R.one}, {xr:R.one, yr:R.one}]
>>> eqs_rhs = [R.zero, -2*R.one]
>>> _solve_lin_sys(eqs, eqs_rhs, R)
{y: 1, x: 1}
```

See also:

`solve_lin_sys` (page 2748)
This function is used internally by `solve_lin_sys()` (page 2748).

`sympy.polys.solvers._solve_lin_sys_component(eqs_coeffs, eqs_rhs, ring)`
Solve a linear system from dict of PolynomialRing coefficients
Explanation

This is an internal function used by `solve_lin_sys()` (page 2748) after the equations have been preprocessed. After `solve_lin_sys()` (page 2751) splits the system into connected components this function is called for each component. The system of equations is solved using Gauss-Jordan elimination with division followed by back-substitution.

Examples

Setup a system for \( x - y = 0 \) and \( x + y = 2 \) and solve:

```python
>>> from sympy import symbols, sring
>>> from sympy.polys.solvers import _solve_lin_sys_component
>>> x, y = symbols('x, y')
>>> R, (xr, yr) = sring([x, y], [x, y])
>>> eqs = [{xr: R.one, yr: -R.one}, {xr: R.one, yr: R.one}]
>>> eqs_rhs = [R.zero, -2*R.one]
>>> _solve_lin_sys_component(eqs, eqs_rhs, R)
{y: 1, x: 1}
```

See also:

`solve_lin_sys` (page 2748)

This function is used internally by `solve_lin_sys()` (page 2748).

Introducing the domainmatrix of the poly module

This page introduces the idea behind domainmatrix which is used in SymPy’s `sympy.polys` (page 2435) module. This is a relatively advanced topic so for a better understanding it is recommended to read about `Domain` (page 2584) and `DDM` (page 2772) along with `sympy.matrices` (page 1260) module.

What is domainmatrix?

It is way of associating Matrix with `Domain` (page 2584).

A domainmatrix represents a matrix with elements that are in a particular Domain. Each domainmatrix internally wraps a DDM which is used for the lower-level operations. The idea is that the domainmatrix class provides the convenience routines for converting between Expr and the poly domains as well as unifying matrices with different domains.

In general, we represent a matrix without concerning about the `Domain` (page 2584) as:

```python
>>> from sympy import Matrix
>>> from sympy.polys.matrices import DomainMatrix
>>> A = Matrix([[
... [1, 2],
... [3, 4]])
>>> A
```
class sympy.polys.matrices.domainmatrix.DomainMatrix(rows, shape, domain, *, fmt=None)

Associate Matrix with Domain (page 2584)

Explanation

DomainMatrix uses Domain (page 2584) for its internal representation which makes it faster than the SymPy Matrix class (currently) for many common operations, but this advantage makes it not entirely compatible with Matrix. DomainMatrix are analogous to numpy arrays with “dtype”. In the DomainMatrix, each element has a domain such as ZZ (page 2605) or QQ<a> (page 2619).

Examples

Creating a DomainMatrix from the existing Matrix class:

```python
>>> from sympy import Matrix
>>> from sympy.polys.matrices import DomainMatrix
>>> Matrix1 = Matrix([...
...     [1, 2],
...     [3, 4]])
>>> A = DomainMatrix.from_Matrix(Matrix1)
>>> A
DomainMatrix({0: {0: 1, 1: 2}, 1: {0: 3, 1: 4}}, (2, 2), ZZ)
```

Directly forming a DomainMatrix:

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([...
...     [ZZ(1), ZZ(2)],
...     [ZZ(3), ZZ(4)]], (2, 2), ZZ)
>>> A
DomainMatrix([[1, 2], [3, 4]], (2, 2), ZZ)
```

See also:

DDM (page 2772), SDM (page 2774), Domain (page 2584), Poly (page 2453)

add(B)

Adds two DomainMatrix matrices of the same Domain

Parameters

A, B: DomainMatrix

matrices to add

Returns

DomainMatrix
DomainMatrix after Addition

**Raises**

**DMShapeError**
If the dimensions of the two DomainMatrix are not equal

**ValueError**
If the domain of the two DomainMatrix are not same

**Examples**

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([[
...     ZZ(1), ZZ(2)],
...     [ZZ(3), ZZ(4)]], (2, 2), ZZ)
>>> B = DomainMatrix([[
...     ZZ(4), ZZ(3)],
...     [ZZ(2), ZZ(1)]], (2, 2), ZZ)
>>> A.add(B)
DomainMatrix([[5, 5], [5, 5]], (2, 2), ZZ)
```

**See also:**

`sub` (page 2769), `matmul` (page 2763)

**charpoly()**

Returns the coefficients of the characteristic polynomial of the DomainMatrix. These elements will be domain elements. The domain of the elements will be same as domain of the DomainMatrix.

**Returns**

list

coefficients of the characteristic polynomial

**Raises**

**DMNonSquareMatrixError**
If the DomainMatrix is not a not Square DomainMatrix

**Examples**

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([[
...     ZZ(1), ZZ(2)],
...     [ZZ(3), ZZ(4)]], (2, 2), ZZ)
>>> A.charpoly()
[1, -5, -2]
```
columnspace()

Returns the columnspace for the DomainMatrix

**Returns**
DomainMatrix

The columns of this matrix form a basis for the column space.

**Examples**

```python
>>> from sympy import QQ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([
... [QQ(1), QQ(-1)],
... [QQ(2), QQ(-2)], (2, 2), QQ)
>>> A.columnspace()
DomainMatrix([[1], [2]], (2, 1), QQ)
```

convert_to(K)

Change the domain of DomainMatrix to desired domain or field

**Parameters**

- **K**: Represents the desired domain or field.

Alternatively, None may be passed, in which case this method just returns a copy of this DomainMatrix.

**Returns**

DomainMatrix

DomainMatrix with the desired domain or field

**Examples**

```python
>>> from sympy import ZZ, ZZ_I
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([
... [ZZ(1), ZZ(2)],
... [ZZ(3), ZZ(4)]], (2, 2), ZZ)
>>> A.convert_to(ZZ_I)
DomainMatrix([[1, 2], [3, 4]], (2, 2), ZZ_I)
```

det()

Returns the determinant of a Square DomainMatrix

**Returns**

S.Complexes
determinant of Square DomainMatrix

**Raises**

ValueError

If the domain of DomainMatrix not a Field
Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([
...     [ZZ(1), ZZ(2)],
...     [ZZ(3), ZZ(4)]], (2, 2), ZZ)
>>> A.det()
-2
```

**classmethod diag**(diagonal, domain, shape=None)

Return diagonal matrix with entries from diagonal.

Examples

```python
>>> from sympy.polys.matrices import DomainMatrix
>>> from sympy import ZZ
>>> DomainMatrix.diag([ZZ(5), ZZ(6)], ZZ)
DomainMatrix({0: {0: 5}, 1: {1: 6}}, (2, 2), ZZ)
```

**classmethod eye**(shape, domain)

Return identity matrix of size n

Examples

```python
>>> from sympy.polys.matrices import DomainMatrix
>>> from sympy import QQ
>>> DomainMatrix.eye(3, QQ)
DomainMatrix({0: {0: 1}, 1: {1: 1}, 2: {2: 1}}, (3, 3), QQ)
```

**classmethod from_Matrix**(M, fmt='sparse', **kwargs)

Convert Matrix to DomainMatrix

**Parameters**

M: Matrix

**Returns**

Returns DomainMatrix with identical elements as M

Examples

```python
>>> from sympy import Matrix
>>> from sympy.polys.matrices import DomainMatrix
>>> M = Matrix([)
...     [1.0, 3.4],
...     [2.4, 1]])
>>> A = DomainMatrix.from_Matrix(M)
```
We can keep internal representation as ddm using fmt='dense'

```python
>>> from sympy import Matrix, QQ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix.from_Matrix(Matrix([[QQ(1, 2), QQ(3, 4)], [QQ(0, 1), QQ(0, 1)]]), fmt='dense')
```

```python
>>> A.rep
\[
\begin{pmatrix}
\frac{1}{2} & \frac{3}{4} \\
0 & 0
\end{pmatrix}
\]
```

See also:
- Matrix (page 1406)

### classmethod from_dict_sympy(nrows, ncols, elemsdict, **kwargs)

**Parameters**
- `nrows`: number of rows
- `ncols`: number of cols
- `elemsdict`: dict of dicts containing non-zero elements of the DomainMatrix

**Returns**
- DomainMatrix containing elements of `elemsdict`

### Examples

```python
>>> from sympy.polys.matrices import DomainMatrix
>>> from sympy.abc import x, y, z
>>> elemsdict = {0: {0: x}, 1: {1: y}, 2: {2: z}}
>>> A = DomainMatrix.from_dict_sympy(3, 3, elemsdict)
>>> A
DomainMatrix({0: {0: x}, 1: {1: y}, 2: {2: z}}, (3, 3), ZZ[x,y,z])
```

See also:
- from_list_sympy (page 2758)

### classmethod from_list(rows, domain)

Convert a list of lists into a DomainMatrix

**Parameters**
- `rows`: list of lists

  Each element of the inner lists should be either the single arg, or tuple of args, that would be passed to the domain constructor in order to form an element of the domain. See examples.

**Returns**
- DomainMatrix containing elements defined in rows
Examples

```python
>>> from sympy.polys.matrices import DomainMatrix
>>> from sympy import FF, QQ, ZZ
>>> A = DomainMatrix.from_list([[1, 0, 1], [0, 0, 1]], ZZ)
>>> A
DomainMatrix([[1, 0, 1], [0, 0, 1]], (2, 3), ZZ)
>>> B = DomainMatrix.from_list([[1, 0, 1], [0, 0, 1]], FF(7))
>>> B
DomainMatrix([[1 mod 7, 0 mod 7, 1 mod 7], [0 mod 7, 0 mod 7, 1 mod 7]], (2, 3), GF(7))
>>> C = DomainMatrix.from_list([[1, 2], [3, 1]], [[1, 4], [5, 1]], QQ)
>>> C
DomainMatrix([[1/2, 3], [1/4, 5]], (2, 2), QQ)
```

See also:

- `from_list_sympy` (page 2758)

classmethod `from_list_sympy(nrows, ncols, rows, **kwargs)`
Convert a list of lists of Expr into a DomainMatrix using construct_domain

Parameters
  - `nrows`: number of rows
  - `ncols`: number of columns
  - `rows`: list of lists

Returns
  - DomainMatrix containing elements of rows

Examples

```python
>>> from sympy.polys.matrices import DomainMatrix
>>> from sympy.abc import x, y, z
>>> A = DomainMatrix.from_list_sympy(1, 3, [[x, y, z]])
>>> A
DomainMatrix([[x, y, z]], (1, 3), ZZ[x,y,z])
```

See also:

- `sympy.polys.constructor.construct_domain` (page 2503), `from_dict_sympy` (page 2757)

classmethod `from_rep(rep)`
Create a new DomainMatrix efficiently from DDM/SDM.

Parameters
  - `rep`: SDM or DDM

The internal sparse or dense representation of the matrix.

Returns
  - DomainMatrix

A `DomainMatrix` (page 2753) wrapping `rep`. 
Examples

Create a `DomainMatrix` (page 2753) with an dense internal representation as `DDM` (page 2772):

```python
>>> from sympy.polys.domains import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> from sympy.polys.matrices.ddm import DDM
>>> drep = DDM([[ZZ(1), ZZ(2)], [ZZ(3), ZZ(4)]], (2, 2), ZZ)
>>> dM = DomainMatrix.from_rep(drep)
>>> dM
DomainMatrix([[1, 2], [3, 4]], (2, 2), ZZ)
```

Create a `DomainMatrix` (page 2753) with a sparse internal representation as `SDM` (page 2774):

```python
>>> from sympy.polys.matrices import DomainMatrix
>>> from sympy.polys.matrices.sdm import SDM
>>> from sympy import ZZ
>>> drep = SDM({0: {1: ZZ(1)}, 1: {0: ZZ(2)}}, (2, 2), ZZ)
>>> dM = DomainMatrix.from_rep(drep)
>>> dM
DomainMatrix({0: {1: 1}, 1: {0: 2}}, (2, 2), ZZ)
```

Notes

This takes ownership of `rep` as its internal representation. If `rep` is being mutated elsewhere then a copy should be provided to `from_rep`. Only minimal verification or checking is done on `rep` as this is supposed to be an efficient internal routine.

### hstack(*B)

Horizontally stack the given matrices.

**Parameters**

- **B**: `DomainMatrix`

  Matrices to stack horizontally.

**Returns**

- `DomainMatrix`

  DomainMatrix by stacking horizontally.

Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix

>>> A = DomainMatrix([[ZZ(1), ZZ(2)], [ZZ(3), ZZ(4)]], (2, 2), ZZ)
>>> B = DomainMatrix([[ZZ(5), ZZ(6)], [ZZ(7), ZZ(8)]], (2, 2), ZZ)
>>> A.hstack(B)
DomainMatrix([[1, 2, 5, 6], [3, 4, 7, 8]], (2, 4), ZZ)
```
>>> C = DomainMatrix([[ZZ(9), ZZ(10)], [ZZ(11), ZZ(12)]], (2, 2), ZZ)
>>> A.hstack(B, C)
DomainMatrix([[1, 2, 5, 6, 9, 10], [3, 4, 7, 8, 11, 12]], (2, 6), ZZ)

See also:
unify (page 2771)

inv()
Finds the inverse of the DomainMatrix if exists

Returns
DomainMatrix
    DomainMatrix after inverse

Raises
ValueError
    If the domain of DomainMatrix not a Field

DMNonSquareMatrixError
    If the DomainMatrix is not a not Square DomainMatrix

Examples

>>> from sympy import QQ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([...
... [QQ(2), QQ(-1), QQ(0)],
... [QQ(-1), QQ(2), QQ(-1)],
... [QQ(0), QQ(0), QQ(2)]], (3, 3), QQ)
>>> A.inv()
DomainMatrix([[-2/3, 1/3, 1/6], [1/3, 2/3, 1/3], [0, 0, 1/2]], (3, 3), QQ)

See also:
neg (page 2764)

property is_lower
    Says whether this matrix is lower-triangular. True can be returned even if the matrix
    is not square.

property is_upper
    Says whether this matrix is upper-triangular. True can be returned even if the matrix
    is not square.

lll(delta=MPQ(3, 4))
    Performs the Lenstra-Lenstra-Lovász (LLL) basis reduction algorithm. See [R713] and
    [R714].

    Parameters
    delta : QQ, optional
The Lovász parameter. Must be in the interval (0.25, 1), with larger values producing a more reduced basis. The default is 0.75 for historical reasons.

**Returns**
The reduced basis as a DomainMatrix over ZZ.

**Throws**
DMValueError: if delta is not in the range (0.25, 1) DMShapeError: if the matrix is not of shape (m, n) with m <= n DMDomainError: if the matrix domain is not ZZ DMRankError: if the matrix contains linearly dependent rows

**Examples**

```python
>>> from sympy.polys.domains import ZZ, QQ
>>> from sympy.polys.matrices import DM
>>> x = DM([[1, 0, 0, 0, -20160],
          ... [0, 1, 0, 0, 33768],
          ... [0, 0, 1, 0, 39578],
          ... [0, 0, 0, 1, 47757]], ZZ)
>>> y = DM([[10, -3, -2, 8, -4],
          ... [3, -9, 8, 1, -11],
          ... [-3, 13, -9, -3, -9],
          ... [-12, -7, -11, 9, -1]], ZZ)
>>> assert x.lll(delta=QQ(5, 6)) == y
```

**Notes**
The implementation is derived from the Maple code given in Figures 4.3 and 4.4 of [R715] (pp.68-69). It uses the efficient method of only calculating state updates as they are required.

**See also:**
lll_transform (page 2761)

**References**

[R713], [R714], [R715]

lll_transform(delta=MPQ(3, 4))
Performs the Lenstra–Lenstra–Lovász (LLL) basis reduction algorithm and returns the reduced basis and transformation matrix.
**Explanation**

Parameters, algorithm and basis are the same as for `lll()` (page 2760) except that the return value is a tuple \((B, T)\) with \(B\) the reduced basis and \(T\) a transformation matrix. The original basis \(A\) is transformed to \(B\) with \(T \cdot A = B\). If only \(B\) is needed then `lll()` (page 2760) should be used as it is a little faster.

**Examples**

```python
>>> from sympy.polys.domains import ZZ, QQ
>>> from sympy.polys.matrices import DM
>>> X = DM([[1, 0, 0, 0, -20160],
          [0, 1, 0, 0, 33768],
          [0, 0, 1, 0, 39578],
          [0, 0, 0, 1, 47757]], ZZ)
>>> B, T = X.lll_transform(delta=QQ(5,6))
>>> T * X == B
True
```

See also:

`lll` (page 2760)

**lu()**

Returns Lower and Upper decomposition of the DomainMatrix

**Returns**

\((L, U, \text{exchange})\)

\(L, U\) are Lower and Upper decomposition of the DomainMatrix, exchange is the list of indices of rows exchanged in the decomposition.

**Raises**

`ValueError`

If the domain of DomainMatrix not a Field

**Examples**

```python
>>> from sympy import QQ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([[QQ(1), QQ(-1)],
                    [QQ(2), QQ(-2)]], (2, 2), QQ)
>>> A.lu()
(DomainMatrix([[1, 0], [2, 1]], (2, 2), QQ), DomainMatrix([[1, -1],
                                                         [0, 0]], (2, 2), QQ), [])
```

See also:

`lu_solve` (page 2762)

**lu_solve**(rhs)

Solver for DomainMatrix \(x\) in the \(A\times x = B\)
Parameters
   - `rhs` : DomainMatrix B

Returns
   - DomainMatrix
     - $x$ in $A \times x = B$

Raises
   - `DMShapeError`
     - If the DomainMatrix A and rhs have different number of rows
   - `ValueError`
     - If the domain of DomainMatrix A not a Field

Examples

```python
>>> from sympy import QQ
>>> from sympy.polys.matrices import DomainMatrix

>>> A = DomainMatrix([[
...                     [QQ(1), QQ(2)],
...                     [QQ(3), QQ(4)]],
...                    (2, 2), QQ)

>>> B = DomainMatrix([[
...                     [QQ(1), QQ(1)],
...                     [QQ(0), QQ(1)]],
...                    (2, 2), QQ)

>>> A.lu_solve(B)
DomainMatrix([[[-2, -1], [3/2, 1]], (2, 2), QQ])
```

See also:

- `lu` (page 2762)
- `matmul(B)`
  - Performs matrix multiplication of two DomainMatrix matrices

Parameters
   - `A`, `B` : DomainMatrix
     - to multiply

Returns
   - DomainMatrix
     - DomainMatrix after multiplication
Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([[
...     ZZ(1), ZZ(2)],
...     ZZ(3), ZZ(4)]), (2, 2), ZZ)
>>> B = DomainMatrix([[
...     ZZ(1), ZZ(1)],
...     ZZ(0), ZZ(1)]), (2, 2), ZZ)
```

```python
>>> A.matmul(B)
DomainMatrix([[1, 3], [3, 7]], (2, 2), ZZ)
```

See also:

mul (page 2764), pow (page 2766), add (page 2753), sub (page 2769)

**mul(b)**

Performs term by term multiplication for the second DomainMatrix w.r.t first DomainMatrix. Returns a DomainMatrix whose rows are list of DomainMatrix matrices created after term by term multiplication.

**Parameters**

- **A, B: DomainMatrix**

  matrices to multiply term-wise

**Returns**

- **DomainMatrix**

  DomainMatrix after term by term multiplication

Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([[
...     ZZ(1), ZZ(2)],
...     ZZ(3), ZZ(4)]), (2, 2), ZZ)
>>> B = DomainMatrix([[
...     ZZ(1), ZZ(1)],
...     ZZ(0), ZZ(1)]), (2, 2), ZZ)
```

```python
>>> A.mul(B)
DomainMatrix([[DomainMatrix([[1, 1], [0, 1]], (2, 2), ZZ),
    DomainMatrix([[2, 2], [0, 2]], (2, 2), ZZ)],
    [DomainMatrix([[3, 3], [0, 3]], (2, 2), ZZ),
    DomainMatrix([[4, 4], [0, 4]], (2, 2), ZZ)]), (2, 2), ZZ)
```

See also:

matmul (page 2763)
neg()

Returns the negative of DomainMatrix

Parameters
A : Represents a DomainMatrix

Returns
DomainMatrix
DomainMatrix after Negation

Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([
...     [ZZ(1), ZZ(2)],
...     [ZZ(3), ZZ(4)]], (2, 2), ZZ)
>>> A.neg()
DomainMatrix([[[-1, -2]], [-3, -4]], (2, 2), ZZ)
```

nullspace()

Returns the nullspace for the DomainMatrix

Returns
DomainMatrix
The rows of this matrix form a basis for the nullspace.

Examples

```python
>>> from sympy import QQ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([[
...     [QQ(1), QQ(-1)],
...     [QQ(2), QQ(-2)]]], (2, 2), QQ)
>>> A.nullspace()
DomainMatrix([[1, 1]], (1, 2), QQ)
```

classmethod ones(shape, domain)

Returns a DomainMatrix of 1s, of size shape, belonging to the specified domain
Examples

>>> from sympy.polys.matrices import DomainMatrix
>>> from sympy import QQ
>>> DomainMatrix.ones((2,3), QQ)
DomainMatrix([[1, 1, 1], [1, 1, 1]], (2, 3), QQ)

\textit{pow}(n)

Computes $A^n$

\textbf{Parameters}

$A$ : DomainMatrix
$n$ : exponent for $A$

\textbf{Returns}

DomainMatrix

DomainMatrix on computing $A^n$

\textbf{Raises}

\texttt{NotImplementedError}

if $n$ is negative.

Examples

>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([...
... [ZZ(1), ZZ(1)],
... [ZZ(0), ZZ(1)]], (2, 2), ZZ)

>>> A.pow(2)
DomainMatrix([[1, 2], [0, 1]], (2, 2), ZZ)

\textbf{See also:}

\textit{matmul} (page 2763)

\textbf{rowspace}()

Returns the rowspace for the DomainMatrix

\textbf{Returns}

DomainMatrix

The rows of this matrix form a basis for the rowspace.
Examples

```python
>>> from sympy import QQ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([[
...     [QQ(1), QQ(-1)],
...     [QQ(2), QQ(-2)]], (2, 2), QQ)
>>> A.rowspace()
DomainMatrix([[1, -1]], (1, 2), QQ)
```

**rref()**

Returns reduced-row echelon form and list of pivots for the DomainMatrix

**Returns**

(DomainMatrix, list)

reduced-row echelon form and list of pivots for the DomainMatrix

**Raises**

ValueError

If the domain of DomainMatrix not a Field

Examples

```python
>>> from sympy import QQ
>>> from sympy.polys.matrices import DomainMatrix
>>>
>>> A = DomainMatrix([[
...     [QQ(2), QQ(-1), QQ(0)],
...     [QQ(-1), QQ(2), QQ(-1)],
...     [QQ(0), QQ(0), QQ(2)]], (3, 3), QQ)
>>> rref_matrix, rref_pivots = A.rref()
>>> rref_matrix
DomainMatrix([[1, 0, 0], [0, 1, 0], [0, 0, 1]], (3, 3), QQ)
>>> rref_pivots
(0, 1, 2)
```

**See also:**

convert_to (page 2755), lu (page 2762)

**scc()**

Compute the strongly connected components of a DomainMatrix

**Returns**

List of lists of integers

Each list represents a strongly connected component.
Explanation

A square matrix can be considered as the adjacency matrix for a directed graph where the row and column indices are the vertices. In this graph if there is an edge from vertex \( i \) to vertex \( j \) if \( M[i, j] \) is nonzero. This routine computes the strongly connected components of that graph which are subsets of the rows and columns that are connected by some nonzero element of the matrix. The strongly connected components are useful because many operations such as the determinant can be computed by working with the submatrices corresponding to each component.

Examples

Find the strongly connected components of a matrix:

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> M = DomainMatrix([[ZZ(1), ZZ(0), ZZ(2)],
...                    [ZZ(0), ZZ(3), ZZ(0)],
...                    [ZZ(4), ZZ(6), ZZ(5)]], (3, 3), ZZ)
>>> M.scc()
[[1], [0, 2]]
```

Compute the determinant from the components:

```python
>>> MM = M.to_Matrix()
>>> MM
Matrix([[1, 0, 2],
        [0, 3, 0],
        [4, 6, 5]])
>>> MM[[1], [1]].det()
Matrix([[3]])
>>> MM[[0, 2], [0, 2]].det()
Matrix([[1, 2],
        [4, 5]])
```

The components are given in reverse topological order and represent a permutation of the rows and columns that will bring the matrix into block lower-triangular form:

```python
>>> MM[[1, 0, 2], [1, 0, 2]]
Matrix([[3, 0, 0],
        [0, 1, 2],
        [6, 4, 5]])
```

See also:

*sympy.matrices.matrices.MatrixBase.strongly_connected_components*
*(page 1355), sympy.utilities.iterables.strongly_connected_components*
\textbf{\texttt{sub}(\texttt{B})}

Subtracts two \texttt{DomainMatrix} matrices of the same Domain

\textbf{Parameters}

- \texttt{A, B: DomainMatrix}
  matrices to subtract

\textbf{Returns}

- \texttt{DomainMatrix}
  DomainMatrix after Subtraction

\textbf{Raises}

- \texttt{DMShapeError}
  If the dimensions of the two \texttt{DomainMatrix} are not equal

- \texttt{ValueError}
  If the domain of the two \texttt{DomainMatrix} are not same

\textbf{Examples}

```
>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix(
... [ZZ(1), ZZ(2)],
... [ZZ(3), ZZ(4)], (2, 2), ZZ)
>>> B = DomainMatrix(
... [ZZ(4), ZZ(3)],
... [ZZ(2), ZZ(1)], (2, 2), ZZ)

>>> A.sub(B)
DomainMatrix([[[-3, -1], [1, 3]], (2, 2), ZZ])
```

\textbf{See also:}

- \texttt{add} (page 2753), \texttt{matmul} (page 2763)

\textbf{\texttt{to\_Matrix}()}

Convert \texttt{DomainMatrix} to Matrix

\textbf{Returns}

- \texttt{Matrix}
  \texttt{MutableDenseMatrix} for the \texttt{DomainMatrix}
Examples

>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([[
...    ZZ(1), ZZ(2)],
...    [ZZ(3), ZZ(4)]], (2, 2), ZZ)

>>> A.to_Matrix()
Matrix([[1, 2], [3, 4]])

See also:

from Matrix (page 2756)

to_dense()

Return a dense DomainMatrix representation of self.

Examples

>>> from sympy.polys.matrices import DomainMatrix
>>> from sympy import QQ
>>> A = DomainMatrix({0: {0: 1}, 1: {1: 2}}, (2, 2), QQ)

>>> A.rep
{0: {0: 1}, 1: {1: 2}}

>>> B = A.to_dense()

>>> B.rep
[[1, 0], [0, 2]]

to_field()

Returns a DomainMatrix with the appropriate field

Returns

DomainMatrix

DomainMatrix with the appropriate field

Examples

>>> from sympy import ZZ

>>> from sympy.polys.matrices import DomainMatrix

>>> A = DomainMatrix([[
...    ZZ(1), ZZ(2)],
...    [ZZ(3), ZZ(4)]], (2, 2), ZZ)

>>> A.to_field()
DomainMatrix([[1, 2], [3, 4]], (2, 2), QQ)

to_sparse()

Return a sparse DomainMatrix representation of self.
Examples

```python
>>> from sympy.polys.matrices import DomainMatrix
>>> from sympy import QQ
>>> A = DomainMatrix([[1, 0],[0, 2]], (2, 2), QQ)
>>> A.rep
[[1, 0], [0, 2]]
>>> B = A.to_sparse()
>>> B.rep
{0: {0: 1}, 1: {1: 2}}
```

**transpose()**
Matrix transpose of self

**unify(**others, fmt=None**)
Unifies the domains and the format of self and other matrices.

Parameters
- **others**: DomainMatrix
- **fmt**: string ‘dense’, ‘sparse’ or `None` (default)
  The preferred format to convert to if self and other are not already in the same format. If `None` or not specified then no conversion if performed.

Returns
- **Tuple[DomainMatrix]**
  Matrices with unified domain and format

Examples

Unify the domain of DomainMatrix that have different domains:

```python
>>> from sympy import ZZ, QQ
>>> from sympy.polys.matrices import DomainMatrix
>>> A = DomainMatrix([[ZZ(1), ZZ(2)]], (1, 2), ZZ)
>>> B = DomainMatrix([[QQ(1, 2), QQ(2)]], (1, 2), QQ)
>>> Aq, Bq = A.unify(B)
>>> Aq
DomainMatrix([[1, 2]], (1, 2), QQ)
>>> Bq
DomainMatrix([[1/2, 2]], (1, 2), QQ)
```

Unify the format (dense or sparse):

```python
>>> A = DomainMatrix([[ZZ(1), ZZ(2)]], (1, 2), ZZ)
>>> B = DomainMatrix({0:{0: ZZ(1)}}, (2, 2), ZZ)
>>> B.rep
{0: {0: 1}}

>>> A2, B2 = A.unify(B, fmt='dense')
>>> B2.rep
[[[1, 0], [0, 0]]
```
See also:

*convert_to* (page 2755), *to_dense* (page 2770), *to_sparse* (page 2770)

**vstack(*B*)**

Vertically stack the given matrices.

**Parameters**

- **B**: *DomainMatrix*
  
  Matrices to stack vertically.

**Returns**

- **DomainMatrix**
  
  DomainMatrix by stacking vertically.

**Examples**

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix

>>> A = DomainMatrix([[ZZ(1), ZZ(2)], [ZZ(3), ZZ(4)]], (2, 2), ZZ)
>>> B = DomainMatrix([[ZZ(5), ZZ(6)], [ZZ(7), ZZ(8)]], (2, 2), ZZ)
>>> A.vstack(B)
DomainMatrix([[1, 2], [3, 4], [5, 6], [7, 8], (4, 2), ZZ])

>>> C = DomainMatrix([[ZZ(9), ZZ(10)], [ZZ(11), ZZ(12)]], (2, 2), ZZ)
>>> A.vstack(B, C)
DomainMatrix([[1, 2], [3, 4], [5, 6], [7, 8], [9, 10], [11, 12], (6, 2), ZZ])
```

See also:

*unify* (page 2771)

**classmethod** **zeros**(shape, domain, *, fmt='sparse')

Returns a zero DomainMatrix of size shape, belonging to the specified domain.

**Examples**

```python
>>> from sympy.polys.matrices import DomainMatrix

>>> from sympy import QQ

>>> DomainMatrix.zeros((2, 3), QQ)
DomainMatrix({}, (2, 3), QQ)
```

**class** `sympy.polys.matrices.ddm.DDM(rowslist, shape, domain)`

Dense matrix based on polys domain elements

This is a list subclass and is a wrapper for a list of lists that supports basic matrix arithmetic +, -, *, .

**add**(b)

a + b
charpoly()
Coefficients of characteristic polynomial of a

det()
Determinant of a

hstack(*B)
Horizontally stacks DDM (page 2772) matrices.

Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices.sdm import DDM

>>> A = DDM([[ZZ(1), ZZ(2)], [ZZ(3), ZZ(4)]], (2, 2), ZZ)
>>> B = DDM([[ZZ(5), ZZ(6)], [ZZ(7), ZZ(8)]], (2, 2), ZZ)
>>> A.hstack(B)
[[[1, 2, 5, 6], [3, 4, 7, 8]]

>>> C = DDM([[ZZ(9), ZZ(10)], [ZZ(11), ZZ(12)]], (2, 2), ZZ)
>>> A.hstack(B, C)
[[[1, 2, 5, 6, 9, 10], [3, 4, 7, 8, 11, 12]]
```

inv()
Inverse of a

is_lower()
Says whether this matrix is lower-triangular. True can be returned even if the matrix is not square.

is_upper()
Says whether this matrix is upper-triangular. True can be returned even if the matrix is not square.

is_zero_matrix()
Says whether this matrix has all zero entries.

lu()
L, U decomposition of a

lu_solve(b)
x where a\times b

matmul(b)
a \times b (matrix product)

neg()
-a

rref()
Reduced-row echelon form of a and list of pivots

scc()
Strongly connected components of a square matrix a.
Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices.sdm import DDM
>>> A = DDM([[ZZ(1), ZZ(0)], [ZZ(0), ZZ(1)]], (2, 2), ZZ)
>>> A.scc()
[[0], [1]]
```

See also:

`sympy.polys.matrices.domainmatrix.DomainMatrix.scc` (page 2767)

`sub(b)`

- a - b

`vstack(*B)`

Vertically stacks `DDM` (page 2772) matrices.

Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices.sdm import DDM
>>> A = DDM([[ZZ(1), ZZ(2)], [ZZ(3), ZZ(4)]], (2, 2), ZZ)
>>> B = DDM([[ZZ(5), ZZ(6)], [ZZ(7), ZZ(8)]], (2, 2), ZZ)
>>> A.vstack(B)
[[1, 2], [3, 4], [5, 6], [7, 8]]
```

```python
>>> C = DDM([[ZZ(9), ZZ(10)], [ZZ(11), ZZ(12)]], (2, 2), ZZ)
>>> A.vstack(B, C)
[[1, 2], [3, 4], [5, 6], [7, 8], [9, 10], [11, 12]]
```

**class** `sympy.polys.matrices.sdm.SDM(elemsdict, shape, domain)`

Sparse matrix based on polys domain elements

This is a dict subclass and is a wrapper for a dict of dicts that supports basic matrix arithmetic `+,-,*,`.

In order to create a new `SDM` (page 2774), a dict of dicts mapping non-zero elements to their corresponding row and column in the matrix is needed.

We also need to specify the shape and `Domain` (page 2584) of our `SDM` (page 2774) object.

We declare a 2x2 `SDM` (page 2774) matrix belonging to QQ domain as shown below. The 2x2 Matrix in the example is

\[
A = \begin{bmatrix}
0 & \frac{1}{2} \\
0 & 0
\end{bmatrix}
\]

```python
>>> from sympy.polys.matrices.sdm import SDM
>>> from sympy import QQ
>>> elemsdict = {0:{1:QQ(1, 2)}}
>>> A = SDM(elemsdict, (2, 2), QQ)
>>> A
{0: {1: 1/2}}
```
We can manipulate SDM (page 2774) the same way as a Matrix class.

```python
>>> from sympy import ZZ
>>> A = SDM({0: {1: ZZ(2)}, 1: {0: ZZ(1)}}, (2, 2), ZZ)
>>> B = SDM({0: {0: ZZ(3)}, 1: {1: ZZ(4)}}, (2, 2), ZZ)
>>> A + B
{0: {0: 3, 1: 2}, 1: {0: 1, 1: 4}}
```

Multiplication

```python
>>> A*B
{0: {0: 8}, 1: {0: 3}}
>>> A*ZZ(2)
{0: {1: 4}, 1: {0: 2}}
```

add(B)

Adds two SDM (page 2774) matrices

```
Examples

>>> from sympy import ZZ
>>> A = SDM({0: {0: ZZ(1)}, 1: {0: ZZ(2)}}, (2, 2), ZZ)
>>> A + B
{0: {0: 3, 1: 2}, 1: {0: 1, 1: 4}}
```

ccharpoly()

Returns the coefficients of the characteristic polynomial of the SDM (page 2774) matrix. These elements will be domain elements. The domain of the elements will be same as domain of the SDM (page 2774).

```
Examples

>>> from sympy import QQ, Symbol
>>> from sympy.polys.matrices.sdm import SDM
>>> A = SDM({0: {0: QQ(1)}, 1: QQ(2)}, (2, 2), QQ)
>>> A.charpoly()
[1, -5, -2]
```

We can create a polynomial using the coefficients using Poly (page 2453)

```python
>>> x = Symbol('x')
>>> p = Poly(A.charpoly(), x, domain=A.domain)
>>> p
Poly(x**2 - 5*x - 2, x, domain='QQ')
```

convert_to(K)

Converts the Domain (page 2584) of a SDM (page 2774) matrix to K
Examples

```python
>>> from sympy import ZZ, QQ
>>> from sympy.polys.matrices.sdm import SDM
>>> A = SDM({0:{1: ZZ(2)}, 1:{0:ZZ(1)}}, (2, 2), ZZ)
>>> A.convert_to(QQ)
{0: {1: 2}, 1: {0: 1}}
```

copy()
Returns the copy of a SDM (page 2774) object

Examples

```python
>>> from sympy.polys.matrices.sdm import SDM
>>> from sympy import QQ
>>> elemsdict = {0:{1:QQ(2)}, 1:{}}
>>> A = SDM(elemsdict, (2, 2), QQ)
>>> B = A.copy()
>>> B
{0: {1: 2}, 1: {}}
```

det()
Returns determinant of A

Examples

```python
>>> from sympy import QQ
>>> from sympy.polys.matrices.sdm import SDM
>>> A = SDM({0:{0:QQ(1), 1:QQ(2)}, 1:{0:QQ(3), 1:QQ(4)}}, (2, 2), QQ)
>>> A.det()
-2
```

classmethod eye(shape, domain)
Returns a identity SDM (page 2774) matrix of dimensions size x size, belonging to the specified domain

Examples

```python
>>> from sympy.polys.matrices.sdm import SDM
>>> from sympy import QQ
>>> I = SDM.eye((2, 2), QQ)
>>> I
{0: {0: 1}, 1: {1: 1}}
```

classmethod from_ddm(ddm)
converts object of DDM (page 2772) to SDM (page 2774)
Examples

```python
>>> from sympy.polys.matrices.ddm import DDM
>>> from sympy.polys.matrices.sdm import SDM
>>> from sympy import QQ

>>> ddm = DDM([[QQ(1, 2), 0], [0, QQ(3, 4)]], (2, 2), QQ)
>>> A = SDM.from_ddm(ddm)
>>> A
{0: {0: 1/2}, 1: {1: 3/4}}
```

classmethod `from_list`(ddm, shape, domain)

Parameters:
- **ddm**: list of lists containing domain elements
- **shape**: Dimensions of SDM (page 2774) matrix
- **domain**: Represents Domain (page 2584) of SDM (page 2774) object

Returns
- SDM (page 2774) containing elements of ddm

Examples

```python
>>> from sympy.polys.matrices.sdm import SDM

>>> from sympy import QQ

>>> ddm = [[QQ(1, 2), QQ(0)], [QQ(0), QQ(3, 4)]]
>>> A = SDM.from_list(ddm, (2, 2), QQ)
>>> A
{0: {0: 1/2}, 1: {1: 3/4}}
```

`hstack(*B)`

Horizontally stacks SDM (page 2774) matrices.

Examples

```python
>>> from sympy import ZZ

>>> from sympy.polys.matrices.sdm import SDM

>>> A = SDM({0: {0: ZZ(1), 1: ZZ(2)}, 1: {0: ZZ(3), 1: ZZ(4)}}, (2, 2), ZZ)
>>> B = SDM({0: {0: ZZ(5), 1: ZZ(6)}, 1: {0: ZZ(7), 1: ZZ(8)}}, (2, 2), ZZ)
>>> A.hstack(B)
{0: {0: 1, 1: 2, 2: 5, 3: 6}, 1: {0: 3, 1: 4, 2: 7, 3: 8}}
```
inv()

Returns inverse of a matrix A

Examples

>>> from sympy import QQ
>>> from sympy.polys.matrices.sdm import SDM
>>> A = SDM({0:{0:QQ(1), 1:QQ(2)}, 1:{0:QQ(3), 1:QQ(4)}}, (2, 2), QQ)
>>> A.inv()
{0: {0: -2, 1: 1}, 1: {0: 3/2, 1: -1/2}}

is_lower()

Says whether this matrix is lower-triangular. True can be returned even if the matrix is not square.

is_upper()

Says whether this matrix is upper-triangular. True can be returned even if the matrix is not square.

is_zero_matrix()

Says whether this matrix has all zero entries.

lu()

Returns LU decomposition for a matrix A

Examples

>>> from sympy import QQ
>>> from sympy.polys.matrices.sdm import SDM
>>> A = SDM({0:{0:QQ(1), 1:QQ(2)}, 1:{0:QQ(3), 1:QQ(4)}}, (2, 2), QQ)
>>> A.lu()
({0: {0: 1}, 1: {0: 3, 1: 1}}, {0: {0: 1, 1: 2}, 1: {1: -2}}, [])

lu_solve(b)

Uses LU decomposition to solve Ax = b,
Examples

```python
>>> from sympy import QQ
>>> from sympy.polys.matrices.sdm import SDM
>>> A = SDM({0:{0:QQ(1), 1:QQ(2)}, 1:{0:QQ(3), 1:QQ(4)}}, (2, 2), QQ)
>>> b = SDM({0:{0:QQ(1), 1:QQ(2)}}, (2, 1), QQ)
>>> A.lu_solve(b)
{1: {0: 1/2}}
```

**matmul(B)**

Performs matrix multiplication of two SDM matrices

**Parameters**

A, B: SDM to multiply

**Returns**

SDM

SDM after multiplication

**Raises**

DomainError

If domain of A does not match with that of B

Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices.sdm import SDM
>>> A = SDM({0:{1:ZZ(2), 1:ZZ(1)}}, (2, 2), ZZ)
>>> B = SDM({0:{0:ZZ(2), 1:ZZ(3)}}, (2, 2), ZZ)
>>> A.matmul(B)
{0: {0: 8}, 1: {0: 2, 1: 3}}
```

**mul(b)**

Multiplies each element of A with a scalar b

Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices.sdm import SDM
>>> A = SDM({0:{1:ZZ(2), 1:ZZ(1)}}, (2, 2), ZZ)
>>> A.mul(ZZ(3))
{0: {1: 6}, 1: {0: 3}}
```

**neg()**

Returns the negative of a SDM (page 2774) matrix
Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices.sdm import SDM
>>> A = SDM({0:{1: ZZ(2)}, 1:{0:ZZ(1)}}, (2, 2), ZZ)
>>> A.neg()
{0: {1: -2}, 1: {0: -1}}
```

classmethod `new`  
```
Parameters
sdm: A dict of dicts for non-zero elements in SDM
shape: tuple representing dimension of SDM
domain: Represents :py:class:`~.Domain` of SDM

Returns
An SDM (page 2774) object
```

Examples

```python
>>> from sympy.polys.matrices.sdm import SDM
>>> from sympy import QQ
>>> elemsdict = {0:{1: QQ(2)}}
>>> A = SDM.new(elemsdict, (2, 2), QQ)
>>> A
{0: {1: 2}}
```

`nullspace`  
```
Returns nullspace for a SDM (page 2774) matrix A
```

Examples

```python
>>> from sympy import QQ
>>> from sympy.polys.matrices.sdm import SDM
>>> A = SDM({0:{0:QQ(1), 1:QQ(2)}, 1:{0: QQ(2), 1: QQ(4)}}, (2, 2), QQ)
>>> A.nullspace()
({{0: {0: -2, 1: 1}}, [1])
```

`rref`  
```
Returns reduced-row echelon form and list of pivots for the SDM (page 2774)
```
Examples

```python
>>> from sympy import QQ
>>> from sympy.polys.matrices.sdm import SDM
>>> A = SDM({0:{0:QQ(1), 1:QQ(2)}, 1:{0:QQ(2), 1:QQ(4)}}, (2, 2), QQ)
>>> A.rref()
({0: {0: 1, 1: 2}}, [0])
```

`scc()`
Strongly connected components of a square matrix A.

Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices.sdm import SDM
>>> A = SDM({0:{0: ZZ(2)}, 1:{1: ZZ(1)}}, (2, 2), ZZ)
>>> A.scc()
[[0], [1]]
```

See also:
`sympy.polys.matrices.domainmatrix.DomainMatrix.scc` (page 2767)

`sub(B)`
Subtracts two $SDM$ (page 2774) matrices

Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices.sdm import SDM
>>> A = SDM({0:{1: ZZ(2)}, 1:{0: ZZ(1)}}, (2, 2), ZZ)
>>> B = SDM({0:{0: ZZ(3)}, 1:{1: ZZ(4)}}, (2, 2), ZZ)
>>> A.sub(B)
{0: {0: -3, 1: 2}, 1: {0: 1, 1: -4}}
```

`to_ddm()`
Convert a $SDM$ (page 2774) object to a $DDM$ (page 2772) object

Examples

```python
>>> from sympy.polys.matrices.sdm import SDM
>>> from sympy import QQ
>>> A = SDM({0:{1:QQ(2)}, 1:{}}}, (2, 2), QQ)
>>> A.to_ddm()
[[[0, 2], [0, 0]]
```

`to_list()`
Converts a $SDM$ (page 2774) object to a list
Examples

```python
>>> from sympy.polys.matrices.sdm import SDM
>>> from sympy import QQ
>>> elemsdict = {0:{1:QQ(2)}, 1: {}}
>>> A = SDM(elemsdict, (2, 2), QQ)
>>> A.to_list()
[[0, 2], [0, 0]]
```

**transpose()**

Returns the transpose of a *SDM* (page 2774) matrix

Examples

```python
>>> from sympy.polys.matrices.sdm import SDM
>>> from sympy import QQ
>>> A = SDM({0: {1: QQ(2)}, 1: {}}, (2, 2), QQ)
>>> A.transpose()
{1: {0: 2}}
```

**vstack(*B)**

Vertically stacks *SDM* (page 2774) matrices.

Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices.sdm import SDM

>>> A = SDM({0: {0: ZZ(1), 1: ZZ(2)}, 1: {0: ZZ(3), 1: ZZ(4)}}, (2, 2), ZZ)
>>> B = SDM({0: {0: ZZ(5), 1: ZZ(6)}, 1: {0: ZZ(7), 1: ZZ(8)}}, (2, 2), ZZ)
>>> A.vstack(B)
{0: {0: 1, 1: 2}, 1: {0: 3, 1: 4}, 2: {0: 5, 1: 6}, 3: {0: 7, 1: 8}}
```

**classmethod zeros(shape, domain)**

Returns a *SDM* (page 2774) of size `shape`, belonging to the specified domain

In the example below we declare a matrix A where,

\[
A := \begin{bmatrix}
0 & 0 & 0 \\
0 & 0 & 0
\end{bmatrix}
\]
Return the Smith Normal Form of a matrix $m$ over the ring $domain$. This will only work if the ring is a principal ideal domain.

Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> from sympy.polys.matrices.normalforms import smith_normal_form
>>> m = DomainMatrix([[ZZ(12), ZZ(6), ZZ(4)],
                    [ZZ(3), ZZ(9), ZZ(6)],
                    [ZZ(2), ZZ(16), ZZ(14)]], (3, 3), ZZ)
>>> print(smith_normal_form(m).to_Matrix())
Matrix([[1, 0, 0], [0, 10, 0], [0, 0, -30]])
```

Compute the Hermite Normal Form of $DomainMatrix$ (page 2753) $A$ over $ZZ$ (page 2605).

Parameters

- **A**: $m \times n$ $DomainMatrix$ over $ZZ$ (page 2605).
- **D**: $ZZ$ (page 2605), optional
  
  Let $W$ be the HNF of $A$. If known in advance, a positive integer $D$ being any multiple of $\det(W)$ may be provided. In this case, if $A$ also has rank $m$, then we may use an alternative algorithm that works mod $D$ in order to prevent coefficient explosion.

- **check_rank**: boolean, optional (default=False)
  
  The basic assumption is that, if you pass a value for $D$, then you already believe that $A$ has rank $m$, so we do not waste time checking it for you. If you do want this to be checked (and the ordinary, non-modulo $D$ algorithm to be used if the check fails), then set $check\_rank$ to True.

Returns

- **DomainMatrix** (page 2753)
  
  The HNF of matrix $A$.

Raises

- **DMDomainError**
  
  If the domain of the matrix is not $ZZ$ (page 2605), or if $D$ is given but is not in $ZZ$ (page 2605).

- **DMShapeError**
If the mod $D$ algorithm is used but the matrix has more rows than columns.

Examples

```python
>>> from sympy import ZZ
>>> from sympy.polys.matrices import DomainMatrix
>>> from sympy.polys.matrices.normalforms import hermite_normal_form
>>> m = DomainMatrix([[ZZ(12), ZZ(6), ZZ(4)],
                   [ZZ(3), ZZ(9), ZZ(6)],
                   [ZZ(2), ZZ(16), ZZ(14)]], (3, 3), ZZ)
>>> print(hermite_normal_form(m).to_Matrix())
Matrix([[10, 0, 2], [0, 15, 3], [0, 0, 2]])
```

Number Fields

Introduction

Like many other computations in algebraic number theory, the splitting of rational primes can be treated by rational methods only. This fact is very important if computation by automatic computing machinery is considered. Only the knowledge of the irreducible polynomial $f(x)$, a zero of which generates the field in question, is needed.

—Olga Taussky, 1953

Concepts like number fields and algebraic numbers are essential to our understanding of algebraic number theory, but to the computer the subject is all about polynomials: the ring $\mathbb{Q}[x]$ reduced modulo irreducible polynomials $f(x) \in \mathbb{Q}[x]$. It thus finds a natural home under the `polys` (page 2435) module in SymPy.

Various authors (such as Taussky, Zimmer, Pohst and Zassenhaus, or Cohen) have articulated the main goals of computational algebraic number theory in different ways, but invariably the list centers around a certain essential set of tasks. As a goal for the `numberfields` module in SymPy, we may set the following list, based on [Cohen93], Sec. 4.9.3.

For a number field $K = \mathbb{Q}(\theta)$, whose ring of algebraic integers is denoted $\mathbb{Z}_K$, compute:

1. an integral basis of $\mathbb{Z}_K$
2. the decomposition of rational primes in $\mathbb{Z}_K$
3. $p$-adic valuations for ideals and elements
4. the Galois group of the Galois closure of $K$
5. a system of fundamental units of $K$
6. the regulator $R(K)$
7. the class number
8. the structure of the class group $Cl(K)$
9. decide whether a given ideal is principal, and if so compute a generator.

As a foundation, and to support our basic ability to define and work with number fields and algebraic numbers, we also set the following problems, following [Cohen93], Sec. 4.5.

10. Given an algebraic number – expressed by radicals and rational operations, or even as a special value of a transcendental function – determine its minimal polynomial over $\mathbb{Q}$.
11. The Subfield Problem: Given two number fields $\mathbb{Q}(\alpha)$, $\mathbb{Q}(\beta)$ via the minimal polynomials for their generators $\alpha$ and $\beta$, decide whether one field is isomorphic to a subfield of the other, and if so exhibit an embedding.
12. The Field Membership Problem: Given two algebraic numbers $\alpha, \beta$, decide whether $\alpha \in \mathbb{Q}(\beta)$, and if so write $\alpha = f(\beta)$ for some $f(x) \in \mathbb{Q}[x]$.
13. The Primitive Element Problem: Given several algebraic numbers $\alpha_1, \ldots, \alpha_m$, compute a single algebraic number $\theta$ such that $\mathbb{Q}(\alpha_1, \ldots, \alpha_m) = \mathbb{Q}(\theta)$.

At present only a subset of the tasks enumerated above is yet supported in SymPy, and if you are interested in expanding support, you are encouraged to contribute! An excellent source, providing solutions to all the remaining problems (as well as those already solved) is [Cohen93].

At time of writing, the existing solutions to the above problems are found in the following places:

Solving the Main Problems

Integral Basis

sympy.polys.numberfields.basis.round_two\(T, \text{radicals=\textit{None}}\)

Zassenhaus’s “Round 2” algorithm.

**Parameters**

\(T\) : Poly (page 2453), AlgebraicField (page 2619)

Either (1) the irreducible polynomial over ZZ (page 2605) or QQ (page 2609) defining the number field, or (2) an AlgebraicField (page 2619) representing the number field itself.

\(\text{radicals}\) : dict, optional

This is a way for any \(p\)-radicals (if computed) to be returned by reference. If desired, pass an empty dictionary. If the algorithm reaches the point where it computes the nilradical mod \(p\) of the ring of integers \(Z_K\), then an \(\mathbb{F}_p\)-basis for this ideal will be stored in this dictionary under the key \(p\). This can be useful for other algorithms, such as prime decomposition.

**Returns**

Pair \((Z_K, d_K)\), where:

- \(Z_K\) is a Submodule (page 2810) representing the maximal order.
- \(d_K\) is the discriminant of the field \(K = \mathbb{Q}[x]/(T(x))\).

**Explanation**

Carry out Zassenhaus’s “Round 2” algorithm on an irreducible polynomial \(T\) over ZZ (page 2605) or QQ (page 2609). This computes an integral basis and the discriminant for the field \(K = \mathbb{Q}[x]/(T(x))\).

Alternatively, you may pass an AlgebraicField (page 2619) instance, in place of the polynomial \(T\), in which case the algorithm is applied to the minimal polynomial for the field’s primitive element.

Ordinarily this function need not be called directly, as one can instead access the maximal_order() (page 2625), integral_basis() (page 2624), and discriminant() (page 2623) methods of an AlgebraicField (page 2619).

**Examples**

Working through an AlgebraicField:

```python
>>> from sympy import Poly, QQ
>>> from sympy.abc import x
>>> T = Poly(x**3 + x**2 - 2*x + 8)
>>> K = QQ.alg_field_from_poly(T, "theta")
>>> print(K.maximal_order())
Submodule[[2, 0, 0], [0, 2, 0], [0, 1, 1]]/2
>>> print(K.discriminant())
```

(continues on next page)
>>> print(K.integral_basis(fmt='sympy'))
[1, theta, theta/2 + theta**2/2]

Calling directly:

```python
>>> from sympy import Poly
>>> from sympy import x
>>> from sympy.polys.numberfields.basis import round_two
>>> T = Poly(x**3 + x**2 - 2*x + 8)
>>> print(round_two(T))
(Submodule[[2, 0, 0], [0, 2, 0], [0, 1, 1]]/2, -503)
```

The nilradicals mod \( p \) that are sometimes computed during the Round Two algorithm may be useful in further calculations. Pass a dictionary under `radicals` to receive these:

```python
>>> T = Poly(x**3 + 3*x**2 + 5)
>>> rad = {}
>>> ZK, dK = round_two(T, radicals=rad)
>>> print(rad)
{3: Submodule[[-1, 1, 0], [-1, 0, 1]]}
```

Prime Decomposition

sympy.polys.numberfields.primes.prime_decomp(p, T=None, ZK=None, dK=None, radical=None)

Compute the decomposition of rational prime \( p \) in a number field.

Parameters

- **p**: int
  The rational prime whose decomposition is desired.
- **T**: `Poly` (page 2453), optional
  Monic irreducible polynomial defining the number field \( K \) in which to factor. NOTE: at least one of \( T \) or \( ZK \) must be provided.
- **ZK**: `Submodule` (page 2810), optional
  The maximal order for \( K \), if already known. NOTE: at least one of \( T \) or \( ZK \) must be provided.
- **dK**: int, optional
  The discriminant of the field \( K \), if already known.
### radical

**Submodule** (page 2810), optional

The nilradical mod $p$ in the integers of $K$, if already known.

**Returns**

List of **PrimeIdeal** (page 2788) instances.

#### Explanation

Ordinarily this should be accessed through the *primes_above()* (page 2626) method of an *AlgebraicField* (page 2619).

#### Examples

```python
>>> from sympy import Poly, QQ
>>> from sympy.abc import x, theta

>>> T = Poly(x ** 3 + x ** 2 - 2 * x + 8)
>>> K = QQ.algebraic_field((T, theta))
>>> print(K.primes_above(2))
[[ (2, x**2 + 1) e=1, f=1 ],
 [ (2, (x**2 + 3*x + 2)/2) e=1, f=1 ],
 [ (2, (3*x**2 + 3*x)/2) e=1, f=1 ]]
```

#### References

[R737]

```python
class sympy.polys.numberfields.primes.PrimeIdeal(ZK, p, alpha, f, e=None)
A prime ideal in a ring of algebraic integers.

__init__ (ZK, p, alpha, f, e=None)
```

**Parameters**

- **ZK** : **Submodule** (page 2810)
  The maximal order where this ideal lives.

- **p** : int
  The rational prime this ideal divides.

- **alpha** : **PowerBasisElement** (page 2816)
  Such that the ideal is equal to $p*ZK + alpha*ZK$.

- **f** : int
  The inertia degree.

- **e** : int, None, optional
  The ramification index, if already known. If None, we will compute it here.
__add__(other)
Convert to a Submodule (page 2810) and add to another Submodule (page 2810).

See also:
as_submodule (page 2789)

__mul__(other)
Convert to a Submodule (page 2810) and multiply by another Submodule (page 2810)
or a rational number.

See also:
as_submodule (page 2789)
as_submodule()
Represent this prime ideal as a Submodule (page 2810).

Returns
Submodule (page 2810)
Will be equal to self.p * self.ZK + self.alpha * self.ZK.

Explanation
The PrimeIdeal (page 2788) class serves to bundle information about a prime ideal, such as its inertia degree, ramification index, and two-generator representation, as well as to offer helpful methods like valuation() (page 2791) and test_factor() (page 2791).

However, in order to be added and multiplied by other ideals or rational numbers, it must first be converted into a Submodule (page 2810), which is a class that supports these operations.

In many cases, the user need not perform this conversion deliberately, since it is automatically performed by the arithmetic operator methods __add__() (page 2788) and __mul__() (page 2789).

Raising a PrimeIdeal (page 2788) to a non-negative integer power is also supported.

Examples

```python
>>> from sympy import Poly, cyclotomic_poly, prime_decomp
>>> T = Poly(cyclotomic_poly(7))
>>> P0 = prime_decomp(7, T)[0]
>>> print(P0**6 == 7*P0.ZK)
True
```

Note that, on both sides of the equation above, we had a Submodule (page 2810). In the next equation we recall that adding ideals yields their GCD. This time, we need a deliberate conversion to Submodule (page 2810) on the right:

```python
>>> print(P0 + 7*P0.ZK == P0.as_submodule())
True
```
property is_inert
Say whether the rational prime we divide is inert, i.e. stays prime in our ring of integers.

reduce_ANP(a)
Reduce an ANP (page 2650) to a “small representative” modulo this prime ideal.

Parameters
elt : ANP (page 2650)
The element to be reduced.

Returns
ANP (page 2650)
The reduced element.

reduce_alg_num(a)
Reduce an AlgebraicNumber (page 1039) to a “small representative” modulo this prime ideal.

Parameters
elt : AlgebraicNumber (page 1039)
The element to be reduced.

Returns
AlgebraicNumber (page 1039)
The reduced element.

reduce_element(elt)
Reduce a PowerBasisElement (page 2816) to a “small representative” modulo this prime ideal.

Parameters
elt : PowerBasisElement (page 2816)
The element to be reduced.

Returns
PowerBasisElement (page 2816)
The reduced element.

See also:
reduce_element (page 2790), reduce_alg_num (page 2790), Submodule.
reduce_element (page 2812)
The SymPy documentation for the `repr` function with parameters `field_gen=None, just_gens=False` is as follows:

Print a representation of this prime ideal.

**Parameters**

- **field_gen**: Symbol (default=None), optional
  
The symbol to use for the generator of the field. This will appear in our representation of `self.alpha`. If None, we use the variable of the defining polynomial of `self.ZK`.

- **just_gens**: bool, optional (default=False)
  
If True, just print the “(p, alpha)” part, showing “just the generators” of the prime ideal. Otherwise, print a string of the form “[(p, alpha) \( e=\ldots, f=\ldots \)]”, giving the ramification index and inertia degree, along with the generators.

**Examples**

```python
>>> from sympy import cyclotomic_poly, QQ
>>> from sympy.abc import x, zeta
>>> T = cyclotomic_poly(7, x)
>>> K = QQ.algebraic_field((T, zeta))
>>> P = K.primes_above(11)
>>> print(P[0].repr())
[ (11, x**3 + 5*x**2 + 4*x - 1) e=1, f=3 ]
>>> print(P[0].repr(field_gen=zeta))
[ (11, zeta**3 + 5*zeta**2 + 4*zeta - 1) e=1, f=3 ]
>>> print(P[0].repr(field_gen=zeta, just_gens=True))
(11, zeta**3 + 5*zeta**2 + 4*zeta - 1)
```

test_factor()

Compute a test factor for this prime ideal.

**Explanation**

Write \( p \) for this prime ideal, \( p \) for the rational prime it divides. Then, for computing \( p \)-adic valuations it is useful to have a number \( \beta \in \mathbb{Z}_K \) such that \( p/p = p\mathbb{Z}_K + \beta \mathbb{Z}_K \).

Essentially, this is the same as the number \( \Psi \) (or the “reagent”) from Kummer’s 1847 paper (*Ueber die Zerlegung...,* Crelle vol. 35) in which ideal divisors were invented.

valuation(I)

Compute the \( p \)-adic valuation of integral ideal I at this prime ideal.

**Parameters**

- **I**: Submodule (default=None)

**See also:**

`prime_valuation`
**p-adic Valuation**

sympy.polys.numberfields.primes.prime_valuation(I, P)

Compute the $P$-adic valuation for an integral ideal $I$.

**Parameters**

- **I**: *Submodule* (page 2810)
  An integral ideal whose valuation is desired.
- **P**: *PrimeIdeal* (page 2788)
  The prime at which to compute the valuation.

**Returns**

int

**Examples**

```python
>>> from sympy import QQ
>>> from sympy.polys.numberfields import prime_valuation
>>> K = QQ.cyclotomic_field(5)
>>> P = K.primes_above(5)
>>> ZK = K.maximal_order()
>>> print(prime_valuation(25*ZK, P[0]))
8
```

**See also:**

PrimeIdeal.valuation (page 2791)

**References**

[R738]

**Galois Groups**

sympy.polys.numberfields.galoisgroups.galois_group(f, *gens, by_name=False, max_tries=30, randomize=False, **args)

Compute the Galois group for polynomials $f$ up to degree 6.

**Parameters**

- **f**: Expr
  Irreducible polynomial over $\mathbb{Z}$ (page 2605) or $\mathbb{Q}$ (page 2609), whose Galois group is to be determined.
- **gens**: optional list of symbols
  For converting $f$ to Poly, and will be passed on to the poly_from_expr() (page 2435) function.
- **by_name**: bool, default False
If True, the Galois group will be returned by name. Otherwise it will be returned as a `PermutationGroup` (page 343).

**max_tries**: int, default 30

Make at most this many attempts in those steps that involve generating Tschirnhaus transformations.

**randomize**: bool, default False

If True, then use random coefficients when generating Tschirnhaus transformations. Otherwise try transformations in a fixed order. Both approaches start with small coefficients and degrees and work upward.

**args**: optional

For converting \( f \) to Poly, and will be passed on to the `poly_from_expr` (page 2435) function.

**Returns**

Pair \((G, alt)\)

The first element \(G\) indicates the Galois group. It is an instance of one of the `sympy.combinatorics.galois.S1TransitiveSubgroups` (page 411) `sympy.combinatorics.galois.S2TransitiveSubgroups` (page 411), etc. enum classes if `by_name` was True, and a `PermutationGroup` (page 343) if False.

The second element is a boolean, saying whether the group is contained in the alternating group \(A_n\) (\(n\) the degree of \(T\)).

**Raises**

**ValueError**

if \(f\) is of an unsupported degree.

**MaxTriesException**

if could not complete before exceeding `max_tries` in those steps that involve generating Tschirnhaus transformations.

**Examples**

```python
>>> from sympy import galois_group
>>> from sympy.abc import x
>>> f = x**4 + 1
>>> G, alt = galois_group(f)
>>> print(G)
PermutationGroup([[(0 1)(2 3), (0 2)(1 3)]]
```

The group is returned along with a boolean, indicating whether it is contained in the alternating group \(A_n\), where \(n\) is the degree of \(T\). Along with other group properties, this can help determine which group it is:
Alternatively, the group can be returned by name:

```python
>>> G_name, _ = galois_group(f, by_name=True)
>>> print(G_name)
S4TransitiveSubgroups.V
```

The group itself can then be obtained by calling the name’s `get_perm_group()` method:

```python
>>> G_name.get_perm_group()
PermutationGroup([
    (0 1)(2 3),
    (0 2)(1 3)])
```

Group names are values of the enum classes `sympy.combinatorics.galois.S1TransitiveSubgroups` (page 411), `sympy.combinatorics.galois.S2TransitiveSubgroups` (page 411), etc.

`Poly.galois_group` (page 2469)

### Finding Minimal Polynomials

`sympy.polys.numberfields.minpoly.minimal_polynomial(ex, x=None, compose=True, polys=False, domain=None)`

Computes the minimal polynomial of an algebraic element.

**Parameters**

- **ex**: Expr
  Element or expression whose minimal polynomial is to be calculated.

- **x**: Symbol, optional
  Independent variable of the minimal polynomial

- **compose**: boolean, optional (default=True)
  Method to use for computing minimal polynomial. If `compose=True` (default) then `_minpoly_compose` is used, if `compose=False` then groebner bases are used.

- **polys**: boolean, optional (default=False)
  If True returns a Poly object else an Expr object.

- **domain**: Domain, optional
  Ground domain
Notes

By default compose=True, the minimal polynomial of the subexpressions of \texttt{ex} are computed, then the arithmetic operations on them are performed using the resultant and factorization. If compose=False, a bottom-up algorithm is used with \texttt{groebner}. The default algorithm stalls less frequently.

If no ground domain is given, it will be generated automatically from the expression.

Examples

```python
>>> from sympy import minimal_polynomial, sqrt, solve, QQ
>>> from sympy.abc import x, y

>>> minimal_polynomial(sqrt(2), x)
x**2 - 2
>>> minimal_polynomial(sqrt(2), x, domain=QQ.algebraic_field(sqrt(2)))
x - sqrt(2)
>>> minimal_polynomial(sqrt(2) + sqrt(3), x)
x**4 - 10*x**2 + 1
>>> minimal_polynomial(solve(x**3 + x + 3)[0], x)
x**3 + x + 3
>>> minimal_polynomial(sqrt(y), x)
x**2 - y
```

\texttt{sympy.polys.numberfields.minpoly.minpoly(\texttt{ex}, \texttt{x=None}, \texttt{compose=True, polys=False, domain=None})}

This is a synonym for \texttt{minimal_polynomial()} (page 2794).

The Subfield Problem

Functions in \texttt{polys.numberfields.subfield} solve the “Subfield Problem” and allied problems, for algebraic number fields.

Following Cohen (see [Cohen93] Section 4.5), we can define the main problem as follows:

- **Subfield Problem:**

  Given two number fields \( \mathbb{Q}(\alpha), \mathbb{Q}(\beta) \) via the minimal polynomials for their generators \( \alpha \) and \( \beta \), decide whether one field is isomorphic to a subfield of the other.

  From a solution to this problem flow solutions to the following problems as well:

- **Primitive Element Problem:**

  Given several algebraic numbers \( \alpha_1, \ldots, \alpha_m \), compute a single algebraic number \( \theta \) such that \( \mathbb{Q}(\alpha_1, \ldots, \alpha_m) = \mathbb{Q}(\theta) \).

- **Field Isomorphism Problem:**

  Decide whether two number fields \( \mathbb{Q}(\alpha), \mathbb{Q}(\beta) \) are isomorphic.

- **Field Membership Problem:**

  Given two algebraic numbers \( \alpha, \beta \), decide whether \( \alpha \in \mathbb{Q}(\beta) \), and if so write \( \alpha = f(\beta) \) for some \( f(x) \in \mathbb{Q}[x] \).
Find an embedding of one number field into another.

**Parameters**

- **a**: `Expr` (page 999)
  
  Any expression representing an algebraic number.

- **b**: `Expr` (page 999)
  
  Any expression representing an algebraic number.

- **fast**: boolean, optional (default=True)
  
  If True, we first attempt a potentially faster way of computing the isomorphism, falling back on a slower method if this fails. If False, we go directly to the slower method, which is guaranteed to return a result.

**Returns**

List of rational numbers, or None

- If $\mathbb{Q}(a)$ is not isomorphic to some subfield of $\mathbb{Q}(b)$, then return None.
- Otherwise, return a list of rational numbers representing an element of $\mathbb{Q}(b)$ to which $a$ may be mapped, in order to define a monomorphism, i.e. an isomorphism from $\mathbb{Q}(a)$ to some subfield of $\mathbb{Q}(b)$. The elements of the list are the coefficients of falling powers of $b$.

**Explanation**

This function looks for an isomorphism from $\mathbb{Q}(a)$ onto some subfield of $\mathbb{Q}(b)$. Thus, it solves the Subfield Problem.

**Examples**

```python
>>> from sympy import sqrt, field_isomorphism, I
>>> print(field_isomorphism(3, sqrt(2)))
[3]
>>> print(field_isomorphism(I*sqrt(3), I*sqrt(3)/2))
[2, 0]
```

Find a single generator for a number field given by several generators.

**Parameters**

- **extension**: list of `Expr` (page 999)
  
  Each expression must represent an algebraic number $\alpha_i$.

- **x**: `Symbol` (page 1028), optional (default=None)
  
  The desired symbol to appear in the computed minimal polynomial for the primitive element $\theta$. If None, we use a dummy symbol.

- **ex**: boolean, optional (default=False)
If and only if True, compute the representation of each $\alpha_i$ as a $\mathbb{Q}$-linear combination over the powers of $\theta$.

**polys** : boolean, optional (default=False)

If True, return the minimal polynomial as a *Poly* (page 2453). Otherwise return it as an *Expr* (page 999).

**Returns**
Pair (f, coeffs) or triple (f, coeffs, reps), where:

- f is the minimal polynomial for the primitive element.
- coeffs gives the primitive element as a linear combination of the given generators.
- reps is present if and only if argument ex=True was passed, and is a list of lists of rational numbers. Each list gives the coefficients of falling powers of the primitive element, to recover one of the original, given generators.

**Explanation**

The basic problem is this: Given several algebraic numbers $\alpha_1, \alpha_2, \ldots, \alpha_n$, find a single algebraic number $\theta$ such that $\mathbb{Q}(\alpha_1, \alpha_2, \ldots, \alpha_n) = \mathbb{Q}(\theta)$.

This function actually guarantees that $\theta$ will be a linear combination of the $\alpha_i$, with non-negative integer coefficients.

Furthermore, if desired, this function will tell you how to express each $\alpha_i$ as a $\mathbb{Q}$-linear combination of the powers of $\theta$.

**Examples**

```python
>>> from sympy import primitive_element, sqrt, S, minpoly, simplify
>>> from sympy.abc import x
>>> f, lincomb, reps = primitive_element([sqrt(2), sqrt(3)], x, ex=True)
```

Then lincomb tells us the primitive element as a linear combination of the given generators $\sqrt{2}$ and $\sqrt{3}$.

```python
>>> print(lincomb)
[1, 1]
```

This means the primitive element is $\sqrt{2} + \sqrt{3}$. Meanwhile f is the minimal polynomial for this primitive element.

```python
>>> print(f)
x**4 - 10*x**2 + 1
>>> print(minpoly(sqrt(2) + sqrt(3), x))
x**4 - 10*x**2 + 1
```

Finally, reps (which was returned only because we set keyword arg ex=True) tells us how to recover each of the generators $\sqrt{2}$ and $\sqrt{3}$ as $\mathbb{Q}$-linear combinations of the powers of the primitive element $\sqrt{2} + \sqrt{3}$.
SymPy Documentation, Release 1.12.1

```python
>>> print([S(r) for r in reps[0]])
[1/2, 0, -9/2, 0]
>>> theta = sqrt(2) + sqrt(3)
>>> print(simplify(theta**3/2 - 9*theta/2))
sqrt(2)
>>> print([S(r) for r in reps[1]])
[-1/2, 0, 11/2, 0]
>>> print(simplify(-theta**3/2 + 11*theta/2))
sqrt(3)
```

```python
sympy.polys.numberfields.subfield.to_number_field(extension, theta=None, *, gen=None, alias=None)
```

Express one algebraic number in the field generated by another.

**Parameters**

- **extension**: `Expr` (page 999) or list of `Expr` (page 999)
  
  Either the algebraic number that is to be expressed in the other field, or else a list of algebraic numbers, a primitive element for which is to be expressed in the other field.

- **theta**: `Expr` (page 999), None, optional (default=None)
  
  If an `Expr` (page 999) representing an algebraic number, behavior is as described under Explanation. If None, then this function reduces to a shorthand for calling `primitive_element()` (page 2796) on extension and turning the computed primitive element into an `AlgebraicNumber` (page 1039).

- **gen**: `Symbol` (page 1028), None, optional (default=None)
  
  If provided, this will be used as the generator symbol for the minimal polynomial in the returned `AlgebraicNumber` (page 1039).

- **alias**: str, `Symbol` (page 1028), None, optional (default=None)
  
  If provided, this will be used as the alias symbol for the returned `AlgebraicNumber` (page 1039).

**Returns**

- `AlgebraicNumber`:
  
  Belonging to \( \mathbb{Q}(\theta) \) and equaling \( \eta \).

**Raises**

- `IsomorphismFailed`
  
  If \( \eta \notin \mathbb{Q}(\theta) \).
Explanation

Given two algebraic numbers $\eta, \theta$, this function either expresses $\eta$ as an element of $\mathbb{Q}(\theta)$, or else raises an exception if $\eta \notin \mathbb{Q}(\theta)$.

This function is essentially just a convenience, utilizing field_isomorphism() (page 2795) (our solution of the Subfield Problem) to solve this, the Field Membership Problem.

As an additional convenience, this function allows you to pass a list of algebraic numbers $\alpha_1, \alpha_2, \ldots, \alpha_n$ instead of $\eta$. It then computes $\eta$ for you, as a solution of the Primitive Element Problem, using primitive_element() (page 2796) on the list of $\alpha_i$.

Examples

```python
>>> from sympy import sqrt, to_number_field
>>> eta = sqrt(2)
>>> theta = sqrt(2) + sqrt(3)
>>> a = to_number_field(eta, theta)
>>> print(type(a))
<class 'sympy.core.numbers.AlgebraicNumber'>
>>> a.root
sqrt(2) + sqrt(3)
>>> print(a)
sqrt(2)
>>> a.coeffs()
[1/2, 0, -9/2, 0]
```

We get an AlgebraicNumber (page 1039), whose .root is $\theta$, whose value is $\eta$, and whose .coeffs() show how to write $\eta$ as a $\mathbb{Q}$-linear combination in falling powers of $\theta$.

field_isomorphism (page 2795), primitive_element (page 2796)

Internals

Algebraic number fields

Algebraic number fields are represented in SymPy by the AlgebraicField (page 2619) class, which is a part of the polynomial domains system (page 2584).

Representing algebraic numbers

There are several different ways to represent algebraic numbers, and different forms may be preferable for different computational tasks. See [Cohen93], Sec. 4.2.
As number field elements

In SymPy, there is a distinction between number and expression classes defined in the `sympy.core.numbers` (page 1033) module on the one hand, and domains and domain elements defined in the `polys` (page 2435) module on the other. This is explained in more detail here (page 2557).

When it comes to algebraic numbers, the `sympy.core.numbers` (page 1033) module offers the `AlgebraicNumber` (page 1039) class, while the `polys` (page 2435) module offers the `ANP` (page 2650) class. This is the type of domain elements belonging to the `AlgebraicField` (page 2619) domain.

As elements of finitely-generated modules

In computational algebraic number theory, finitely-generated \( \mathbb{Z} \)-modules are of central importance. For example, every order and every ideal is such a module.

In particular, the maximal order - or ring of integers - in a number field is a finitely-generated \( \mathbb{Z} \)-module, whose generators form an integral basis for the field.

Classes allowing us to represent such modules, and their elements, are provided in the `modules` (page 2800) module. Here, the `ModuleElement` (page 2813) class provides another way to represent algebraic numbers.

Finitely-generated modules

Modules in number fields.

The classes defined here allow us to work with finitely generated, free modules, whose generators are algebraic numbers.

There is an abstract base class called `Module` (page 2803), which has two concrete subclasses, `PowerBasis` (page 2809) and `Submodule` (page 2810).

Every module is defined by its basis, or set of generators:

- For a `PowerBasis` (page 2809), the generators are the first \( n \) powers (starting with the zeroth) of an algebraic integer \( \theta \) of degree \( n \). The `PowerBasis` (page 2809) is constructed by passing either the minimal polynomial of \( \theta \), or an `AlgebraicField` (page 2619) having \( \theta \) as its primitive element.

- For a `Submodule` (page 2810), the generators are a set of \( \mathbb{Q} \)-linear combinations of the generators of another module. That other module is then the “parent” of the `Submodule` (page 2810). The coefficients of the \( \mathbb{Q} \)-linear combinations may be given by an integer matrix, and a positive integer denominator. Each column of the matrix defines a generator.

```python
>>> from sympy.polys import Poly, cyclotomic_poly, ZZ
>>> from sympy.abc import x
>>> from sympy.polys.matrices import DomainMatrix, DM
>>> from sympy.polys.numberfields.modules import PowerBasis
>>> T = Poly(cyclotomic_poly(5, x))
>>> A = PowerBasis(T)
>>> print(A)
(continues on next page)```
Thus, every module is either a \texttt{PowerBasis} (page 2809), or a \texttt{Submodule} (page 2810), some ancestor of which is a \texttt{PowerBasis} (page 2809). (If \texttt{S} is a \texttt{Submodule} (page 2810), then its ancestors are \texttt{S.parent}, \texttt{S.parent.parent}, and so on).

The \texttt{ModuleElement} (page 2813) class represents a linear combination of the generators of any module. Critically, the coefficients of this linear combination are not restricted to be integers, but may be any rational numbers. This is necessary so that any and all algebraic integers be representable, starting from the power basis in a primitive element \( \theta \) for the number field in question. For example, in a quadratic field \( \mathbb{Q}(\sqrt{d}) \) where \( d \equiv 1 \mod 4 \), a denominator of 2 is needed.

A \texttt{ModuleElement} (page 2813) can be constructed from an integer column vector and a denominator:

```python
>>> U = Poly(x**2 - 5)
>>> M = PowerBasis(U)
>>> e = M(DM([[1], [1]], ZZ), denom=2)
>>> print(e)
[1, 1]/2
>>> print(e.module)
PowerBasis(x**2 - 5)
```

The \texttt{PowerBasisElement} (page 2816) class is a subclass of \texttt{ModuleElement} (page 2813) that represents elements of a \texttt{PowerBasis} (page 2809), and adds functionality pertinent to elements represented directly over powers of the primitive element \( \theta \).

### Arithmetic with module elements

While a \texttt{ModuleElement} (page 2813) represents a linear combination over the generators of a particular module, recall that every module is either a \texttt{PowerBasis} (page 2809) or a descendant (along a chain of \texttt{Submodule} (page 2810) objects) thereof, so that in fact every \texttt{ModuleElement} (page 2813) represents an algebraic number in some field \( \mathbb{Q}(\theta) \), where \( \theta \) is the defining element of some \texttt{PowerBasis} (page 2809). It thus makes sense to talk about the number field to which a given \texttt{ModuleElement} (page 2813) belongs.

This means that any two \texttt{ModuleElement} (page 2813) instances can be added, subtracted, multiplied, or divided, provided they belong to the same number field. Similarly, since \( \mathbb{Q} \) is a subfield of every number field, any \texttt{ModuleElement} (page 2813) may be added, multiplied, etc. by any rational number.

```python
>>> from sympy import QQ
>>> from sympy.polys.numberfields.modules import to_col
>>> T = Poly(cyclotomic_poly(5))
>>> A = PowerBasis(T)
>>> C = A.submodule_from_matrix(3 * DomainMatrix.eye(4, ZZ))
>>> e = A(to_col([0, 2, 0, 0]), denom=3)
```

(continues on next page)
However, care must be taken with arithmetic operations on `ModuleElement` (page 2813), because the module $C$ to which the result will belong will be the nearest common ancestor (NCA) of the modules $A, B$ to which the two operands belong, and $C$ may be different from either or both of $A$ and $B$.

```
>>> A = PowerBasis(T)
>>> B = A.submodule_from_matrix(2 * DomainMatrix.eye(4, ZZ))
>>> C = A.submodule_from_matrix(3 * DomainMatrix.eye(4, ZZ))
>>> print((B(0) * C(0)).module == A)
True
```

Before the arithmetic operation is performed, copies of the two operands are automatically converted into elements of the NCA (the operands themselves are not modified). This upward conversion along an ancestor chain is easy: it just requires the successive multiplication by the defining matrix of each `Submodule` (page 2810).

Conversely, downward conversion, i.e. representing a given `ModuleElement` (page 2813) in a submodule, is also supported – namely by the `represent()` (page 2813) method – but is not guaranteed to succeed in general, since the given element may not belong to the submodule. The main circumstance in which this issue tends to arise is with multiplication, since modules, while closed under addition, need not be closed under multiplication.

**Multiplication**

Generally speaking, a module need not be closed under multiplication, i.e. need not form a ring. However, many of the modules we work with in the context of number fields are in fact rings, and our classes do support multiplication.

Specifically, any `Module` (page 2803) can attempt to compute its own multiplication table, but this does not happen unless an attempt is made to multiply two `ModuleElement` (page 2813) instances belonging to it.
>>> A = PowerBasis(T)
>>> print(A._mult_tab is None)
True
>>> a = A(0)*A(1)
>>> print(A._mult_tab is None)
False

Every PowerBasis (page 2809) is, by its nature, closed under multiplication, so instances of PowerBasis (page 2809) can always successfully compute their multiplication table.

When a Submodule (page 2810) attempts to compute its multiplication table, it converts each of its own generators into elements of its parent module, multiplies them there, in every possible pairing, and then tries to represent the results in itself, i.e. as \(\mathbb{Z}\)-linear combinations over its own generators. This will succeed if and only if the submodule is in fact closed under multiplication.

### Module Homomorphisms

Many important number theoretic algorithms require the calculation of the kernel of one or more module homomorphisms. Accordingly we have several lightweight classes, ModuleHomomorphism (page 2817), ModuleEndomorphism (page 2818), InnerEndomorphism (page 2818), and EndomorphismRing (page 2818), which provide the minimal necessary machinery to support this.

### Class Reference

```python
class sympy.polys.numberfields.modules.Module
    Generic finitely-generated module.

    This is an abstract base class, and should not be instantiated directly. The two concrete subclasses are PowerBasis (page 2809) and Submodule (page 2810).

    Every Submodule (page 2810) is derived from another module, referenced by its parent attribute. If S is a submodule, then we refer to S.parent, S.parent.parent, and so on, as the "ancestors" of S. Thus, every Module (page 2803) is either a PowerBasis (page 2809) or a Submodule (page 2810), some ancestor of which is a PowerBasis (page 2809).

    __call__(spec, denom=1)
    Generate a ModuleElement (page 2813) belonging to this module.

    Parameters
    spec : DomainMatrix (page 2753), int
        Specifies the numerators of the coefficients of the ModuleElement (page 2813). Can be either a column vector over \(\mathbb{Z}\) (page 2605), whose length must equal the number \(n\) of generators of this module, or else an integer \(j\), \(0 \leq j < n\), which is a shorthand for column \(j\) of \(I_n\), the \(n \times n\) identity matrix.

    denom : int, optional (default=1)
        Denominator for the coefficients of the ModuleElement (page 2813).

    Returns
    ModuleElement (page 2813)
```

5.8. Topics 2803
The coefficients are the entries of the `spec` vector, divided by `denom`.

**Examples**

```python
>>> from sympy.polys import Poly, cyclotomic_poly
>>> from sympy.polys.numberfields.modules import PowerBasis, to_col
>>> T = Poly(cyclotomic_poly(5))
>>> A = PowerBasis(T)
>>> e = A(to_col([1, 2, 3, 4]), denom=3)
>>> print(e)
[1, 2, 3, 4]/3
>>> f = A(2)
>>> print(f)
[0, 0, 1, 0]
```

**ancestors(include_self=False)**

Return the list of ancestor modules of this module, from the foundational `PowerBasis` (page 2809) downward, optionally including self.

**See also:**

*Module* (page 2803)

**basis_elements()**

Get list of *ModuleElement* (page 2813) being the generators of this module.

**element_from_rational(a)**

Return a *ModuleElement* (page 2813) representing a rational number.

**Parameters**

- `a`: int, ZZ (page 2605), QQ (page 2609)

**Returns**

*ModuleElement* (page 2813)

**Explanation**

The returned *ModuleElement* (page 2813) will belong to the first module on this module’s ancestor chain (including this module itself) that starts with unity.

**Examples**

```python
>>> from sympy.polys import Poly, cyclotomic_poly, QQ
>>> from sympy.polys.numberfields.modules import PowerBasis
>>> T = Poly(cyclotomic_poly(5))
>>> A = PowerBasis(T)
>>> a = A.element_from_rational(QQ(2, 3))
>>> print(a)
[2, 0, 0, 0]/3
```

**endomorphism_ring()**

Form the *EndomorphismRing* (page 2818) for this module.
**is_compat_col(col)**

Say whether `col` is a suitable column vector for this module.

**mult_tab()**

Get the multiplication table for this module (if closed under mult).

**Returns**

dict of dict of lists

**Raises**

**ClosureFailure**

If the module is not closed under multiplication.

**Explanation**

Computes a dictionary `M` of dictionaries of lists, representing the upper triangular half of the multiplication table.

In other words, if `0 <= i <= j < self.n`, then `M[i][j]` is the list of coefficients such that `g[i] * g[j] = sum(c[k]*g[k], k in range(self.n))`, where `g` is the list of generators of this module.

If `j < i` then `M[i][j]` is undefined.

**Examples**

```python
>>> from sympy.polys import Poly, cyclotomic_poly
>>> from sympy.polys.numberfields.modules import PowerBasis
>>> T = Poly(cyclotomic_poly(5))
>>> A = PowerBasis(T)
>>> print(A.mult_tab())
{0: {0: [1, 0, 0, 0], 1: [0, 1, 0, 0], 2: [0, 0, 1, 0], 3: [0, 0, 0, 1]},
 1: {1: [0, 0, 1, 0], 2: [0, 0, 0, 1], 3: [-1, -1, -1, -1]},
 2: {2: [-1, -1, -1, -1], 3: [1, 0, 0, 0]},
 3: {3: [0, 1, 0, 0]}}
```

**property n**

The number of generators of this module.

**nearest_common_ancestor(other)**

Locate the nearest common ancestor of this module and another.

**Returns**

`Module` (page 2803), None

**See also:**  
`Module` (page 2803)
property number_field
    Return the associated \textit{AlgebraicField} (page 2619), if any.

    \textbf{Returns}
    \textit{AlgebraicField} (page 2619), \textit{None}

\textbf{Explanation}

A \textit{PowerBasis} (page 2809) can be constructed on a \textit{Poly} (page 2453) \textit{f} or on an \textit{AlgebraicField} (page 2619) \textit{K}. In the latter case, the \textit{PowerBasis} (page 2809) and all its descendant modules will return \textit{K} as their \texttt{.number_field} property, while in the former case they will all return \textit{None}.

\textbf{one()}
    Return a \textit{ModuleElement} (page 2813) representing unity, and belonging to the first ancestor of this module (including itself) that starts with unity.

property parent
    The parent module, if any, for this module.

    \textbf{Returns}
    \textit{Module} (page 2803), \textit{None}

\textbf{Explanation}

For a \textit{Submodule} (page 2810) this is its parent attribute; for a \textit{PowerBasis} (page 2809) this is \textit{None}.

\textbf{See also:}
\textit{Module} (page 2803)

\textbf{power_basis_ancestor()}
    Return the \textit{PowerBasis} (page 2809) that is an ancestor of this module.

    \textbf{See also:}
    \textit{Module} (page 2803)

\textbf{represent(elt)}
    Represent a module element as an integer-linear combination over the generators of this module.

    \textbf{Parameters}
    \texttt{elt : ModuleElement} (page 2813)
    The module element to be represented. Must belong to some ancestor module of this module (including this module itself).

    \textbf{Returns}
    \textit{DomainMatrix} (page 2753) over \textit{ZZ} (page 2605)
    This will be a column vector, representing the coefficients of a linear combination of this module's generators, which equals the given element.

    \textbf{Raises}
    \textit{ClosureFailure}
If the given element cannot be represented as a \( \mathbb{Z} \) (page 2605)-linear combination over this module.

**Explanation**

In our system, to “represent” always means to write a \textit{ModuleElement} (page 2813) as a \( \mathbb{Z} \) (page 2605)-linear combination over the generators of the present \textit{Module} (page 2803). Furthermore, the incoming \textit{ModuleElement} (page 2813) must belong to an ancestor of the present \textit{Module} (page 2803) (or to the present \textit{Module} (page 2803) itself).

The most common application is to represent a \textit{ModuleElement} (page 2813) in a \textit{Submodule} (page 2810). For example, this is involved in computing multiplication tables.

On the other hand, representing in a \textit{PowerBasis} (page 2809) is an odd case, and one which tends not to arise in practice, except for example when using a \textit{ModuleEndomorphism} (page 2818) on a \textit{PowerBasis} (page 2809).

In such a case, (1) the incoming \textit{ModuleElement} (page 2813) must belong to the \textit{PowerBasis} (page 2809) itself (since the latter has no proper ancestors) and (2) it is “representable” iff it belongs to \( \mathbb{Z}[\theta] \) (although generally a \textit{PowerBasisElement} (page 2816) may represent any element of \( \mathbb{Q}(\theta) \), i.e. any algebraic number).

**Examples**

```python
>>> from sympy import Poly, cyclotomic_poly
>>> from sympy.polys.numberfields.modules import PowerBasis, to_col
>>> from sympy.abc import zeta

>>> T = Poly(cyclotomic_poly(5))
>>> A = PowerBasis(T)
>>> a = A(to_col([2, 4, 6, 8]))

The \textit{ModuleElement} (page 2813) \( a \) has all even coefficients. If we represent \( a \) in the submodule \( B = 2^*A \), the coefficients in the column vector will be halved:

```python
>>> B = A.submodule_from_gens([2^*A(i) for i in range(4)])
>>> b = B.represent(a)
>>> print(b.transpose())
DomainMatrix([[1, 2, 3, 4]], (1, 4), ZZ)
```

However, the element of \( B \) so defined still represents the same algebraic number:

```python
>>> print(a.poly(zeta).as_expr())
8*zeta**3 + 6*zeta**2 + 4*zeta + 2
>>> print(B(b).over_power_basis().poly(zeta).as_expr())
8*zeta**3 + 6*zeta**2 + 4*zeta + 2
```

**See also:**

\textit{Submodule.represent} (page 2813), \textit{PowerBasis.represent} (page 2809)

\textit{starts_with_unity}()

Say whether the module’s first generator equals unity.
**submodule_from_gens**(\(gens, hnf=True, hnf_modulus=None\))

Form the submodule generated by a list of `ModuleElement` (page 2813) belonging to this module.

**Parameters**
- **gens**: list of `ModuleElement` (page 2813) belonging to this module.
- **hnf**: boolean, optional (default=True)
  - If True, we will reduce the matrix into Hermite Normal Form before forming the `Submodule` (page 2810).
- **hnf_modulus**: int, None, optional (default=None)
  - Modulus for use in the HNF reduction algorithm. See `hermite_normal_form()` (page 2783).

**Returns**
- `Submodule` (page 2810)

**Examples**

```python
>>> from sympy.polys import Poly, cyclotomic_poly
>>> from sympy.polys.numberfields.modules import PowerBasis
>>> T = Poly(cyclotomic_poly(5))
>>> A = PowerBasis(T)
>>> gens = [A(0), 2*A(1), 3*A(2), 4*A(3)/5]
>>> B = A.submodule_from_gens(gens)
>>> print(B)
Submodule[[5, 0, 0, 0], [0, 10, 0, 0], [0, 0, 15, 0], [0, 0, 0, 4]]/5
```

See also:
- `submodule_from_matrix` (page 2808)

**submodule_from_matrix**(\(B, denom=1\))

Form the submodule generated by the elements of this module indicated by the columns of a matrix, with an optional denominator.

**Parameters**
- **B**: `DomainMatrix` (page 2753) over `ZZ` (page 2605)
  - Each column gives the numerators of the coefficients of one generator of the submodule. Thus, the number of rows of \(B\) must equal the number of generators of the present module.
- **denom**: int, optional (default=1)
  - Common denominator for all generators of the submodule.

**Returns**
- `Submodule` (page 2810)

**Raises**
- `ValueError`
  - If the given matrix \(B\) is not over `ZZ` (page 2605) or its number of rows does not equal the number of generators of the present module.
Examples

```python
>>> from sympy.polys import Poly, cyclotomic_poly, ZZ
>>> from sympy.polys.matrices import DM
>>> from sympy.polys.numberfields.modules import PowerBasis
>>> T = Poly(cyclotomic_poly(5))
>>> A = PowerBasis(T)
>>> B = A.submodule_from_matrix(DM([...
    [0, 10, 0, 0],
    [0, 0, 7, 0],
    ...], ZZ).transpose(), denom=15)
>>> print(B)
Submodule[[0, 10, 0, 0], [0, 0, 7, 0]]/15
```

See also:
- `submodule_from_gens` (page 2807)

`whole_submodule()`
Return a submodule equal to this entire module.

Explanation

This is useful when you have a `PowerBasis` (page 2809) and want to turn it into a `Submodule` (page 2810) (in order to use methods belonging to the latter).

`zero()`
Return a `ModuleElement` (page 2813) representing zero.

```python
class sympy.polys.numberfields.modules.PowerBasis(T)
The module generated by the powers of an algebraic integer.
__init__(T)
Parameters
T : `Poly` (page 2453), `AlgebraicField` (page 2619)
Either (1) the monic, irreducible, univariate polynomial over `ZZ`
(page 2605), a root of which is the generator of the power basis, or
(2) an `AlgebraicField` (page 2619) whose primitive element is the
generator of the power basis.

`element_from_ANP(a)`
Convert an ANP into a PowerBasisElement.

`element_from_alg_num(a)`
Convert an AlgebraicNumber into a PowerBasisElement.

`element_from_poly(f)`
Produce an element of this module, representing $f$ after reduction mod our defining
minimal polynomial.

Parameters
f : `Poly` (page 2453) over `ZZ` (page 2605) in same var as our defining poly.

Returns
`PowerBasisElement` (page 2816)```
represent(elt)

Represent a module element as an integer-linear combination over the generators of this module.

See also:

Module.represent (page 2806), Submodule.represent (page 2813)

class sympy.polys.numberfields.modules.Submodule(parent, matrix, denom=1, mult_tab=None)

A submodule of another module.

__init__(parent, matrix, denom=1, mult_tab=None)

Parameters

parent : Module (page 2803)

The module from which this one is derived.

matrix : DomainMatrix (page 2753) over ZZ (page 2605)

The matrix whose columns define this submodule's generators as linear combinations over the parent's generators.

denom : int, optional (default=1)

Denominator for the coefficients given by the matrix.

mult_tab : dict, None, optional

If already known, the multiplication table for this module may be supplied.

property QQ_matrix

DomainMatrix (page 2753) over QQ (page 2609), equal to self.matrix / self.denom, and guaranteed to be dense.

Returns

DomainMatrix (page 2753) over QQ (page 2609)

Explanation

Depending on how it is formed, a DomainMatrix (page 2753) may have an internal representation that is sparse or dense. We guarantee a dense representation here, so that tests for equivalence of submodules always come out as expected.

Examples

```python
>>> from sympy.polys import Poly, cyclotomic_poly, ZZ
>>> from sympy.abc import x
>>> from sympy.polys.matrices import DomainMatrix
>>> from sympy.polys.numberfields.modules import PowerBasis
>>> T = Poly(cyclotomic_poly(5, x))
>>> A = PowerBasis(T)
>>> B = A.submodule_from_matrix(3*DomainMatrix.eye(4, ZZ), denom=6)
>>> C = A.submodule_from_matrix(DomainMatrix.eye(4, ZZ), denom=2)
```
from sympy import *

B = Matrix(((1, 0, 0), (0, 1, 0), (0, 0, 1)))
C = Matrix(((1, 0, 0), (0, 1, 0), (0, 0, 1)))

print(B * C)
print(B * C == C * B)

add(other, hnf=True, hnf_modulus=None)

Parameters
other : Submodule (page 2810)

hnf : boolean, optional (default=True)

If True, reduce the matrix of the combined module to its Hermite Normal Form.

hnf_modulus : ZZ (page 2605), None, optional

If a positive integer is provided, use this as modulus in the HNF reduction. See hermite_normal_form() (page 2783).

Returns
Submodule (page 2810)

Explanation
This represents the module generated by the union of the two modules’ sets of generators.

basis_element_pullbacks()

Return list of this submodule’s basis elements as elements of the submodule’s parent module.

discard_before(r)

Produce a new module by discarding all generators before a given index r.

mul(other, hnf=True, hnf_modulus=None)

Multiply this Submodule (page 2810) by a rational number, a ModuleElement (page 2813), or another Submodule (page 2810).

Parameters
other : int, ZZ (page 2605), QQ (page 2609), ModuleElement (page 2813), Submodule (page 2810)

hnf : boolean, optional (default=True)

If True, reduce the matrix of the product module to its Hermite Normal Form.

hnf_modulus : ZZ (page 2605), None, optional

If a positive integer is provided, use this as modulus in the HNF reduction. See hermite_normal_form() (page 2783).

Returns
Submodule (page 2810)
Explanation

To multiply by a rational number or `ModuleElement` (page 2813) means to form the submodule whose generators are the products of this quantity with all the generators of the present submodule.

To multiply by another `Submodule` (page 2810) means to form the submodule whose generators are all the products of one generator from the one submodule, and one generator from the other.

**reduce_element(elt)**

If this submodule $B$ has defining matrix $W$ in square, maximal-rank Hermite normal form, then, given an element $x$ of the parent module $A$, we produce an element $y \in A$ such that $x - y \in B$, and the $i$th coordinate of $y$ satisfies $0 \leq y_i < w_{i,i}$. This representative $y$ is unique, in the sense that every element of the coset $x + B$ reduces to it under this procedure.

**Parameters**

`elt : ModuleElement` (page 2813)

An element of this submodule’s parent module.

**Returns**

`elt : ModuleElement` (page 2813)

An element of this submodule’s parent module.

**Raises**

`NotImplementedError`

If the given `ModuleElement` (page 2813) does not belong to this submodule’s parent module.

`StructureError`

If this submodule’s defining matrix is not in square, maximal-rank Hermite normal form.

Explanation

In the special case where $A$ is a power basis for a number field $K$, and $B$ is a submodule representing an ideal $I$, this operation represents one of a few important ways of reducing an element of $K$ modulo $I$ to obtain a “small” representative. See [Cohen00] Section 1.4.3.

Examples

```python
>>> from sympy import QQ, Poly, symbols
>>> t = symbols('t')
>>> k = QQ.alg_field_from_poly(Poly(t**3 + t**2 - 2*t + 8))
>>> Zk = k.maximal_order()
>>> A = Zk.parent
>>> B = (A(2) - 3*A(0))*Zk
>>> B.reduce_element(A(2))
[3, 0, 0]
```
References

[Cohen00]

reduced()

Produce a reduced version of this submodule.

Returns

Submodule (page 2810)

Explanation

In the reduced version, it is guaranteed that 1 is the only positive integer dividing both the submodule’s denominator, and every entry in the submodule’s matrix.

represent(elt)

Represent a module element as an integer-linear combination over the generators of this module.

See also:

Module.represent (page 2806), PowerBasis.represent (page 2809)

class sympy.polys.numberfields.modules.ModuleElement(module, col, denom=1)

Represents an element of a Module (page 2803).

NOTE: Should not be constructed directly. Use the __call__() (page 2803) method or the make_mod_elt() (page 2817) factory function instead.

__init__(module, col, denom=1)

Parameters

module : Module (page 2803)

The module to which this element belongs.

col : DomainMatrix (page 2753) over ZZ (page 2605)

Column vector giving the numerators of the coefficients of this element.

denom : int, optional (default=1)

Denominator for the coefficients of this element.

__add__(other)

A ModuleElement (page 2813) can be added to a rational number, or to another ModuleElement (page 2813).
Explanation

When the other summand is a rational number, it will be converted into a `ModuleElement` (belonging to the first ancestor of this module that starts with unity).

In all cases, the sum belongs to the nearest common ancestor (NCA) of the modules of the two summands. If the NCA does not exist, we return `NotImplemented`.

__mul__(other)

A `ModuleElement` can be multiplied by a rational number, or by another `ModuleElement`.

Explanation

When the multiplier is a rational number, the product is computed by operating directly on the coefficients of this `ModuleElement`.

When the multiplier is another `ModuleElement`, the product will belong to the nearest common ancestor (NCA) of the modules of the two operands, and that NCA must have a multiplication table. If the NCA does not exist, we return `NotImplemented`. If the NCA does not have a mult. table, `ClosureFailure` will be raised.

__mod__(m)

Reduce this `ModuleElement` mod a `Submodule`.

Parameters

- m : int, `ZZ`, `QQ`, `Submodule`

If a `Submodule`, reduce `self` relative to this. If an integer or rational, reduce relative to the `Submodule` that is our own module times this constant.

See also:

- `Submodule.reduce_element`

property `QQ_col`

`DomainMatrix` over `QQ`, equal to `self.col / self.denom`, and guaranteed to be dense.

See also:

- `Submodule.QQ_matrix`

`column(domain=None)`

Get a copy of this element’s column, optionally converting to a domain.

`equiv(other)`

A `ModuleElement` may test as equivalent to a rational number or another `ModuleElement`, if they represent the same algebraic number.

Parameters

- other : int, `ZZ`, `QQ`, `ModuleElement`

Returns

bool
Raises
UnificationFailed

If self and other do not share a common PowerBasis (page 2809) ancestor.

Explanation

This method is intended to check equivalence only in those cases in which it is easy to test; namely, when other is either a ModuleElement (page 2813) that can be unified with this one (i.e. one which shares a common PowerBasis (page 2809) ancestor), or else a rational number (which is easy because every PowerBasis (page 2809) represents every rational number).

classmethod from_int_list(module, coeffs, denom=1)

Make a ModuleElement (page 2813) from a list of ints (instead of a column vector).

is_compat(other)

Test whether other is another ModuleElement (page 2813) with same module.

property n

The length of this element’s column.

over_power_basis()

Transform into a PowerBasisElement (page 2816) over our PowerBasis (page 2809) ancestor.

reduced()

Produce a reduced version of this ModuleElement, i.e. one in which the gcd of the denominator together with all numerator coefficients is 1.

reduced_mod_p(p)

Produce a version of this ModuleElement (page 2813) in which all numerator coefficients have been reduced mod p.

to_ancestor(anc)

Transform into a ModuleElement (page 2813) belonging to a given ancestor of this element’s module.

Parameters
anc : Module (page 2803)

to_parent()

Transform into a ModuleElement (page 2813) belonging to the parent of this element’s module.

unify(other)

Try to make a compatible pair of ModuleElement (page 2813), one equivalent to this one, and one equivalent to the other.

Returns
Pair (e1, e2)

Each ei is a ModuleElement (page 2813), they belong to the same Module (page 2803), e1 is equivalent to self, and e2 is equivalent to other.
Raises
UnificationFailed

If self and other have no common ancestor module.

Explanation

We search for the nearest common ancestor module for the pair of elements, and represent each one there.

class sympy.polys.numberfields.modules.PowerBasisElement(module, col, denom=1)

Subclass for ModuleElement (page 2813) instances whose module is a PowerBasis (page 2809).

property T
Access the defining polynomial of the PowerBasis (page 2809).

as_expr(x=None)
Create a Basic expression from self.

property generator
Return a Symbol (page 1028) to be used when expressing this element as a polynomial.

If we have an associated AlgebraicField (page 2619) whose primitive element has an alias symbol, we use that. Otherwise we use the variable of the minimal polynomial defining the power basis to which we belong.

property is_rational
Say whether this element represents a rational number.

norm(T=None)
Compute the norm of this number.

numerator(x=None)
Obtain the numerator as a polynomial over ZZ (page 2605).

poly(x=None)
Obtain the number as a polynomial over QQ (page 2609).

to_ANP()  
Convert to an equivalent ANP (page 2650).

to_alg_num()  
Try to convert to an equivalent AlgebraicNumber (page 1039).

Returns
AlgebraicNumber (page 1039)

Raises
StructureError
    If the PowerBasis (page 2809) to which this element belongs does not have an associated AlgebraicField (page 2619).
**Explanation**

In general, the conversion from an `AlgebraicNumber` (page 1039) to a `PowerBasisElement` (page 2816) throws away information, because an `AlgebraicNumber` (page 1039) specifies a complex embedding, while a `PowerBasisElement` (page 2816) does not. However, in some cases it is possible to convert a `PowerBasisElement` (page 2816) back into an `AlgebraicNumber` (page 1039), namely when the associated `PowerBasis` (page 2809) has a reference to an `AlgebraicField` (page 2619).

```python
from sympy import Poly, cyclotomic_poly
from sympy.polys.numberfields.modules import PowerBasis,
    ModuleHomomorphism

T = Poly(cyclotomic_poly(5))
A = PowerBasis(T)
B = A.submodule_from_gens([2*A(j) for j in range(4)])
phi = ModuleHomomorphism(A, B, lambda x: 6*x)
print(phi.matrix())
```

```
DomainMatrix([[3, 0, 0, 0], [0, 3, 0, 0], [0, 0, 3, 0], [0, 0, 0, 3]],
    (4, 4), ZZ)
```

**Examples**

```python
>>> from sympy import Poly, cyclotomic_poly
>>> from sympy.polys.numberfields.modules import PowerBasis,
    ModuleHomomorphism
>>> T = Poly(cyclotomic_poly(5))
>>> A = PowerBasis(T)
>>> B = A.submodule_from_gens([2*A(j) for j in range(4)])
>>> phi = ModuleHomomorphism(A, B, lambda x: 6*x)
```

```
Kernel([0, 0, 0, 0])
```

**Kernel**

Compute a Submodule representing the kernel of this homomorphism.

```python
>>> print(phi.kernel())
```

```
Submodule([0, 0, 0, 0])
```

**kernel**

Compute a Submodule representing the kernel of this homomorphism.

```python
>>> print(phi.kernel())
```

```
Submodule([0, 0, 0, 0])
```

**5.8. Topics**
This submodule's generators span the kernel of this homomorphism over \( \mathbb{Z} \) (page 2605), or else over \( GF(p) \) (page 2602) if a modulus was given.

**matrix**(modulus=None)

Compute the matrix of this homomorphism.

**Parameters**

- **modulus**: int, optional
  
  A positive prime number \( p \) if the matrix should be reduced mod \( p \).

**Returns**

- **DomainMatrix** (page 2753)
  
  The matrix is over \( \mathbb{Z} \) (page 2605), or else over \( GF(p) \) (page 2602) if a modulus was given.

**class** sympy.polys.numberfields.modules.ModuleEndomorphism(domain, mapping)

A homomorphism from one module to itself.

**__init__**(domain, mapping)

**Parameters**

- **domain**: Module (page 2803)
  
  The common domain and codomain of the mapping.

- **mapping**: callable
  
  An arbitrary callable is accepted, but should be chosen so as to represent an actual module endomorphism. In particular, should accept and return elements of \( domain \).

**class** sympy.polys.numberfields.modules.InnerEndomorphism(domain, multiplier)

An inner endomorphism on a module, i.e. the endomorphism corresponding to multiplication by a fixed element.

**__init__**(domain, multiplier)

**Parameters**

- **domain**: Module (page 2803)
  
  The domain and codomain of the endomorphism.

- **multiplier**: ModuleElement (page 2813)
  
  The element \( a \) defining the mapping as \( x \mapsto ax \).

**class** sympy.polys.numberfields.modules.EndomorphismRing(domain)

The ring of endomorphisms on a module.

**__init__**(domain)

**Parameters**

- **domain**: Module (page 2803)
  
  The domain and codomain of the endomorphisms.

**inner_endomorphism**(multiplier)

Form an inner endomorphism belonging to this endomorphism ring.

**Parameters**

- **multiplier**: ModuleElement (page 2813)
Element $a$ defining the inner endomorphism $x \mapsto ax$.

**Returns**

*InnerEndomorphism* (page 2818)

**represent**(element)

Represent an element of this endomorphism ring, as a single column vector.

**Parameters**

*element* : *ModuleEndomorphism* (page 2818) belonging to this ring.

**Returns**

*DomainMatrix* (page 2753)

Column vector equalling the vertical stacking of all the columns of the matrix that represents the given *element* as a mapping.

**Explanation**

Let $M$ be a module, and $E$ its ring of endomorphisms. Let $N$ be another module, and consider a homomorphism $\varphi : N \to E$. In the event that $\varphi$ is to be represented by a matrix $A$, each column of $A$ must represent an element of $E$. This is possible when the elements of $E$ are themselves representable as matrices, by stacking the columns of such a matrix into a single column.

This method supports calculating such matrices $A$, by representing an element of this endomorphism ring first as a matrix, and then stacking that matrix’s columns into a single column.

**Examples**

Note that in these examples we print matrix transposes, to make their columns easier to inspect.

```python
>>> from sympy import Poly, cyclotomic_poly
>>> from sympy.polys.numberfields.modules import PowerBasis
>>> from sympy.polys.numberfields.modules import ModuleHomomorphism
>>> T = Poly(cyclotomic_poly(5))
>>> M = PowerBasis(T)
>>> E = M.endomorphism_ring()
```

Let $\zeta$ be a primitive 5th root of unity, a generator of our field, and consider the inner endomorphism $\tau$ on the ring of integers, induced by $\zeta$:

```python
>>> zeta = M(1)
>>> tau = E.inner_endomorphism(zeta)
>>> tau.matrix().transpose()
```

```
DomainMatrix([ [0, 1, 0, 0], [0, 0, 1, 0], [0, 0, 0, 1], [-1, -1, -1, -1]], (4, 4), ZZ)
```

The matrix representation of $\tau$ is as expected. The first column shows that multiplying by $\zeta$ carries $1$ to $\zeta$, the second column that it carries $\zeta$ to $\zeta^2$, and so forth.

The represent method of the endomorphism ring $E$ stacks these into a single column:
This is useful when we want to consider a homomorphism $\varphi$ having $E$ as codomain:

```python
>>> phi = ModuleHomomorphism(M, E, lambda x: E.inner_endomorphism(x))
```

and we want to compute the matrix of such a homomorphism:

```python
>>> phi.matrix().transpose()
```

Note that the stacked matrix of $\tau$ occurs as the second column in this example. This is because $\zeta$ is the second basis element of $M$, and $\varphi(\zeta) = \tau$.

sympy.polys.numberfields.modules.find_min_poly(alpha, domain, x=None, powers=None)

Find a polynomial of least degree (not necessarily irreducible) satisfied by an element of a finitely-generated ring with unity.

**Parameters**

- **alpha**: ModuleElement (page 2813)
  
The element whose min poly is to be found, and whose module has multiplication and starts with unity.

- **domain**: Domain (page 2584)
  
The desired domain of the polynomial.

- **x**: Symbol (page 1028), optional
  
The desired variable for the polynomial.

- **powers**: list, optional
  
If desired, pass an empty list. The powers of $alpha$ (as ModuleElement (page 2813) instances) from the zeroth up to the degree of the min poly will be recorded here, as we compute them.

**Returns**

- **Poly** (page 2453), None
  
The minimal polynomial for alpha, or None if no polynomial could be found over the desired domain.

**Raises**

- **MissingUnityError**
  
If the module to which alpha belongs does not start with unity.
If the module to which alpha belongs is not closed under multiplication.

**Examples**

For the $n$th cyclotomic field, $n$ an odd prime, consider the quadratic equation whose roots are the two periods of length $(n - 1)/2$. Article 356 of Gauss tells us that we should get $x^2 + x - (n - 1)/4$ or $x^2 + x + (n + 1)/4$ according to whether $n$ is 1 or 3 mod 4, respectively.

```python
>>> from sympy import Poly, cyclotomic_poly, primitive_root, QQ
>>> from sympy.abc import x
>>> from sympy.polys.numberfields.modules import PowerBasis, find_min_poly
>>> n = 13
>>> g = primitive_root(n)
>>> C = PowerBasis(Poly(cyclotomic_poly(n, x)))
>>> ee = [g**(2*k+1) % n for k in range((n-1)//2)]
>>> eta = sum(C(e) for e in ee)
>>> print(find_min_poly(eta, QQ, x=x).as_expr())
x**2 + x - 3
>>> n = 19
>>> g = primitive_root(n)
>>> C = PowerBasis(Poly(cyclotomic_poly(n, x)))
>>> ee = [g**(2*k+2) % n for k in range((n-1)//2)]
>>> eta = sum(C(e) for e in ee)
>>> print(find_min_poly(eta, QQ, x=x).as_expr())
x**2 + x + 5
```

**Utilities**

`sympy.polys.numberfields.utilities.is_rat(c)`

Test whether an argument is of an acceptable type to be used as a rational number.

**Explanation**

Returns True on any argument of type int, ZZ (page 2605), or QQ (page 2609).

**See also:**

`is_int` (page 2821)

`sympy.polys.numberfields.utilities.is_int(c)`

Test whether an argument is of an acceptable type to be used as an integer.
Explanation

Returns True on any argument of type int or ZZ (page 2605).

See also:

is_rat (page 2821)
sympy.polys.numberfields.utilities.get_num_denom(c)

Given any argument on which is_rat() (page 2821) is True, return the numerator and denominator of this number.

See also:

is_rat (page 2821)
sympy.polys.numberfields.utilities.extract_fundamental_discriminant(a)

Extract a fundamental discriminant from an integer a.

Parameters

a: int, must be 0 or 1 mod 4

Returns

Pair (D, F) of dictionaries.

Raises

ValueError

If a is not 0 or 1 mod 4.

Explanation

Given any rational integer a that is 0 or 1 mod 4, write \( a = df^2 \), where \( d \) is either 1 or a fundamental discriminant, and return a pair of dictionaries \( (D, F) \) giving the prime factorizations of \( d \) and \( f \) respectively, in the same format returned by factorint() (page 1539).

A fundamental discriminant \( d \) is different from unity, and is either 1 mod 4 and square-free, or is 0 mod 4 and such that \( d/4 \) is squarefree and 2 or 3 mod 4. This is the same as being the discriminant of some quadratic field.

Examples

```python
>>> from sympy.polys.numberfields.utilities import extract_fundamental_discriminant
>>> print(extract_fundamental_discriminant(-432))
({3: 1, -1: 1}, {2: 2, 3: 1})
```

For comparison:

```python
>>> from sympy import factorint
>>> print(factorint(-432))
{2: 4, 3: 3, -1: 1}
```
References

[R739]

class sympy.polys.numberfields.utilities.AlgIntPowers(T, modulus=None)
Compute the powers of an algebraic integer.

Explanation

Given an algebraic integer $\theta$ by its monic irreducible polynomial $T$ over $\mathbb{Z}$ (page 2605), this class computes representations of arbitrarily high powers of $\theta$, as $\mathbb{Z}$ (page 2605)-linear combinations over $\{1, \theta, \ldots, \theta^{n-1}\}$, where $n = \text{deg}(T)$.

The representations are computed using the linear recurrence relations for powers of $\theta$, derived from the polynomial $T$. See [1], Sec. 4.2.2.

Optionally, the representations may be reduced with respect to a modulus.

Examples

```python
>>> from sympy import Poly, cyclotomic_poly
>>> from sympy.polys.numberfields.utilities import AlgIntPowers
>>> T = Poly(cyclotomic_poly(5))
>>> zeta_pow = AlgIntPowers(T)
>>> print(zeta_pow[0])
[1, 0, 0, 0]
>>> print(zeta_pow[1])
[0, 1, 0, 0]
>>> print(zeta_pow[4])
[-1, -1, -1, -1]
>>> print(zeta_pow[24])
[-1, -1, -1, -1]
```

References

[R740]

__init__(T, modulus=None)

Parameters

- **T**: Poly (page 2453)
  
The monic irreducible polynomial over $\mathbb{Z}$ (page 2605) defining the algebraic integer.

- **modulus**: int, None, optional
  
  If not None, all representations will be reduced w.r.t. this.

sympy.polys.numberfields.utilities.coeff_search(m, R)

Generate coefficients for searching through polynomials.

Parameters

- **m**: int
Length of coeff list.

\[ R : \text{int} \]

Initial max abs val for coeffs (will increase as search proceeds).

**Returns**

- generator

Infinite generator of lists of coefficients.

**Explanation**

Lead coeff is always non-negative. Explore all combinations with coeffs bounded in absolute value before increasing the bound. Skip the all-zero list, and skip any repeats. See examples.

**Examples**

```python
>>> from sympy.polys.numberfields.utilities import coeff_search
>>> cs = coeff_search(2, 1)
>>> C = [next(cs) for i in range(13)]
>>> print(C)
[[1, 1], [1, 0], [1, -1], [0, 1], [2, 2], [2, 1], [2, 0], [2, -1], [2, -2],
 [1, 2], [1, -2], [0, 2], [3, 3]]
```

**sympy.polys.numberfields.utilities.supplement_a_subspace(M)**

Extend a basis for a subspace to a basis for the whole space.

**Parameters**

- \( M : \text{DomainMatrix} \) (page 2753)

  The columns give the basis for the subspace.

**Returns**

- DomainMatrix (page 2753)

  This matrix is invertible and its first \( r \) columns equal \( M \).

**Raises**

- DMRankError

  If \( M \) was not of maximal rank.

**Explanation**

Given an \( n \times r \) matrix \( M \) of rank \( r \) (so \( r \leq n \)), this function computes an invertible \( n \times n \) matrix \( B \) such that the first \( r \) columns of \( B \) equal \( M \).

This operation can be interpreted as a way of extending a basis for a subspace, to give a basis for the whole space.

To be precise, suppose you have an \( n \)-dimensional vector space \( V \), with basis \( \{v_1, v_2, \ldots, v_n\} \), and an \( r \)-dimensional subspace \( W \) of \( V \), spanned by a basis \( \{w_1, w_2, \ldots, w_r\} \), where the \( w_j \) are given as linear combinations of the \( v_i \). If the columns of \( M \) represent
the $w_j$ as such linear combinations, then the columns of the matrix $B$ computed by this function give a new basis $\{u_1, u_2, \ldots, u_n\}$ for $V$, again relative to the $\{v_i\}$ basis, and such that $u_j = w_j$ for $1 \leq j \leq r$.

**Examples**

Note: The function works in terms of columns, so in these examples we print matrix transposes in order to make the columns easier to inspect.

```python
>>> from sympy.polys.matrices import DM
>>> from sympy import QQ, FF
>>> from sympy.polys.numberfields.utilities import supplement_a_subspace

>>> M = DM([[1, 7, 0], [2, 3, 4]], QQ).transpose()
>>> print(supplement_a_subspace(M).to_Matrix().transpose())
Matrix([[1, 7, 0], [2, 3, 4], [1, 0, 0]])

>>> M2 = M.convert_to(FF(7))
>>> print(M2.to_Matrix().transpose())
Matrix([[1, 0, 0], [2, 3, -3]])

>>> print(supplement_a_subspace(M2).to_Matrix().transpose())
Matrix([[1, 0, 0], [2, 3, -3], [0, 1, 0]])
```

**References**

sympy.polys.numberfields.utilities.\texttt{isolate}(\textit{alg, eps=None, fast=False})

Find a rational isolating interval for a real algebraic number.

**Parameters**

- \textit{alg} : str, int, \texttt{Expr} (page 999)
  
  The algebraic number to be isolated. Must be a real number, to use this particular function. However, see also \texttt{Poly.intervals} (page 2473), which isolates complex roots when you pass all=True.

- \textit{eps} : positive element of \texttt{QQ} (page 2609), None, optional (default=None)
  
  Precision to be passed to \texttt{Poly.refine_root} (page 2488).

- \textit{fast} : boolean, optional (default=False)
  
  Say whether fast refinement procedure should be used. (Will be passed to \texttt{Poly.refine_root} (page 2488).

**Returns**

Pair of rational numbers defining an isolating interval for the given algebraic number.
Examples

```python
>>> from sympy import isolate, sqrt, Rational
>>> print(isolate(sqrt(2)))
(1, 2)
>>> print(isolate(sqrt(2), eps=Rational(1, 100)))
(24/17, 17/12)
```

Poly.intervals (page 2473)

Category Theory

Introduction

The category theory module for SymPy will allow manipulating diagrams within a single category, including drawing them in TikZ and deciding whether they are commutative or not.

The general reference work this module tries to follow is

The latest version of this book should be available for free download from

katmat.math.uni-bremen.de/acc/acc.pdf

The module is still in its pre-embryonic stage.

Base Class Reference

This section lists the classes which implement some of the basic notions in category theory: objects, morphisms, categories, and diagrams.

```python
class sympy.categories.Object(name, **assumptions)
    The base class for any kind of object in an abstract category.
```

Explanation

While technically any instance of Basic (page 979) will do, this class is the recommended way to create abstract objects in abstract categories.

```python
class sympy.categories.Morphism(domain, codomain)
    The base class for any morphism in an abstract category.
```
**Explanation**

In abstract categories, a morphism is an arrow between two category objects. The object where the arrow starts is called the domain, while the object where the arrow ends is called the codomain.

Two morphisms between the same pair of objects are considered to be the same morphisms. To distinguish between morphisms between the same objects use `NamedMorphism` (page 2828).

It is prohibited to instantiate this class. Use one of the derived classes instead.

**See also:**

- `IdentityMorphism` (page 2830), `NamedMorphism` (page 2828), `CompositeMorphism` (page 2828)

**property codomain**

Returns the codomain of the morphism.

**Examples**

```python
>>> from sympy.categories import Object, NamedMorphism
>>> A = Object("A")
>>> B = Object("B")
>>> f = NamedMorphism(A, B, "f")
>>> f.codomain
Object("B")
```

**compose**(*other*)

Composes self with the supplied morphism.

The order of elements in the composition is the usual order, i.e., to construct \( g \circ f \) use \( g.compose(f) \).

**Examples**

```python
>>> from sympy.categories import Object, NamedMorphism
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> g * f
CompositeMorphism(((NamedMorphism(Object("A"), Object("B"), "f"), NamedMorphism(Object("B"), Object("C"), "g")))
>>> (g * f).domain
Object("A")
>>> (g * f).codomain
Object("C")
```

**property domain**

Returns the domain of the morphism.
class sympy.categories.NamedMorphism(domain, codomain, name)

Represents a morphism which has a name.

Examples

```python
from sympy.categories import Object, NamedMorphism
A = Object("A")
B = Object("B")
f = NamedMorphism(A, B, "f")
f.domain
Object("A")
f.name
'f'
```

See also:

Morphism (page 2826)

property name

Returns the name of the morphism.

Examples

```python
from sympy.categories import Object, NamedMorphism
A = Object("A")
B = Object("B")
f = NamedMorphism(A, B, "f")
f.name
'f'
```

class sympy.categories.CompositeMorphism(*components)

Represents a morphism which is a composition of other morphisms.
**Explanation**

Two composite morphisms are equal if the morphisms they were obtained from (components) are the same and were listed in the same order.

The arguments to the constructor for this class should be listed in diagram order: to obtain the composition $g \circ f$ from the instances of `Morphism` (page 2826) $g$ and $f$ use `CompositeMorphism(f, g)`.

**Examples**

```python
>>> from sympy.categories import Object, NamedMorphism, CompositeMorphism
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> g * f
CompositeMorphism((NamedMorphism(Object("A"), Object("B"), "f"),
                   NamedMorphism(Object("B"), Object("C"), "g")))
>>> CompositeMorphism(f, g) == g * f
True
```

**property codomain**

Returns the codomain of this composite morphism.

The codomain of the composite morphism is the codomain of its last component.

**Examples**

```python
>>> from sympy.categories import Object, NamedMorphism
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> (g * f).codomain
Object("C")
```

**property components**

Returns the components of this composite morphism.
Examples

```python
>>> from sympy.categories import Object, NamedMorphism
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> (g * f).components
(NamedMorphism(Object("A"), Object("B"), "f"),
 NamedMorphism(Object("B"), Object("C"), "g"))
```

**property domain**

Returns the domain of this composite morphism.

The domain of the composite morphism is the domain of its first component.

Examples

```python
>>> from sympy.categories import Object, NamedMorphism
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
```

```python
>>> (g * f).domain
Object("A")
```

**flatten(new_name)**

Forgets the composite structure of this morphism.

Explanation

If new_name is not empty, returns a `NamedMorphism` (page 2828) with the supplied name, otherwise returns a `Morphism` (page 2826). In both cases the domain of the new morphism is the domain of this composite morphism and the codomain of the new morphism is the codomain of this composite morphism.

Examples

```python
>>> from sympy.categories import Object, NamedMorphism
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> (g * f).flatten("h")
NamedMorphism(Object("A"), Object("C"), "h")
```
class sympy.categories.IdentityMorphism(domain)

Represents an identity morphism.

Explanation

An identity morphism is a morphism with equal domain and codomain, which acts as an identity with respect to composition.

Examples

```python
>>> from sympy.categories import Object, NamedMorphism, IdentityMorphism
>>> A = Object("A")
>>> B = Object("B")
>>> f = NamedMorphism(A, B, "f")
>>> id_A = IdentityMorphism(A)
>>> id_B = IdentityMorphism(B)
>>> f * id_A == f
True
>>> id_B * f == f
True
```

See also:

Morphism (page 2826)

class sympy.categories.Category(name, objects=EmptySet,
    commutative_diagrams=EmptySet)

An (abstract) category.

Explanation

A category [JoyOfCats] is a quadruple \( K = (O, \text{hom}, id, \circ) \) consisting of

- a (set-theoretical) class \( O \), whose members are called \( K \)-objects,
- for each pair \((A, B)\) of \( K \)-objects, a set \( \text{hom}(A, B) \) whose members are called \( K \)-morphisms from \( A \) to \( B \),
- for a each \( K \)-object \( A \), a morphism \( id : A \to A \), called the \( K \)-identity of \( A \),
- a composition law \( \circ \) associating with every \( K \)-morphisms \( f : A \to B \) and \( g : B \to C \) a \( K \)-morphism \( g \circ f : A \to C \), called the composite of \( f \) and \( g \).

Composition is associative, \( K \)-identities are identities with respect to composition, and the sets \( \text{hom}(A, B) \) are pairwise disjoint.

This class knows nothing about its objects and morphisms. Concrete cases of (abstract) categories should be implemented as classes derived from this one.

Certain instances of Diagram (page 2833) can be asserted to be commutative in a Category (page 2831) by supplying the argument commutative_diagrams in the constructor.
Examples

```python
>>> from sympy.categories import Object, NamedMorphism, Diagram, Category
>>> from sympy import FiniteSet
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> d = Diagram([f, g])
>>> K = Category("K", commutative_diagrams=[d])
>>> K.commutative_diagrams == FiniteSet(d)
True
```

**See also:**

`Diagram` (page 2833)

**property commutative_diagrams**

Returns the `FiniteSet` (page 1241) of diagrams which are known to be commutative in this category.

Examples

```python
>>> from sympy.categories import Object, NamedMorphism, Diagram, Category
>>> from sympy import FiniteSet
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> d = Diagram([f, g])
>>> K = Category("K", commutative_diagrams=[d])
>>> K.commutative_diagrams == FiniteSet(d)
True
```

**property name**

Returns the name of this category.

Examples

```python
>>> from sympy.categories import Category
>>> K = Category("K")
>>> K.name
'K'
```

**property objects**

Returns the class of objects of this category.
Examples

```python
>>> from sympy.categories import Object, Category
>>> from sympy import FiniteSet
>>> A = Object("A")
>>> B = Object("B")
>>> K = Category("K", FiniteSet(A, B))
>>> K.objects
Class({Object("A"), Object("B")})
```

class sympy.categories.Diagram(*args)
Represents a diagram in a certain category.

Explanation

Informally, a diagram is a collection of objects of a category and certain morphisms between them. A diagram is still a monoid with respect to morphism composition; i.e., identity morphisms, as well as all composites of morphisms included in the diagram belong to the diagram. For a more formal approach to this notion see [Pare1970].

The components of composite morphisms are also added to the diagram. No properties are assigned to such morphisms by default.

A commutative diagram is often accompanied by a statement of the following kind: “if such morphisms with such properties exist, then such morphisms which such properties exist and the diagram is commutative”. To represent this, an instance of Diagram (page 2833) includes a collection of morphisms which are the premises and another collection of conclusions. premises and conclusions associate morphisms belonging to the corresponding categories with the FiniteSet (page 1241)'s of their properties.

The set of properties of a composite morphism is the intersection of the sets of properties of its components. The domain and codomain of a conclusion morphism should be among the domains and codomains of the morphisms listed as the premises of a diagram.

No checks are carried out of whether the supplied object and morphisms do belong to one and the same category.

Examples

```python
>>> from sympy.categories import Object, NamedMorphism, Diagram
>>> from sympy import pprint, default_sort_key
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> d = Diagram([f, g])
>>> premises_keys = sorted(d.premises.keys(), key=default_sort_key)
>>> pprint(premises_keys, use_unicode=False)
>>> pprint(d.premises, use_unicode=False)
{g*f:A-->C: EmptySet, id:A-->A: EmptySet, id:B-->B: EmptySet, id:C-->C: }
```

References

property conclusions
Returns the conclusions of this diagram.

Examples

```python
>>> from sympy.categories import Object, NamedMorphism
>>> from sympy.categories import IdentityMorphism, Diagram
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> d = Diagram([f, g])
>>> IdentityMorphism(A) in d.premises.keys()
True
>>> g * f in d.premises.keys()
True
>>> d = Diagram([f, g], {g * f: "unique"})
>>> d.conclusions[g * f] == FiniteSet("unique")
True
```

hom(A, B)
Returns a 2-tuple of sets of morphisms between objects A and B: one set of morphisms listed as premises, and the other set of morphisms listed as conclusions.

Examples

```python
>>> from sympy.categories import Object, NamedMorphism, Diagram
>>> from sympy import pretty
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> d = Diagram([f, g])
>>> pretty(d.hom(A, C), use_unicode=False)
({g+f:A-->C}, {g+f:A-->C})
```
See also:

Object (page 2826), Morphism (page 2826)

is_subdiagram(diagram)
Checks whether diagram is a subdiagram of self. Diagram $D'$ is a subdiagram of $D$ if all premises (conclusions) of $D'$ are contained in the premises (conclusions) of $D$. The morphisms contained both in $D'$ and $D$ should have the same properties for $D'$ to be a subdiagram of $D$.

Examples

```python
>>> from sympy.categories import Object, NamedMorphism, Diagram
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> d = Diagram([f, g], {g * f: "unique"})
>>> d1 = Diagram([f])
>>> d.is_subdiagram(d1)
True
>>> d1.is_subdiagram(d)
False
```

property objects
Returns the FiniteSet (page 1241) of objects that appear in this diagram.

Examples

```python
>>> from sympy.categories import Object, NamedMorphism, Diagram
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> d = Diagram([f, g])
>>> d.objects
{Object("A"), Object("B"), Object("C"))
```

property premises
Returns the premises of this diagram.
Examples

```python
>>> from sympy.categories import Object, NamedMorphism
>>> from sympy.categories import IdentityMorphism, Diagram
>>> from sympy import pretty

>>> A = Object("A")
>>> B = Object("B")
>>> f = NamedMorphism(A, B, "f")
>>> id_A = IdentityMorphism(A)
>>> id_B = IdentityMorphism(B)
>>> d = Diagram([f])
>>> print(pretty(d.premises, use_unicode=False))
{id:A-->A: EmptySet, id:B-->B: EmptySet, f:A-->B: EmptySet}
```

**subdiagram_from_objects**(*objects*)

If objects is a subset of the objects of self, returns a diagram which has as premises all those premises of self which have a domains and codomains in objects, likewise for conclusions. Properties are preserved.

Examples

```python
>>> from sympy.categories import Object, NamedMorphism, Diagram
>>> from sympy import FiniteSet

>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> d = Diagram([f, g], {f: "unique", g*f: "veryunique"})
>>> d1 = d.subdiagram_from_objects(FiniteSet(A, B))
>>> d1 == Diagram([f], {f: "unique"})
True
```

Diagram Drawing

This section lists the classes which allow automatic drawing of diagrams.

**class** sympy.categories.diagram_drawing.DiagramGrid(*diagram, groups=None, **hints*)

Constructs and holds the fitting of the diagram into a grid.
Explanation

The mission of this class is to analyse the structure of the supplied diagram and to place its objects on a grid such that, when the objects and the morphisms are actually drawn, the diagram would be “readable”, in the sense that there will not be many intersections of morphisms. This class does not perform any actual drawing. It does strive nevertheless to offer sufficient metadata to draw a diagram.

Consider the following simple diagram.

```python
from sympy.categories import Object, NamedMorphism
from sympy.categories import Diagram, DiagramGrid
from sympy import pprint

A = Object("A")
B = Object("B")
C = Object("C")
f = NamedMorphism(A, B, "f")
g = NamedMorphism(B, C, "g")
diagram = Diagram([f, g])
```

The simplest way to have a diagram laid out is the following:

```python
grid = DiagramGrid(diagram)
(grid.width, grid.height)
(2, 2)
pprint(grid)
A B
C
```

Sometimes one sees the diagram as consisting of logical groups. One can advise `DiagramGrid` as to such groups by employing the `groups` keyword argument.

Consider the following diagram:

```python
D = Object("D")
f = NamedMorphism(A, B, "f")
g = NamedMorphism(B, C, "g")
h = NamedMorphism(D, A, "h")
k = NamedMorphism(D, B, "k")
diagram = Diagram([f, g, h, k])
```

Lay it out with generic layout:

```python
grid = DiagramGrid(diagram)
pprint(grid)
A B D
C
```

Now, we can group the objects $A$ and $D$ to have them near one another:

```python
grid = DiagramGrid(diagram, groups=[[A, D], B, C])
pprint(grid)
B C
```

(continues on next page)
Note how the positioning of the other objects changes.

Further indications can be supplied to the constructor of `DiagramGrid` using keyword arguments. The currently supported hints are explained in the following paragraphs.

`DiagramGrid` (page 2836) does not automatically guess which layout would suit the supplied diagram better. Consider, for example, the following linear diagram:

```python
>>> E = Object("E")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> h = NamedMorphism(C, D, "h")
>>> i = NamedMorphism(D, E, "i")
>>> diagram = Diagram([f, g, h, i])
```

When laid out with the generic layout, it does not get to look linear:

```plaintext
A B
C D
E
```

To get it laid out in a line, use `layout="sequential"`:

```python
>>> grid = DiagramGrid(diagram, layout="sequential")
>>> pprint(grid)
A B C D E
```

One may sometimes need to transpose the resulting layout. While this can always be done by hand, `DiagramGrid` (page 2836) provides a hint for that purpose:

```python
>>> grid = DiagramGrid(diagram, layout="sequential", transpose=True)
>>> pprint(grid)
A
B
C
D
E
```

Separate hints can also be provided for each group. For an example, refer to `tests/test_drawing.py`, and see the different ways in which the five lemma [FiveLemma] can be laid out.
See also:

*Diagram* (page 2833)

References

[Five Lemma]

**property height**

Returns the number of rows in this diagram layout.

**Examples**

```python
>>> from sympy.categories import Object, NamedMorphism
>>> from sympy.categories import Diagram, DiagramGrid
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> diagram = Diagram([f, g])
>>> grid = DiagramGrid(diagram)
>>> grid.height
2
```

**property morphisms**

Returns those morphisms (and their properties) which are sufficiently meaningful to be drawn.

**Examples**

```python
>>> from sympy.categories import Object, NamedMorphism
>>> from sympy.categories import Diagram, DiagramGrid
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> diagram = Diagram([f, g])
>>> grid = DiagramGrid(diagram)
>>> grid.morphisms
{NamedMorphism(Object("A"), Object("B"), "f"): EmptySet,
 NamedMorphism(Object("B"), Object("C"), "g"): EmptySet}
```

**property width**

Returns the number of columns in this diagram layout.
class sympy.categories.diagram_drawing.ArrowStringDescription(unit, curving, curving_amount, looping_start, looping_end, horizontal_direction, vertical_direction, label_position, label)

Stores the information necessary for producing an Xy-pic description of an arrow.

The principal goal of this class is to abstract away the string representation of an arrow and to also provide the functionality to produce the actual Xy-pic string.

unit sets the unit which will be used to specify the amount of curving and other distances. horizontal_direction should be a string of "r" or "l" specifying the horizontal offset of the target cell of the arrow relatively to the current one. vertical_direction should specify the vertical offset using a series of either "d" or "u". label_position should be either "^", "_", or "|" to specify that the label should be positioned above the arrow, below the arrow or just over the arrow, in a break. Note that the notions “above” and “below” are relative to arrow direction. label stores the morphism label.

This works as follows (disregard the yet unexplained arguments):

```python
>>> from sympy.categories.diagram_drawing import ArrowStringDescription
>>> astr = ArrowStringDescription(
...     unit="mm", curving=None, curving_amount=None,
...     looping_start=None, looping_end=None, horizontal_direction="d",
...     vertical_direction="r", label_position="_", label="f")
>>> print(str(astr))
\ar[dr]_{f}
```

curving should be one of "^", " " to specify in which direction the arrow is going to curve. curving_amount is a number describing how many unit’s the morphism is going to curve:

```python
>>> astr = ArrowStringDescription(
...     unit="mm", curving="^", curving_amount=12,
...     looping_start=None, looping_end=None, horizontal_direction="d",
...     vertical_direction="r", label_position="_", label="f")
>>> print(str(astr))
\ar@/^12mm/[dr]_{f}
```
looping_start and looping_end are currently only used for loop morphisms, those which have the same domain and codomain. These two attributes should store a valid Xy-pic direction and specify, correspondingly, the direction the arrow gets out into and the direction the arrow gets back from:

```python
>>> astr = ArrowStringDescription(
    unit="mm", curving=\texttt{None}, curving_amount=\texttt{None},
    looping_start="u", looping_end="l", horizontal_direction="",
    vertical_direction="", label_position="\_", label="f")
>>> print(str(astr))
\ar@{(u,l)}\{f}
```

label_displacement controls how far the arrow label is from the ends of the arrow. For example, to position the arrow label near the arrow head, use “>”:

```python
>>> astr = ArrowStringDescription(
    unit="mm", curving="^", curving_amount=12,
    looping_start=\texttt{None}, looping_end=\texttt{None}, horizontal_direction="d",
    vertical_direction="r", label_position="\_", label="f")
>>> astr.label_displacement = ">"
>>> print(str(astr))
\ar@/^12mm/[dr]_{f}
```

Finally, arrow_style is used to specify the arrow style. To get a dashed arrow, for example, use “{-->}” as arrow style:

```python
>>> astr = ArrowStringDescription(
    unit="mm", curving="^", curving_amount=12,
    looping_start=\texttt{None}, looping_end=\texttt{None}, horizontal_direction="d",
    vertical_direction="r", label_position="\_", label="f")
>>> astr.arrow_style = "{-->}"
>>> print(str(astr))
\ar@/^12mm/@{-->}[dr]_{f}
```

**Notes**

Instances of `ArrowStringDescription` (page 2840) will be constructed by `XypicDiagramDrawer` (page 2842) and provided for further use in formatters. The user is not expected to construct instances of `ArrowStringDescription` (page 2840) themselves.

To be able to properly utilise this class, the reader is encouraged to checkout the Xy-pic user guide, available at [Xypic].

**See also:**

`XypicDiagramDrawer` (page 2842)
Given a `Diagram` (page 2833) and the corresponding `DiagramGrid` (page 2836), produces the Xy-pic representation of the diagram.

The most important method in this class is `draw`. Consider the following triangle diagram:

```python
>>> from sympy.categories import Object, NamedMorphism, Diagram
>>> from sympy.categories import DiagramGrid, XypicDiagramDrawer
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> diagram = Diagram([f, g], {g * f: "unique"})
```

To draw this diagram, its objects need to be laid out with a `DiagramGrid` (page 2836):

```python
>>> grid = DiagramGrid(diagram)
```

Finally, the drawing:

```python
>>> drawer = XypicDiagramDrawer()
>>> print(drawer.draw(diagram, grid))
\xymatrix{
A \ar[d]_{g\circ f} \ar[r]^{f} & B \ar[ld]^{g} \\
C &
}
```

For further details see the docstring of this method.

To control the appearance of the arrows, formatters are used. The dictionary `arrow_formatters` maps morphisms to formatter functions. A formatter accepts an `ArrowStringDescription` (page 2840) and is allowed to modify any of the arrow properties exposed thereby. For example, to have all morphisms with the property `unique` appear as dashed arrows, and to have their names prepended with `∃!`, the following should be done:

```python
>>> def formatter(astr):
...     astr.label = r"\exists !" + astr.label
...     astr.arrow_style = "{-->}"
>>> drawer.arrow_formatters["unique"] = formatter
>>> print(drawer.draw(diagram, grid))
\xymatrix{
A \ar@{-->}[d]_{\exists !g\circ f} \ar[r]^{f} & B \ar[ld]^{{g}} \\
C &
}
```

To modify the appearance of all arrows in the diagram, set `default_arrow_formatter`. For example, to place all morphism labels a little bit farther from the arrow head so that they look more centred, do as follows:
In some diagrams some morphisms are drawn as curved arrows. Consider the following diagram:

```
>>> D = Object("D")
>>> h = NamedMorphism(D, A, "h")
>>> k = NamedMorphism(D, B, "k")
>>> diagram = Diagram([f, g, h, k])
>>> grid = DiagramGrid(diagram)
>>> drawer = XypicDiagramDrawer()
>>> print(drawer.draw(diagram, grid))
\xymatrix{
  A \ar[r]_{f} & B \ar[d]^{g} & D \ar[l]^{k} \ar@/_1cm/[ll]^{h} \ar@/_3mm/[lll]^{h}_{h} \& C &
}\n```

To control how far the morphisms are curved by default, one can use the unit and default_curving_amount attributes:

```
>>> drawer.unit = "cm"
>>> drawer.default_curving_amount = 1
>>> print(drawer.draw(diagram, grid))
\xymatrix{
  A \ar[r]_{f} & B \ar[d]^{g} & D \ar[l]^{k} \ar@/_1cm/[ll]^{h} \& C &
}\n```

In some diagrams, there are multiple curved morphisms between the same two objects. To control by how much the curving changes between two such successive morphisms, use default_curving_step:

```
>>> drawer.default_curving_step = 1
>>> h1 = NamedMorphism(A, D, "h1")
>>> diagram = Diagram([f, g, h, k, h1])
>>> grid = DiagramGrid(diagram)
>>> print(drawer.draw(diagram, grid))
\xymatrix{
  A \ar[r]_{f} \ar@/^1cm/[rr]^{h_{1}} & B \ar[d]^{g} & D \ar[l]^{k} \ar@/_2cm/[lll]^{h}_{h} \& C &
}\n```

The default value of default_curving_step is 4 units.
See also:

draw (page 2844), ArrowStringDescription (page 2840)

draw(diagram, grid, masked=None, diagram_format="")

Returns the Xy-pic representation of diagram laid out in grid.

Consider the following simple triangle diagram.

```python
>>> from sympy.categories import Object, NamedMorphism, Diagram
>>> from sympy.categories import DiagramGrid, XypicDiagramDrawer
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> diagram = Diagram([f, g], {g * f: "unique"})
```

To draw this diagram, its objects need to be laid out with a DiagramGrid (page 2836):

```python
>>> grid = DiagramGrid(diagram)
```

Finally, the drawing:

```python
>>> drawer = XypicDiagramDrawer()
>>> print(drawer.draw(diagram, grid))
\xymatrix{
  A \ar[d]_{g\circ f} \ar[r]^{f} & B \ar[ld]^{g} \\
  C & 
}
```

The argument masked can be used to skip morphisms in the presentation of the diagram:

```python
>>> print(drawer.draw(diagram, grid, masked=[g * f]))
\xymatrix{
  A \ar[r]^{f} & B \ar[ld]^{g} \\
  C & 
}
```

Finally, the diagram_format argument can be used to specify the format string of the diagram. For example, to increase the spacing by 1 cm, proceeding as follows:

```python
>>> print(drawer.draw(diagram, grid, diagram_format="@+1cm"))
\xymatrix@+1cm{
  A \ar[d]_{g\circ f} \ar[r]^{f} & B \ar[ld]^{g} \\
  C & 
}
```

sympy.categories.diagram_drawing.xypic_draw_diagram(diagram, masked=None, diagram_format="", groups=None, **hints)

Provides a shortcut combining DiagramGrid (page 2836) and XypicDiagramDrawer (page 2842). Returns an Xy-pic presentation of diagram. The argument masked is a list of morphisms which will be not be drawn. The argument diagram_format is the
format string inserted after “xymatrix”. groups should be a set of logical groups. The hints will be passed directly to the constructor of DiagramGrid (page 2836).

For more information about the arguments, see the docstrings of DiagramGrid (page 2836) and XypicDiagramDrawer.draw.

Examples

```python
>>> from sympy.categories import Object, NamedMorphism, Diagram
>>> from sympy.categories import xypic_draw_diagram
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> diagram = Diagram([f, g], {g * f: "unique"})
>>> print(xypic_draw_diagram(diagram))
\xymatrix{
  A \ar[d]_{g\circ f} \ar[r]^{f} & B \ar[ld]^{g} \\
  C &
}
```

See also:

XypicDiagramDrawer (page 2842), DiagramGrid (page 2836)

sympy.categories.diagram_drawing.preview_diagram(diagram, masked=None,
diagram_format='',
groups=None, output='png',
viewer=None, euler=True,
**hints)

Combines the functionality of xypic_draw_diagram and sympy.printing.preview. The arguments masked, diagram_format, groups, and hints are passed to xypic_draw_diagram, while output, viewer, and `euler` are passed to preview.

Examples

```python
>>> from sympy.categories import Object, NamedMorphism, Diagram
>>> from sympy.categories import preview_diagram
>>> A = Object("A")
>>> B = Object("B")
>>> C = Object("C")
>>> f = NamedMorphism(A, B, "f")
>>> g = NamedMorphism(B, C, "g")
>>> d = Diagram([f, g], {g * f: "unique"})
>>> preview_diagram(d)
```

XypicDiagramDrawer (page 2842)
Cryptography

Warning: This module is intended for educational purposes only. Do not use the functions in this module for real cryptographic applications. If you wish to encrypt real data, we recommend using something like the cryptography module.

Encryption is the process of hiding a message and a cipher is a means of doing so. Included in this module are both block and stream ciphers:

- Shift cipher
- Affine cipher
- substitution ciphers
- Vigenere’s cipher
- Hill’s cipher
- Bifid ciphers
- RSA
- Kid RSA
- linear-feedback shift registers (for stream ciphers)
- ElGamal encryption

In a substitution cipher “units” (not necessarily single characters) of plaintext are replaced with ciphertext according to a regular system.

A transposition cipher is a method of encryption by which the positions held by “units” of plaintext are replaced by a permutation of the plaintext. That is, the order of the units is changed using a bijective function on the position of the characters to perform the encryption.

A monoalphabetic cipher uses fixed substitution over the entire message, whereas a polyalphabetic cipher uses a number of substitutions at different times in the message.

sympy.crypto.crypto.AZ(s=None)

Return the letters of s in uppercase. In case more than one string is passed, each of them will be processed and a list of uppercase strings will be returned.

Examples

```python
>>> from sympy.crypto.crypto import AZ
>>> AZ('Hello, world!')
'HELLOWORLD'
>>> AZ('Hello, world!'.split())
['HELLO', 'WORLD']
```

See also:

check_and_join (page 2847)
sympy.crypto.crypto.padded_key(key, symbols)
Return a string of the distinct characters of symbols with those of key appearing first.
A ValueError is raised if a) there are duplicate characters in symbols or b) there are
characters in key that are not in symbols.

Examples

```python
>>> from sympy.crypto.crypto import padded_key
>>> padded_key('PUPPY', 'OPQRSTUWXY')
'PUYOQRSTVWX'
>>> padded_key('RSA', 'ARTIST')
Traceback (most recent call last):
... ValueError: duplicate characters in symbols: T
```

sympy.crypto.crypto.check_and_join(phrase, symbols=None, filter=None)
Joins characters of phrase and if symbols is given, raises an error if any character in
phrase is not in symbols.

Parameters
phrase
String or list of strings to be returned as a string.
symbols
Iterable of characters allowed in phrase.
   If symbols is None, no checking is performed.

Examples

```python
>>> from sympy.crypto.crypto import check_and_join
>>> check_and_join('a phrase')
'a phrase'
>>> check_and_join('a phrase'.upper().split())
'APHRAE'
>>> check_and_join('a phrase!'.upper().split(), 'ARE', filter=True)
'ARAE'
>>> check_and_join('a phrase!'.upper().split(), 'ARE')
Traceback (most recent call last):
... ValueError: characters in phrase but not symbols: "!HPS"
```

sympy.crypto.crypto.cycle_list(k, n)
Returns the elements of the list range(n) shifted to the left by k (so the list starts with
k (mod n)).
sympy.crypto.crypto.encipher_shift(msg, key, symbols=None)

Performs shift cipher encryption on plaintext msg, and returns the ciphertext.

**Parameters**

- **key**: int
  - The secret key.

- **msg**: str
  - Plaintext of upper-case letters.

**Returns**

- **str**: str
  - Ciphertext of upper-case letters.

**Examples**

```python
>>> from sympy.crypto.crypto import encipher_shift, decipher_shift

>>> msg = "GONAVYBEATARMY"

>>> ct = encipher_shift(msg, 1); ct
'HPOBWZCFBUBSNZ'

To decipher the shifted text, change the sign of the key:

```python

>>> encipher_shift(ct, -1)
'GONAVYBEATARMY'
```

There is also a convenience function that does this with the original key:

```python

>>> decipher_shift(ct, 1)
'GONAVYBEATARMY'
```

**Notes**

**ALGORITHM:**

**STEPS:**

1. Number the letters of the alphabet from 0, ..., N
2. Compute from the string msg a list L1 of corresponding integers.
3. Compute from the list L1 a new list L2, given by adding (k mod 26) to each element in L1.
4. Compute from the list L2 a string ct of corresponding letters.
The shift cipher is also called the Caesar cipher, after Julius Caesar, who, according to Suetonius, used it with a shift of three to protect messages of military significance. Caesar’s nephew Augustus reportedly used a similar cipher, but with a right shift of 1.

**See also:**

decipher_shift (page 2849)

**References**

[R142], [R143]

sympy.crypto.crypto.decipher_shift(msg, key, symbols=None)

Return the text by shifting the characters of msg to the left by the amount given by key.

**Examples**

```python
>>> from sympy.crypto.crypto import encipher_shift, decipher_shift
>>> msg = "GONAVYBEATARMY"
>>> ct = encipher_shift(msg, 1); ct
'HPOBWZCFBUBSNZ'

To decipher the shifted text, change the sign of the key:

```python
>>> encipher_shift(ct, -1)
'GONAVYBEATARMY'
```  

Or use this function with the original key:

```python
>>> decipher_shift(ct, 1)
'GONAVYBEATARMY'
```  

sympy.crypto.crypto.encipher_rot13(msg, symbols=None)

Performs the ROT13 encryption on a given plaintext msg.

**Explanation**

ROT13 is a substitution cipher which substitutes each letter in the plaintext message for the letter furthest away from it in the English alphabet.

Equivalently, it is just a Caesar (shift) cipher with a shift key of 13 (midway point of the alphabet).

**See also:**

decipher_rot13 (page 2850), encipher_shift (page 2848)
References

[R144]
sympy.crypto.crypto.decipher_rot13(msg, symbols=None)
PerformstheROT13decryptiononagivenplaintextmsg.

Explanation

Examples

```python
>>> from sympy.crypto.crypto import encipher_rot13, decipher_rot13
>>> msg = 'GONAVYBEATARMY'
>>> ciphertext = encipher_rot13(msg); ciphertext
'TBANILORNGNEZL'
>>> decipher_rot13(ciphertext)
'GONAVYBEATARMY'
>>> encipher_rot13(msg) == decipher_rot13(msg)
True
>>> msg == decipher_rot13(ciphertext)
True
```

sympy.crypto.crypto.encipher_affine(msg, key, symbols=None, _inverse=False)
Performstheaffinecipherencryptiononplaintextmsg,andreturnstheciphertext.

Parameters
msg : str
Charactersthatappearinsymbols.

a, b : int, int
A pairintegers,withgcd(a, N) = 1 (thesecretkey).

symbols
Stringofcharacters(default = uppercaseletters).

Whennosymbolsaregiven, msg is converted to uppercase letters andall othercharacters are ignored.

Returns
c
Stringofcharacters (theciphertextmessage)
Explanation

Encryption is based on the map \( x \rightarrow ax + b \pmod{N} \) where \( N \) is the number of characters in the alphabet. Decryption is based on the map \( x \rightarrow cx + d \pmod{N} \), where \( c = a^{-1} \pmod{N} \) and \( d = -a^{-1}b \pmod{N} \). In particular, for the map to be invertible, we need \( \gcd(a, N) = 1 \) and an error will be raised if this is not true.

Notes

ALGORITHM:

STEPS:

0. Number the letters of the alphabet from 0, ..., \( N \)

1. Compute from the string \( msg \) a list \( L1 \) of corresponding integers.

2. Compute from the list \( L1 \) a new list \( L2 \), given by replacing \( x \) by \( a*x + b \pmod{N} \), for each element \( x \) in \( L1 \).

3. Compute from the list \( L2 \) a string \( ct \) of corresponding letters.

This is a straightforward generalization of the shift cipher with the added complexity of requiring 2 characters to be deciphered in order to recover the key.

See also:

\texttt{decipher_affine} (page 2851)

References

[R145]

\texttt{sympy.crypto.crypto.decipher_affine}(msg, key, symbols=None)

Return the deciphered text that was made from the mapping, \( x \rightarrow ax + b \pmod{N} \), where \( N \) is the number of characters in the alphabet. Deciphering is done by reciphering with a new key: \( x \rightarrow cx + d \pmod{N} \), where \( c = a^{-1} \pmod{N} \) and \( d = -a^{-1}b \pmod{N} \).

Examples

```python
>>> from sympy.crypto.crypto import encipher_affine, decipher_affine
>>> msg = "GO NAVY BEAT ARMY"
>>> key = (3, 1)
>>> encipher_affine(msg, key)
'TROBMVENBGBALV'
>>> decipher_affine(_, key)
'GONAVYBEATARMY'
```

See also:

\texttt{encipher_affine} (page 2850)

\texttt{sympy.crypto.crypto.encipher_atbash}(msg, symbols=None)

Enciphers a given \( msg \) into its Atbash ciphertext and returns it.
**Explanation**

Atbash is a substitution cipher originally used to encrypt the Hebrew alphabet. Atbash works on the principle of mapping each alphabet to its reverse / counterpart (i.e. a would map to z, b to y etc.)

Atbash is functionally equivalent to the affine cipher with $a = 25$ and $b = 25$

**See also:**

decipher_atbash (page 2852)

```python
sympy.crypto.crypto.decipher_atbash(msg, symbols=None)
```

Deciphers a given msg using Atbash cipher and returns it.

**Explanation**

decipher_atbash is functionally equivalent to encipher_atbash. However, it has still been added as a separate function to maintain consistency.

**Examples**

```python
>>> from sympy.crypto.crypto import encipher_atbash, decipher_atbash
>>> msg = 'GONAVYBEATARMY'
>>> encipher_atbash(msg)
'TLMZEBYVZGZINB'
>>> decipher_atbash(msg)
'TLMZEBYVZGZINB'
>>> encipher_atbash(msg) == decipher_atbash(msg)
True
>>> msg == encipher_atbash(encipher_atbash(msg))
True
```

**See also:**

encipher_atbash (page 2851)

**References**

[R146]

```python
sympy.crypto.crypto.encipher_substitution(msg, old, new=None)
```

Returns the ciphertext obtained by replacing each character that appears in old with the corresponding character in new. If old is a mapping, then new is ignored and the replacements defined by old are used.
**Explanation**

This is a more general than the affine cipher in that the key can only be recovered by determining the mapping for each symbol. Though in practice, once a few symbols are recognized the mappings for other characters can be quickly guessed.

**Examples**

```python
>>> from sympy.crypto.crypto import encipher_substitution, AZ
>>> old = 'OEYAG'
>>> new = '034^6'
>>> msg = AZ("go navy! beat army!")
>>> ct = encipher_substitution(msg, old, new); ct
'60N^V4B3^T^RM4'
```

To decrypt a substitution, reverse the last two arguments:

```python
>>> encipher_substitution(ct, new, old)
'GONAVYBEATARMY'
```

In the special case where `old` and `new` are a permutation of order 2 (representing a transposition of characters) their order is immaterial:

```python
>>> old = 'NAVY'
>>> new = 'ANYV'
>>> encipher = lambda x: encipher_substitution(x, old, new)
>>> encipher('NAVY')
'ANYV'
>>> encipher(_)
'NAVY'
```

The substitution cipher, in general, is a method whereby “units” (not necessarily single characters) of plaintext are replaced with ciphertext according to a regular system.

```python
>>> ords = dict(zip('abc', ['\%i' % ord(i) for i in 'abc']))
>>> print(encipher_substitution('abc', ords))
\97\98\99
```

**References**

[R147]
sympy.crypto.crypto.encipher_vigenere(msg, key, symbols=None)

Performs the Vigenere cipher encryption on plaintext `msg`, and returns the ciphertext.
Examples

```python
>>> from sympy.crypto.crypto import encipher_vigenere, AZ
cipher_vigenere(msg, key)
'QRGKKTHRZQEBPR'
```

Section 1 of the Kryptos sculpture at the CIA headquarters uses this cipher and also changes the order of the alphabet [R149]. Here is the first line of that section of the sculpture:

```python
>>> from sympy.crypto.crypto import decipher_vigenere, padded_key
>>> alp = padded_key('KRYPTOS', AZ())
>>> key = 'PALIMPSEST'
>>> msg = 'EMUFPHZLRFAXYUSDJKZLDKRNSHGNFIVJ'
>>> decipher_vigenere(msg, key, alp)
'BETWEENSUBTLESHADINGANDTHEABSENCE'
```

Explanation

The Vigenere cipher is named after Blaise de Vigenere, a sixteenth century diplomat and cryptographer, by a historical accident. Vigenere actually invented a different and more complicated cipher. The so-called Vigenere cipher was actually invented by Giovan Batista Belaso in 1553.

This cipher was used in the 1800’s, for example, during the American Civil War. The Confederacy used a brass cipher disk to implement the Vigenere cipher (now on display in the NSA Museum in Fort Meade) [R148].

The Vigenere cipher is a generalization of the shift cipher. Whereas the shift cipher shifts each letter by the same amount (that amount being the key of the shift cipher) the Vigenere cipher shifts a letter by an amount determined by the key (which is a word or phrase known only to the sender and receiver).

For example, if the key was a single letter, such as “C”, then the so-called Vigenere cipher is actually a shift cipher with a shift of 2 (since “C” is the 2nd letter of the alphabet, if you start counting at 0). If the key was a word with two letters, such as “CA”, then the so-called Vigenere cipher will shift letters in even positions by 2 and letters in odd positions are left alone (shifted by 0, since “A” is the 0th letter, if you start counting at 0).

ALGORITHM:

INPUT:

msg: string of characters that appear in symbols (the plaintext)
key: a string of characters that appear in symbols (the secret key)
symbols: a string of letters defining the alphabet

OUTPUT:

c: string of characters (the ciphertext message)

STEPS:

0. Number the letters of the alphabet from 0, ..., N
1. Compute from the string key a list L1 of corresponding integers. Let n1 = len(L1).
2. Compute from the string msg a list L2 of corresponding integers. Let n2 = len(L2).
3. Break L2 up sequentially into sublists of size n1; the last sublist may be smaller than n1.
4. For each of these sublists L of L2, compute a new list C given by C[i] = L[i] + L1[i] (mod N) to the i-th element in the sublist, for each i.
5. Assemble these lists C by concatenation into a new list of length n2.
6. Compute from the new list a string ct of corresponding letters.

Once it is known that the key is, say, \( n \) characters long, frequency analysis can be applied to every \( n \)-th letter of the ciphertext to determine the plaintext. This method is called Kasiski examination (although it was first discovered by Babbage). If they key is as long as the message and is comprised of randomly selected characters – a one-time pad – the message is theoretically unbreakable.

The cipher Vigenere actually discovered is an “auto-key” cipher described as follows.

**ALGORITHM:**

**INPUT:**
- key: a string of letters (the secret key)
- msg: string of letters (the plaintext message)

**OUTPUT:**
- ct: string of upper-case letters (the ciphertext message)

**STEPS:**

0. Number the letters of the alphabet from 0, ..., N
1. Compute from the string msg a list L2 of corresponding integers. Let n2 = len(L2).
2. Let n1 be the length of the key. Append to the string key the first n2 - n1 characters of the plaintext message. Compute from this string (also of length n2) a list L1 of integers corresponding to the letter numbers in the first step.
3. Compute a new list C given by C[i] = L1[i] + L2[i] (mod N).
4. Compute from the new list a string ct of letters corresponding to the new integers.

To decipher the auto-key ciphertext, the key is used to decipher the first n1 characters and then those characters become the key to decipher the next n1 characters, etc...:
```python
'MCYDWSHKOGAMKZCELYFGAYR'
>>> n1 = len(key)
>>> pt = []
>>> while ct:
...    part, ct = ct[:n1], ct[n1:]
...    pt.append(decipher_vigenere(part, key))
...    key = pt[-1]
...>>> ''.join(pt) == m
True
```

**References**

[R148], [R149]

```python
sympy.crypto.crypto.decipher_vigenere(msg, key, symbols=None)
```

Decode using the Vigenere cipher.

**Examples**

```python
>>> from sympy.crypto.crypto import decipher_vigenere
>>> key = "encrypt"
>>> ct = "QRGK kt HRZQE BPR"
>>> decipher_vigenere(ct, key)
'MEETMEONMONDAY'
```

```python
sympy.crypto.crypto.encypher_hill(msg, key, symbols=None, pad='Q')
```

Return the Hill cipher encryption of `msg`.

**Parameters**

- `msg`
  
  Plaintext message of \( n \) upper-case letters.

- `key`
  
  A \( k \times k \) invertible matrix \( K \), all of whose entries are in \( Z_{26} \) (or whatever number of symbols are being used).

- `pad`
  
  Character (default "Q") to use to make length of text be a multiple of \( k \).

**Returns**

- `ct`
  
  Ciphertext of upper-case letters.
**Explanation**

The Hill cipher [R150], invented by Lester S. Hill in the 1920’s [R151], was the first polygraphic cipher in which it was practical (though barely) to operate on more than three symbols at once. The following discussion assumes an elementary knowledge of matrices.

First, each letter is first encoded as a number starting with 0. Suppose your message `msg` consists of `n` capital letters, with no spaces. This may be regarded as an `n`-tuple `M` of elements of `Z_26` (if the letters are those of the English alphabet). A key in the Hill cipher is a `k x k` matrix `K`, all of whose entries are in `Z_26`, such that the matrix `K` is invertible (i.e., the linear transformation `K : Z^k_N \rightarrow Z^k_N` is one-to-one).

**Notes**

ALGORITHM:

**STEPS:**

0. Number the letters of the alphabet from 0, ..., N
1. Compute from the string `msg` a list `L` of corresponding integers. Let `n = len(L)`.
2. Break the list `L` up into `t = ceiling(n/k)` sublists `L_1`, ..., `L_t` of size `k` (with the last list “padded” to ensure its size is `k`).
3. Compute new list `C_1`, ..., `C_t` given by `C[i] = K*L_i` (arithmetic is done mod `N`), for each `i`.
4. Concatenate these into a list `C = C_1 + ... + C_t`.
5. Compute from `C` a string `ct` of corresponding letters. This has length `k*t`.

See also:

`decipher_hill` (page 2857)

**References**

[R150], [R151]

sympy.crypto.crypto.decipher_hill(msg, key, symbols=None)

Deciphering is the same as enciphering but using the inverse of the key matrix.

**Examples**

```python
>>> from sympy.crypto.crypto import encipher_hill, decipher_hill
>>> from sympy import Matrix

>>> key = Matrix([[1, 2], [3, 5]])
>>> encipher_hill("meet me on monday", key)
'UEQDUEODOTCWQ'
```

(continues on next page)
When the length of the plaintext (stripped of invalid characters) is not a multiple of the key dimension, extra characters will appear at the end of the enciphered and deciphered text. In order to decipher the text, those characters must be included in the text to be deciphered. In the following, the key has a dimension of 4 but the text is 2 short of being a multiple of 4 so two characters will be added.

```python
>>> key = Matrix([[1, 1, 1, 2], [0, 1, 1, 0],
                [2, 2, 3, 4], [1, 1, 0, 1]])
>>> msg = "ST"
>>> encipher_hill(msg, key)
'HJEB'
>>> decipher_hill(_, key)
'STQQ'
>>> encipher_hill(msg, key, pad="Z")
'ISPK'
>>> decipher_hill(_, key)
'STZZ'
```

If the last two characters of the ciphertext were ignored in either case, the wrong plaintext would be recovered:

```python
>>> decipher_hill("HD", key)
'ORMV'
>>> decipher_hill("IS", key)
'UIKY'
```

See also:

- `encipher_hill` (page 2856)
- `sympy.crypto.crypto.encipher_bifid(msg, key, symbols=None)`

Performs the Bifid cipher encryption on plaintext `msg`, and returns the ciphertext.

This is the version of the Bifid cipher that uses an \( n \times n \) Polybius square.

**Parameters**

- `msg`
  - Plaintext string.

- `key`
  - Short string for key.
  - Duplicate characters are ignored and then it is padded with the characters in `symbols` that were not in the short key.

- `symbols`
  - \( n \times n \) characters defining the alphabet.
  - (default is `string.printable`)

**Returns**

- ciphertext
Ciphertext using Bifid5 cipher without spaces.

See also:

decipher_bifid (page 2859), encipher_bifid5 (page 2860), encipher_bifid6 (page 2862)

References

[R152]
sympy.crypto.crypto.decipher_bifid(msg, key, symbols=None)
Performs the Bifid cipher decryption on ciphertext msg, and returns the plaintext.
This is the version of the Bifid cipher that uses the \( n \times n \) Polybius square.

Parameters

msg
Ciphertext string.

key
Short string for key.
Duplicate characters are ignored and then it is padded with the characters in symbols that were not in the short key.

symbols
\( n \times n \) characters defining the alphabet.
(default=string.printable, a 10 \times 10 \) matrix

Returns
deciphered
Deciphered text.

Examples

>>> from sympy.crypto.crypto import (   .... encipher_bifid, decipher_bifid, AZ)

Do an encryption using the bifid5 alphabet:

>>> alp = AZ().replace('J', '')
>>> ct = AZ("meet me on monday!")
>>> key = AZ("gold bug")
>>> encipher_bifid(ct, key, alp)
'IELILHFSTSFQYE'

When entering the text or ciphertext, spaces are ignored so it can be formatted as desired. Re-entering the ciphertext from the preceding, putting 4 characters per line and padding with an extra J, does not cause problems for the deciphering:
When no alphabet is given, all 100 printable characters will be used:

```python
>>> key = ''
>>> encipher_bifid('hello world!', key)
'bmtwmg-bIo*w'
>>> decipher_bifid(_, key)
'hello world'
```

If the key is changed, a different encryption is obtained:

```python
>>> key = 'gold bug'
>>> encipher_bifid('hello world!', 'gold_bug')
'hg2sfuei7t}w'
```

And if the key used to decrypt the message is not exact, the original text will not be perfectly obtained:

```python
>>> decipher_bifid(_, 'gold pug')
'heldo~wor6d!'
```

**sympy.crypto.crypto.bifid5_square(key=None)**

5x5 Polybius square.

Produce the Polybius square for the $5 \times 5$ Bifid cipher.

**Examples**

```python
from sympy.crypto.crypto import bifid5_square
bifid5_square("gold bug")
```

```python
Matrix([G, O, L, D, B],
[U, A, C, E, F],
[H, I, K, M, N],
[P, Q, R, S, T],
[V, W, X, Y, Z])
```

**sympy.crypto.crypto.encipher_bifid5(msg, key)**

Performs the Bifid cipher encryption on plaintext `msg`, and returns the ciphertext.

**Parameters**

- `msg`: str
  - Plaintext string.
  - Converted to upper case and filtered of anything but all letters except J.
- `key`
SymPy Documentation, Release 1.12.1

Short string for key; non-alphabetic letters, J and duplicated characters are ignored and then, if the length is less than 25 characters, it is padded with other letters of the alphabet (in alphabetical order).

Returns

ct

Ciphertext (all caps, no spaces).

Explanation

This is the version of the Bifid cipher that uses the $5 \times 5$ Polybius square. The letter “J” is ignored so it must be replaced with something else (traditionally an “I”) before encryption.

ALGORITHM: (5x5 case)

STEPS:

0. Create the $5 \times 5$ Polybius square $S$ associated to key as follows:
   a) moving from left-to-right, top-to-bottom, place the letters of the key into a $5 \times 5$ matrix,
   b) if the key has less than 25 letters, add the letters of the alphabet not in the key until the $5 \times 5$ square is filled.

1. Create a list $P$ of pairs of numbers which are the coordinates in the Polybius square of the letters in $msg$.

2. Let $L_1$ be the list of all first coordinates of $P$ (length of $L_1 = n$), let $L_2$ be the list of all second coordinates of $P$ (so the length of $L_2$ is also $n$).

3. Let $L$ be the concatenation of $L_1$ and $L_2$ (length $L = 2n$), except that consecutive numbers are paired ($L[2i], L[2i + 1]$). You can regard $L$ as a list of pairs of length $n$.

4. Let $C$ be the list of all letters which are of the form $S[i, j]$, for all $(i, j)$ in $L$. As a string, this is the ciphertext of $msg$.

Examples

```python
>>> from sympy.crypto.crypto import ... encipher_bifid5, decipher_bifid5

“J” will be omitted unless it is replaced with something else:

```
Notes

The Bifid cipher was invented around 1901 by Felix Delastelle. It is a fractional substitution cipher, where letters are replaced by pairs of symbols from a smaller alphabet. The cipher uses a $5 \times 5$ square filled with some ordering of the alphabet, except that “J” is replaced with “I” (this is a so-called Polybius square; there is a $6 \times 6$ analog if you add back in “J” and also append onto the usual 26 letter alphabet, the digits 0, 1, ..., 9). According to Helen Gaines’ book Cryptanalysis, this type of cipher was used in the field by the German Army during World War I.

See also:

- `decipher_bifid5` (page 2862), `encipher_bifid` (page 2858)

sympy.crypto.crypto.decipher_bifid5(msg, key)

Return the Bifid cipher decryption of msg.

Parameters

- **msg**
  
  Ciphertext string.

- **key**
  
  Short string for key; duplicated characters are ignored and if the length is less then 25 characters, it will be padded with other letters from the alphabet omitting “J”. Non-alphabetic characters are ignored.

Returns

- **plaintext**
  
  Plaintext from Bifid5 cipher (all caps, no spaces).

Explanation

This is the version of the Bifid cipher that uses the $5 \times 5$ Polybius square; the letter “J” is ignored unless a key of length 25 is used.

Examples

```python
>>> from sympy.crypto.crypto import encipher_bifid5, decipher_bifid5
>>> key = "gold bug"
>>> encipher_bifid5('meet me on friday', key)
'IIEILEHFSTSFXEE'
>>> encipher_bifid5('meet me on monday', key)
'IIEILHFSTSFQYE'
>>> decipher_bifid5(_, key)
'MEETMEONMONDAY'
```
sympy.crypto.crypto.encipher_bifid6(msg, key)
    Performs the Bifid cipher encryption on plaintext msg, and returns the ciphertext.
    This is the version of the Bifid cipher that uses the $6 \times 6$ Polybius square.

    Parameters
    msg
        Plaintext string (digits okay).

    key
        Short string for key (digits okay).
        If key is less than 36 characters long, the square will be filled with
        letters A through Z and digits 0 through 9.

    Returns
    ciphertext
        Ciphertext from Bifid cipher (all caps, no spaces).

    See also:
    decipher_bifid6 (page 2863), encipher_bifid (page 2858)

sympy.crypto.crypto.decipher_bifid6(msg, key)
    Performs the Bifid cipher decryption on ciphertext msg, and returns the plaintext.
    This is the version of the Bifid cipher that uses the $6 \times 6$ Polybius square.

    Parameters
    msg
        Ciphertext string (digits okay); converted to uppercase

    key
        Short string for key (digits okay).
        If key is less than 36 characters long, the square will be filled with
        letters A through Z and digits 0 through 9. All letters are converted
to uppercase.

    Returns
    plaintext
        Plaintext from Bifid cipher (all caps, no spaces).

Examples

```python
>>> from sympy.crypto.crypto import encipher_bifid6, decipher_bifid6
>>> key = "gold bug"
>>> encipher_bifid6('meet me on monday at 8am', key)
'KFKLIJHFSMMMTFRGPLL'
>>> decipher_bifid6(_, key)
'MEETMEONMONDAYAT8AM'
```
**SymPy Documentation, Release 1.12.1**

```python
sympy.crypto.crypto.bifid6_square(key=None)
```

6x6 Polybius square.

6x6 Polybius square. Produces the Polybius square for the 6 × 6 Bifid cipher. Assumes alphabet of symbols is “A”, …, “Z”, “0”, …, “9”.

**Examples**

```python
>>> from sympy.crypto.crypto import bifid6_square
>>> key = "gold bug"
>>> bifid6_square(key)
Matrix(
    [G, O, L, D, B, U],
    [A, C, E, F, H, I],
    [J, K, M, N, P, Q],
    [R, S, T, V, W, X],
    [Y, Z, 0, 1, 2, 3],
    [4, 5, 6, 7, 8, 9])
```

```python
sympy.crypto.crypto.rsa_public_key(*args, **kwargs)
```

Return the RSA public key pair, (n, e)

**Parameters**

- **args** : naturals

  If specified as p, q, e where p and q are distinct primes and e is a desired public exponent of the RSA, n = pq and e will be verified against the totient \( \phi(n) \) (Euler totient) or \( \lambda(n) \) (Carmichael totient) to be \( \gcd(e, \phi(n)) = 1 \) or \( \gcd(e, \lambda(n)) = 1 \).

  If specified as \( p_1, p_2, \ldots, p_n, e \) where \( p_1, p_2, \ldots, p_n \) are specified as primes, and e is specified as a desired public exponent of the RSA, it will be able to form a multi-prime RSA, which is a more generalized form of the popular 2-prime RSA.

  It can also be possible to form a single-prime RSA by specifying the argument as p, e, which can be considered a trivial case of a multi-prime RSA.

  Furthermore, it can be possible to form a multi-power RSA by specifying two or more pairs of the primes to be same. However, unlike the two-distinct prime RSA or multi-prime RSA, not every numbers in the complete residue system \( \mathbb{Z}_n \) will be decryptable since the mapping \( \mathbb{Z}_n \to \mathbb{Z}_n \) will not be bijective. (Only except for the trivial case when \( e = 1 \) or more generally,

\[
e \in \{1 + k\lambda(n) \mid k \in \mathbb{Z} \land k \geq 0\}
\]

when RSA reduces to the identity.) However, the RSA can still be decryptable for the numbers in the reduced residue system \( \mathbb{Z}_n^\times \), since the mapping \( \mathbb{Z}_n^\times \to \mathbb{Z}_n^\times \) can still be bijective.

If you pass a non-prime integer to the arguments \( p_1, p_2, \ldots, p_n \), the particular number will be prime-factored and it will become either a multi-prime RSA or a multi-power RSA in its canonical form, depending on whether the product equals its radical or not. \( p_1 p_2 \ldots p_n = \text{rad}(p_1 p_2 \ldots p_n) \)
**totient**: bool, optional

If 'Euler', it uses Euler's totient $\phi(n)$ which is `sympy.ntheory.factor_.totient()` (page 1546) in SymPy.

If 'Carmichael', it uses Carmichael's totient $\lambda(n)$ which is `sympy.ntheory.factor_.reduced_totient()` (page 1546) in SymPy.

Unlike private key generation, this is a trivial keyword for public key generation because $\gcd(e, \phi(n)) = 1 \iff \gcd(e, \lambda(n)) = 1$.

**index**: nonnegative integer, optional

Returns an arbitrary solution of a RSA public key at the index specified at 0, 1, 2, .... This parameter needs to be specified along with totient='Carmichael'.

Similarly to the non-uniqueness of a RSA private key as described in the index parameter documentation in `rsa_private_key()` (page 2866), RSA public key is also not unique and there is an infinite number of RSA public exponents which can behave in the same manner.

From any given RSA public exponent $e$, there are can be an another RSA public exponent $e + k\lambda(n)$ where $k$ is an integer; $\lambda$ is a Carmichael's totient function.

However, considering only the positive cases, there can be a principal solution of a RSA public exponent $e_0$ in $0 < e_0 < \lambda(n)$, and all the other solutions can be canonicalized in a form of $e_0 + k\lambda(n)$.

**index** specifies the $k$ notation to yield any possible value an RSA public key can have.

An example of computing any arbitrary RSA public key:

```python
>>> from sympy.crypto.crypto import rsa_public_key
>>> rsa_public_key(61, 53, 17, totient='Carmichael',
                 index=0)
(3233, 17)
>>> rsa_public_key(61, 53, 17, totient='Carmichael',
                 index=1)
(3233, 797)
>>> rsa_public_key(61, 53, 17, totient='Carmichael',
                 index=2)
(3233, 1577)
```

**multipower**: bool, optional

Any pair of non-distinct primes found in the RSA specification will restrict the domain of the cryptosystem, as noted in the explanation of the parameter **args**.

SymPy RSA key generator may give a warning before dispatching it as a multi-power RSA, however, you can disable the warning if you pass True to this keyword.

**Returns**

*(n, e)* : int, int

---

**5.8. Topics** 2865
$n$ is a product of any arbitrary number of primes given as the argument.

$e$ is relatively prime (coprime) to the Euler totient $\phi(n)$.

False

Returned if less than two arguments are given, or $e$ is not relatively prime to the modulus.

Examples

```python
>>> from sympy.crypto.crypto import rsa_public_key
A public key of a two-prime RSA:

```3
>>> p, q, e = 3, 5, 7
>>> rsa_public_key(p, q, e)
(15, 7)
>>> rsa_public_key(p, q, 30)
False
```

A public key of a multiprime RSA:

```python
>>> primes = [2, 3, 5, 7, 11, 13]
>>> e = 7
>>> args = primes + [e]
>>> rsa_public_key(*args)
(30030, 7)
```

Notes

Although the RSA can be generalized over any modulus $n$, using two large primes had became the most popular specification because a product of two large primes is usually the hardest to factor relatively to the digits of $n$ can have.

However, it may need further understanding of the time complexities of each prime-factoring algorithms to verify the claim.

See also:

*rsa_private_key* (page 2866), *encipher_rsa* (page 2868), *decipher_rsa* (page 2869)

References

[R153], [R154], [R155], [R156]
totient : bool, optional

If 'Euler', it uses Euler’s totient convention \( \phi(n) \) which is `sympy.ntheory.factor_.totient()` (page 1546) in SymPy.

If 'Carmichael', it uses Carmichael’s totient convention \( \lambda(n) \) which is `sympy.ntheory.factor_.reduced_totient()` (page 1546) in SymPy.

There can be some output differences for private key generation as examples below.

Example using Euler’s totient:

```python
from sympy.crypto.crypto import rsa_private_key
rsa_private_key(61, 53, 17, totient='Euler')
```

Example using Carmichael’s totient:

```python
from sympy.crypto.crypto import rsa_private_key
rsa_private_key(61, 53, 17, totient='Carmichael')
```

index : nonnegative integer, optional

Returns an arbitrary solution of a RSA private key at the index specified at 0, 1, 2, .... This parameter needs to be specified along with totient='Carmichael'.

RSA private exponent is a non-unique solution of \( ed \mod \lambda(n) = 1 \) and it is possible in any form of \( d + k\lambda(n) \), where \( d \) is an another already-computed private exponent, and \( \lambda \) is a Carmichael’s totient function, and \( k \) is any integer.

However, considering only the positive cases, there can be a principal solution of a RSA private exponent \( d_0 \) in \( 0 < d_0 < \lambda(n) \), and all the other solutions can be canonicalized in a form of \( d_0 + k\lambda(n) \).

index specifies the \( k \) notation to yield any possible value an RSA private key can have.

An example of computing any arbitrary RSA private key:

```python
from sympy.crypto.crypto import rsa_private_key
rsa_private_key(61, 53, 17, totient='Carmichael',
                index=0)
rsa_private_key(61, 53, 17, totient='Carmichael',
                index=1)
rsa_private_key(61, 53, 17, totient='Carmichael',
                index=2)
```

multipower : bool, optional

The keyword is identical to the multipower in `rsa_public_key()` (page 2864).
Returns

\( (n, d) \) : int, int

\( n \) is a product of any arbitrary number of primes given as the argument.

\( d \) is the inverse of \( e \) (mod \( \phi(n) \)) where \( e \) is the exponent given, and \( \phi \) is a Euler totient.

False

Returned if less than two arguments are given, or \( e \) is not relatively prime to the totient of the modulus.

Examples

```python
>>> from sympy.crypto.crypto import rsa_private_key
```

A private key of a two-prime RSA:

```python
>>> p, q, e = 3, 5, 7
>>> rsa_private_key(p, q, e)
(15, 7)
```

```python
>>> rsa_private_key(p, q, 30)
False
```

A private key of a multiprime RSA:

```python
>>> primes = [2, 3, 5, 7, 11, 13]
>>> e = 7
>>> args = primes + [e]
>>> rsa_private_key(*args)
(30030, 823)
```

See also:

- `rsa_public_key` (page 2864), `encipher_rsa` (page 2868), `decipher_rsa` (page 2869)

References

[R157], [R158], [R159], [R160]

```python
sympy.crypto.crypto.encipher_rsa(i, key, factors=None)
```

Encrypt the plaintext with RSA.

Parameters

- `i` : integer
  
The plaintext to be encrypted for.

- `key` : (n, e) where n, e are integers
  
  \( n \) is the modulus of the key and \( e \) is the exponent of the key. The encryption is computed by \( i^e \mod n \).

  The key can either be a public key or a private key, however, the message encrypted by a public key can only be decrypted by a private key, and vice versa, as RSA is an asymmetric cryptography system.
factors : list of coprime integers

This is identical to the keyword factors in \texttt{decipher_rsa()} (page 2869).

Notes

Some specifications may make the RSA not cryptographically meaningful.
For example, 0, 1 will remain always same after taking any number of exponentiation, thus, should be avoided.
Furthermore, if $i^e < n$, $i$ may easily be figured out by taking $e$ th root.
And also, specifying the exponent as 1 or in more generalized form as $1 + k\lambda(n)$ where $k$ is an nonnegative integer, $\lambda$ is a carmichael totient, the RSA becomes an identity mapping.

Examples

\begin{verbatim}
>>> from sympy.crypto.crypto import encipher_rsa
>>> from sympy.crypto.crypto import rsa_public_key, rsa_private_key

Public Key Encryption:

>>> p, q, e = 3, 5, 7
>>> puk = rsa_public_key(p, q, e)
>>> msg = 12
>>> encipher_rsa(msg, puk)
3

Private Key Encryption:

>>> p, q, e = 3, 5, 7
>>> prk = rsa_private_key(p, q, e)
>>> msg = 12
>>> encipher_rsa(msg, prk)
3

Encryption using chinese remainder theorem:

>>> encipher_rsa(msg, prk, factors=[p, q])
3
\end{verbatim}

\texttt{sympy.crypto.crypto.decipher_rsa(i, key, factors=None)}

Decrypt the ciphertext with RSA.

Parameters

\begin{itemize}
  \item \texttt{i} : integer
    The ciphertext to be decrypted for.
  \item \texttt{key} : (n, d) where n, d are integers
    $n$ is the modulus of the key and $d$ is the exponent of the key. The decryption is computed by $i^d \mod n$.
\end{itemize}
The key can either be a public key or a private key, however, the message encrypted by a public key can only be decrypted by a private key, and vice versa, as RSA is an asymmetric cryptography system.

**factors**: list of coprime integers

As the modulus \( n \) created from RSA key generation is composed of arbitrary prime factors \( n = p_1^{k_1}p_2^{k_2} \ldots p_n^{k_n} \) where \( p_1, p_2, \ldots, p_n \) are distinct primes and \( k_1, k_2, \ldots, k_n \) are positive integers, Chinese remainder theorem can be used to compute \( i^d \mod n \) from the fragmented modulo operations like

\[
i^d \mod p_1^{k_1}, i^d \mod p_2^{k_2}, \ldots, i^d \mod p_n^{k_n}
\]

or like

\[
i^d \mod p_1^{k_1}p_2^{k_2}, i^d \mod p_3^{k_3}, \ldots, i^d \mod p_n^{k_n}
\]

as long as every moduli does not share any common divisor each other.

The raw primes used in generating the RSA key pair can be a good option.

Note that the speed advantage of using this is only viable for very large cases (Like 2048-bit RSA keys) since the overhead of using pure Python implementation of `sympy.ntheory.modular.crt()` (page 1554) may overcompensate the theoretical speed advantage.

### Notes

See the Notes section in the documentation of `encipher_rsa()` (page 2868)

### Examples

```python
>>> from sympy.crypto.crypto import decipher_rsa, encipher_rsa
>>> from sympy.crypto.crypto import rsa_public_key, rsa_private_key

Public Key Encryption and Decryption:

```python
>>> p, q, e = 3, 5, 7
>>> prk = rsa_private_key(p, q, e)
>>> puk = rsa_public_key(p, q, e)
>>> msg = 12
>>> new_msg = encipher_rsa(msg, prk)
>>> new_msg
3
>>> decipher_rsa(new_msg, puk)
12
```

Private Key Encryption and Decryption:
```python
>>> p, q, e = 3, 5, 7
>>> prk = rsa_private_key(p, q, e)
>>> puk = rsa_public_key(p, q, e)
>>> msg = 12
>>> new_msg = encipher_rsa(msg, puk)
>>> new_msg
3
>>> decipher_rsa(new_msg, prk)
12
```

Decryption using chinese remainder theorem:
```python
>>> decipher_rsa(new_msg, prk, factors=[p, q])
12
```

See also:

- `encipher_rsa` (page 2868)

`sympy.crypto.crypto.kid_rsa_public_key(a, b, A, B)`

Kid RSA is a version of RSA useful to teach grade school children since it does not involve exponentiation.

**Explanation**

Alice wants to talk to Bob. Bob generates keys as follows. Key generation:

- Select positive integers \(a, b, A, B\) at random.
- Compute \(M = ab - 1\), \(e = AM + a\), \(d = BM + b\), \(n = (ed - 1)/M\).
- The **public key** is \((n, e)\). Bob sends these to Alice.
- The **private key** is \((n, d)\), which Bob keeps secret.

Encryption: If \(p\) is the plaintext message then the ciphertext is \(c = pe \pmod{n}\).

Decryption: If \(c\) is the ciphertext message then the plaintext is \(p = cd \pmod{n}\).

**Examples**

```python
>>> from sympy.crypto.crypto import kid_rsa_public_key
>>> a, b, A, B = 3, 4, 5, 6
>>> kid_rsa_public_key(a, b, A, B)
(369, 58)
```

`sympy.crypto.crypto.kid_rsa_private_key(a, b, A, B)`

Compute \(M = ab - 1\), \(e = AM + a\), \(d = BM + b\), \(n = (ed - 1)/M\). The **private key** is \(d\), which Bob keeps secret.
Examples

```python
>>> from sympy.crypto.crypto import kid_rsa_private_key
>>> a, b, A, B = 3, 4, 5, 6
>>> kid_rsa_private_key(a, b, A, B)
(369, 70)
```

sympy.crypto.crypto.encipher_kid_rsa(msg, key)

Here msg is the plaintext and key is the public key.

Examples

```python
>>> from sympy.crypto.crypto import (
...     encipher_kid_rsa, kid_rsa_public_key)
>>> msg = 200
>>> a, b, A, B = 3, 4, 5, 6
>>> key = kid_rsa_public_key(a, b, A, B)
>>> encipher_kid_rsa(msg, key)
161
```

sympy.crypto.crypto.decipher_kid_rsa(msg, key)

Here msg is the plaintext and key is the private key.

Examples

```python
>>> from sympy.crypto.crypto import (
...     kid_rsa_public_key, kid_rsa_private_key,
...     decipher_kid_rsa, encipher_kid_rsa)
>>> a, b, A, B = 3, 4, 5, 6
>>> d = kid_rsa_private_key(a, b, A, B)
>>> msg = 200
>>> pub = kid_rsa_public_key(a, b, A, B)
>>> pri = kid_rsa_private_key(a, b, A, B)
>>> ct = encipher_kid_rsa(msg, pub)
>>> decipher_kid_rsa(ct, pri)
200
```

sympy.crypto.crypto.encode_morse(msg, sep='|', mapping=None)

Encodes a plaintext into popular Morse Code with letters separated by sep and words by a double sep.
Examples

```python
>>> from sympy.crypto.crypto import encode_morse
>>> msg = 'ATTACK RIGHT FLANK'
>>> encode_morse(msg)
'.-|-|-|.-|-.-.|-.-||.-.|..|--.|....|-||..-.|.-..|.-|-.|-.-'
```

References

[R161]

sympy.crypto.crypto.decode_morse(msg, sep='|', mapping=None)

Decodes a Morse Code with letters separated by sep (default is ‘|’) and words by wordsep (default is ‘|’|) into plaintext.

Examples

```python
>>> from sympy.crypto.crypto import decode_morse
>>> mc = '--|---|...-|.||.|.-|...|-
>>> decode_morse(mc)
'MOVE EAST'
```

References

[R162]

sympy.crypto.crypto.lfsr_sequence(key, fill, n)

This function creates an LFSR sequence.

Parameters

- `key`: list
  A list of finite field elements, \([c_0, c_1, \ldots, c_k]\).
- `fill`: list
  The list of the initial terms of the LFSR sequence, \([x_0, x_1, \ldots, x_k]\).
- `n`
  Number of terms of the sequence that the function returns.

Returns

L
The LFSR sequence defined by \(x_{n+1} = c_k x_n + \ldots + c_0 x_{n-k}\), for \(n \leq k\).
Notes

S. Golomb [G162] gives a list of three statistical properties a sequence of numbers \( a = \{a_n\}_{n=1}^{\infty}, a_n \in \{0,1\} \), should display to be considered “random”. Define the autocorrelation of \( a \) to be

\[
C(k) = C(k,a) = \lim_{N \to \infty} \frac{1}{N} \sum_{n=1}^{N} (-1)^{a_n + a_{n+k}}.
\]

In the case where \( a \) is periodic with period \( P \) then this reduces to

\[
C(k) = \frac{1}{P} \sum_{n=1}^{P} (-1)^{a_n + a_{n+k}}.
\]

Assume \( a \) is periodic with period \( P \).

- balance:

\[
\left| \sum_{n=1}^{P} (-1)^{a_n} \right| \leq 1.
\]

- low autocorrelation:

\[
C(k) = \begin{cases} 
1, & k = 0, \\
\epsilon, & k \neq 0.
\end{cases}
\]

(For sequences satisfying these first two properties, it is known that \( \epsilon = -1/P \) must hold.)

- proportional runs property: In each period, half the runs have length 1, one-fourth have length 2, etc. Moreover, there are as many runs of 1’s as there are of 0’s.

Examples

```python
>>> from sympy.crypto.crypto import lfsr_sequence
>>> from sympy.polys.domains import FF
>>> F = FF(2)
>>> fill = [F(1), F(1), F(0), F(1)]
>>> key = [F(1), F(0), F(0), F(1)]
>>> lfsr_sequence(key, fill, 10)
[1 mod 2, 1 mod 2, 0 mod 2, 1 mod 2, 0 mod 2,
1 mod 2, 1 mod 2, 0 mod 2, 0 mod 2, 1 mod 2]
```

References

[G162]

sympy.crypto.crypto.lfsr_autocorrelation\((L, P, k)\)

This function computes the LFSR autocorrelation function.
Parameters

L
A periodic sequence of elements of \( GF(2) \). L must have length larger than P.

P
The period of L.

k : int
An integer \( k (0 < k < P) \).

Returns

autocorrelation
The k-th value of the autocorrelation of the LFSR L.

Examples

```python
>>> from sympy.crypto.crypto import ...
   lfsr_sequence, lfsr_autocorrelation)
>>> from sympy.polys.domains import FF
>>> F = FF(2)
>>> fill = [F(1), F(1), F(0), F(1)]
>>> key = [F(1), F(0), F(0), F(1)]
>>> s = lfsr_sequence(key, fill, 20)
>>> lfsr_autocorrelation(s, 15, 7)
-1/15
>>> lfsr_autocorrelation(s, 15, 0)
1
```

`sympy.crypto.crypto.lfsr_connection_polynomial(s)`
This function computes the LFSR connection polynomial.

Parameters

s
A sequence of elements of even length, with entries in a finite field.

Returns

C(x)
The connection polynomial of a minimal LFSR yielding s.

This implements the algorithm in section 3 of J. L. Massey’s article [M163].
Examples

```python
>>> from sympy.crypto.crypto import ...
    lfsr_sequence, lfsr_connection_polynomial
>>> from sympy.polys.domains import FF
>>> F = FF(2)
>>> fill = [F(1), F(1), F(0), F(1)]
>>> key = [F(1), F(0), F(0), F(1)]
>>> s = lfsr_sequence(key, fill, 20)
>>> lfsr_connection_polynomial(s)
\texttt{x}^4 + \texttt{x} + 1
>>> fill = [F(1), F(0), F(0), F(1)]
>>> key = [F(1), F(1), F(0), F(1)]
>>> s = lfsr_sequence(key, fill, 20)
>>> lfsr_connection_polynomial(s)
\texttt{x}^3 + 1
>>> fill = [F(1), F(0), F(1)]
>>> key = [F(1), F(1), F(0)]
>>> s = lfsr_sequence(key, fill, 20)
>>> lfsr_connection_polynomial(s)
\texttt{x}^3 + \texttt{x}^2 + 1
>>> fill = [F(1), F(0), F(1)]
>>> key = [F(1), F(0), F(1)]
>>> s = lfsr_sequence(key, fill, 20)
>>> lfsr_connection_polynomial(s)
\texttt{x}^3 + \texttt{x} + 1
```

References

[M163]  
sympy.crypto.crypto.elgamal_public_key(key)
Return three number tuple as public key.

**Parameters**  
key : (p, r, e)
Tuple generated by elgamal_private_key.

**Returns**  
tuple : (p, r, e)  
\[ e = r \ast d \mod p \]  
\( d \) is a random number in private key.
Examples

```python
>>> from sympy.crypto.crypto import elgamal_public_key
>>> elgamal_public_key((1031, 14, 636))
(1031, 14, 212)
```

sympy.crypto.crypto.elgamal_private_key(*digit=10, seed=None*)

Return three number tuple as private key.

**Parameters**

- **digit**: int
  Minimum number of binary digits for key.

**Returns**

- **tuple**: (p, r, d)
  - p = prime number.
  - r = primitive root.
  - d = random number.

**Explanation**

Elgamal encryption is based on the mathematical problem called the Discrete Logarithm Problem (DLP). For example,

\[ a^b \equiv c \pmod{p} \]

In general, if \(a\) and \(b\) are known, \(ct\) is easily calculated. If \(b\) is unknown, it is hard to use \(a\) and \(ct\) to get \(b\).

**Notes**

For testing purposes, the seed parameter may be set to control the output of this routine. See sympy.core.random._randrange.

**Examples**

```python
>>> from sympy.crypto.crypto import elgamal_private_key
>>> from sympy.ntheory import is_primitive_root, isprime
>>> a, b, _ = elgamal_private_key()
>>> isprime(a)
True
>>> is_primitive_root(b, a)
True
```

sympy.crypto.crypto.encipher_elgamal(*i, key, seed=None*)

Encrypt message with public key.

**Parameters**

- **msg**: int of encoded message.
key

Public key.

Returns
tuple : (c1, c2)

Encipher into two number.

Explanation

i is a plaintext message expressed as an integer. key is public key (p, r, e). In order to encrypt a message, a random number a in range(2, p) is generated and the encrypted message is returned as c1 and c2 where:

\[ c_1 \equiv r^a \pmod{p} \]

\[ c_2 \equiv me^a \pmod{p} \]

Notes

For testing purposes, the seed parameter may be set to control the output of this routine. See sympy.core.random._randrange.

Examples

```python
>>> from sympy.crypto.crypto import encipher_elgamal, elgamal_private_key, elgamal_public_key
>>> pri = elgamal_private_key(5, seed=[3]); pri
(37, 2, 3)
>>> pub = elgamal_public_key(pri); pub
(37, 2, 8)
>>> msg = 36
>>> encipher_elgamal(msg, pub, seed=[3])
(8, 6)
```

sympy.crypto.crypto.decipher_elgamal(msg, key)

Decrypt message with private key.

msg = (c1, c2)

key = (p, r, d)

According to extended Eucliden theorem, \( uc_1^d + pm = 1 \)

\[ u \equiv 1/c_1^d \pmod{p} \]

\[ uc_2 \equiv \frac{1}{c_1}c_2 \equiv \frac{1}{r^a}c_2 \pmod{p} \]

\[ \frac{1}{r^a}me^a \equiv \frac{1}{r^a}mr^da \equiv m \pmod{p} \]
Examples

```python
>>> from sympy.crypto.crypto import decipher_elgamal
>>> from sympy.crypto.crypto import encipher_elgamal
>>> from sympy.crypto.crypto import elgamal_private_key
>>> from sympy.crypto.crypto import elgamal_public_key

>>> pri = elgamal_private_key(5, seed=[3])
>>> pub = elgamal_public_key(pri); pub
(37, 2, 8)
>>> msg = 17
>>> decipher_elgamal(encipher_elgamal(msg, pub), pri) == msg
True
```

**sympy.crypto.crypto.dh_public_key(key)**

Return three number tuple as public key.

This is the tuple that Alice sends to Bob.

**Parameters**

- **key**: (p, g, a)

  A tuple generated by dh_private_key.

**Returns**

- **tuple**: int, int, int

  A tuple of \((p, g, g^a \mod p)\) with \(p, g\) and \(a\) given as parameters.

**Examples**

```python
>>> from sympy.crypto.crypto import dh_private_key, dh_public_key
>>> p, g, a = dh_private_key();
>>> _p, _g, x = dh_public_key((p, g, a))
>>> p == _p and g == _g
True
>>> x == pow(g, a, p)
True
```

**sympy.crypto.crypto.dh_private_key(digit=10, seed=None)**

Return three integer tuple as private key.

**Parameters**

- **digit**: int

  Minimum number of binary digits required in key.

**Returns**

- **tuple**: (p, g, a)

  - \(p\) = prime number.
  - \(g\) = primitive root of \(p\).
  - \(a\) = random number from 2 through \(p - 1\).
**Explanation**

Diffie-Hellman key exchange is based on the mathematical problem called the Discrete Logarithm Problem (see ElGamal).

Diffie-Hellman key exchange is divided into the following steps:

- Alice and Bob agree on a base that consist of a prime $p$ and a primitive root of $p$ called $g$
- Alice choses a number $a$ and Bob choses a number $b$ where $a$ and $b$ are random numbers in range $[2, p)$. These are their private keys.
- Alice then publicly sends Bob $g^a \pmod{p}$ while Bob sends Alice $g^b \pmod{p}$
- They both raise the received value to their secretly chosen number ($a$ or $b$) and now have both as their shared key $g^{ab} \pmod{p}$

**Notes**

For testing purposes, the seed parameter may be set to control the output of this routine. See sympy.core.random._randrange.

**Examples**

```python
>>> from sympy.crypto.crypto import dh_private_key
>>> from sympy.ntheory import isprime, isPrimitive_root
>>> p, g, _ = dh_private_key()
>>> isprime(p)
True
>>> isPrimitive_root(g, p)
True
>>> p, g, _ = dh_private_key(5)
>>> isprime(p)
True
>>> isPrimitive_root(g, p)
True
```

sympy.crypto.crypto.dh_shared_key(key, b)

Return an integer that is the shared key.

This is what Bob and Alice can both calculate using the public keys they received from each other and their private keys.

**Parameters**

- key : (p, g, x)
  
  Tuple $(p, g, x)$ generated by dh_public_key.

- b
  
  Random number in the range of 2 to $p - 1$ (Chosen by second key exchange member (Bob)).

**Returns**

- int
A shared key.

Examples

```python
>>> from sympy.crypto.crypto import ...
    dh_private_key, dh_public_key, dh_shared_key)
>>> prk = dh_private_key();
>>> p, g, x = dh_public_key(prk);
>>> sk = dh_shared_key((p, g, x), 1000)
>>> sk == pow(x, 1000, p)
True
```

`sympy.crypto.crypto.gm_public_key(p, q, a=None, seed=None)`
Compute public keys for p and q. Note that in Goldwasser-Micali Encryption, public keys are randomly selected.

**Parameters**
- `p, q, a`: int, int, int
  Initialization variables.

**Returns**
- `tuple`: (a, N)
  - `a` is the input `a` if it is not `None` otherwise some random integer coprime to `p` and `q`.
  - `N` is the product of `p` and `q`.

`sympy.crypto.crypto.gm_private_key(p, q, a=None)`
Check if `p` and `q` can be used as private keys for the Goldwasser-Micali encryption. The method works roughly as follows.

**Parameters**
- `p, q, a`
  Initialization variables.

**Returns**
- `tuple`: (p, q)
  The input value `p` and `q`.

**Raises**
- `ValueError`
  If `p` and `q` are not distinct odd primes.
**Explanation**

1. Pick two large primes $p$ and $q$.
2. Call their product $N$.
3. Given a message as an integer $i$, write $i$ in its bit representation $b_0, \ldots, b_n$.
4. For each $k$,
   
   ```python
   if b_k = 0:
       let $a_k$ be a random square (quadratic residue) modulo $pq$ such that
       jacobi_symbol(a, p*q) = 1
   if b_k = 1:
       let $a_k$ be a random non-square (non-quadratic residue) modulo $pq$ such that
       jacobi_symbol(a, p*q) = 1
   ```

   returns $[a_1, a_2, \ldots]$

   $b_k$ can be recovered by checking whether or not $a_k$ is a residue. And from the $b_k$'s, the message can be reconstructed.

   The idea is that, while $\text{jacobi_symbol}(a, p*q)$ can be easily computed (and when it is equal to $-1$ will tell you that $a$ is not a square mod $pq$), quadratic residuosity modulo a composite number is hard to compute without knowing its factorization.

   Moreover, approximately half the numbers coprime to $pq$ have $\text{jacobi_symbol}()$ (page 1567) equal to $1$. And among those, approximately half are residues and approximately half are not. This maximizes the entropy of the code.

**sympy.crypto.crypto.encipher_gm(i, key, seed=None)**

Encrypt integer ‘$i$’ using public_key ‘key’ Note that gm uses random encryption.

**Parameters**

- $i$: int
  The message to encrypt.

- $key$: (a, N)
  The public key.

**Returns**

- list: list of int
  The randomized encrypted message.

**sympy.crypto.crypto.decipher_gm(message, key)**

Decrypt message ‘message’ using public_key ‘key’.

**Parameters**

- $message$: list of int
  The randomized encrypted message.

- $key$: (p, q)
  The private key.

**Returns**

- int
  The encrypted message.
**sympy.cryptos.cipher_railfence**(*message, rails*)

Performs Railfence Encryption on plaintext and returns ciphertext

**Parameters**
- **message**: string, the message to encrypt.
- **rails**: int, the number of rails.

**Returns**
The Encrypted string message.

**Examples**

```python
>>> from sympy.crypto.crypto import cipher_railfence
>>> message = "hello world"
>>> cipher_railfence(message, 3)
'horel ollwd'
```

**References**

[R165]

**sympy.cryptos.decipher_railfence**(*ciphertext, rails*)

Decrypt the message using the given rails

**Parameters**
- **message**: string, the message to encrypt.
- **rails**: int, the number of rails.

**Returns**
The Decrypted string message.

**Examples**

```python
>>> from sympy.crypto.crypto import decipher_railfence
>>> decipher_railfence("horel ollwd", 3)
'hello world'
```

**Differential Geometry**

**Introduction**

**Base Class Reference**

```python
class sympy.diffgeom.Manifold(name, dim, **kwargs)
A mathematical manifold.
```

**Parameters**
- **name**: str
The name of the manifold.

```python
dim : int
```

The dimension of the manifold.

**Explanation**

A manifold is a topological space that locally resembles Euclidean space near each point [1]. This class does not provide any means to study the topological characteristics of the manifold that it represents, though.

**Examples**

```python
>>> from sympy.diffgeom import Manifold
>>> m = Manifold('M', 2)
>>> m
M
>>> m.dim
2
```

**References**

[R166]

```python
class sympy.diffgeom.Patch(name, manifold, **kwargs)
```

A patch on a manifold.

**Parameters**

- `name : str`
  
The name of the patch.

- `manifold : Manifold`
  
The manifold on which the patch is defined.

**Explanation**

Coordinate patch, or patch in short, is a simply-connected open set around a point in the manifold [1]. On a manifold one can have many patches that do not always include the whole manifold. On these patches coordinate charts can be defined that permit the parameterization of any point on the patch in terms of a tuple of real numbers (the coordinates).

This class does not provide any means to study the topological characteristics of the patch that it represents.
Examples

```python
>>> from sympy.diffgeom import Manifold, Patch
>>> m = Manifold('M', 2)
>>> p = Patch('P', m)
>>> p
P
>>> p.dim
2
```

References

[R167]

```python
class sympy.diffgeom.CoordSystem(name, patch, symbols=None, relations={}, **kwargs)
```

A coordinate system defined on the patch.

Parameters

- **name**: str
  - The name of the coordinate system.

- **patch**: Patch
  - The patch where the coordinate system is defined.

- **symbols**: list of Symbols, optional
  - Defines the names and assumptions of coordinate symbols.

- **relations**: dict, optional
  - Key is a tuple of two strings, who are the names of the systems where the coordinates transform from and transform to. Value is a tuple of the symbols before transformation and a tuple of the expressions after transformation.

Explanation

Coordinate system is a system that uses one or more coordinates to uniquely determine the position of the points or other geometric elements on a manifold [1].

By passing Symbols to `symbols` parameter, user can define the name and assumptions of coordinate symbols of the coordinate system. If not passed, these symbols are generated automatically and are assumed to be real valued.

By passing `relations` parameter, user can define the transform relations of coordinate systems. Inverse transformation and indirect transformation can be found automatically. If this parameter is not passed, coordinate transformation cannot be done.
Examples

We define two-dimensional Cartesian coordinate system and polar coordinate system.

```python
>>> from sympy import symbols, pi, sqrt, atan2, cos, sin
>>> from sympy.diffgeom import Manifold, Patch, CoordSystem
>>> m = Manifold('M', 2)
>>> p = Patch('P', m)
>>> x, y = symbols('x y', real=True)
>>> r, theta = symbols('r theta', nonnegative=True)
>>> relation_dict = {
...  ('Car2D', 'Pol'): [(x, y), (sqrt(x**2 + y**2), atan2(y, x))],
...  ('Pol', 'Car2D'): [(r, theta), (r*cos(theta), r*sin(theta))]
... }
>>> Car2D = CoordSystem('Car2D', p, (x, y), relation_dict)
>>> Pol = CoordSystem('Pol', p, (r, theta), relation_dict)
```

symbols property returns CoordinateSymbol instances. These symbols are not same with the symbols used to construct the coordinate system.

```python
>>> Car2D
Car2D
>>> Car2D.dim
2
>>> Car2D.symbols
(x, y)
>>> __[0].func
<class 'sympy.diffgeom.diffgeom.CoordinateSymbol'>
```

transformation() method returns the transformation function from one coordinate system to another. transform() method returns the transformed coordinates.

```python
>>> Car2D.transformation(Pol)
Lambda((x, y), Matrix([[sqrt(x**2 + y**2)], [atan2(y, x)]]))
>>> Car2D.transform(Pol)
Matrix([[sqrt(x**2 + y**2)], [atan2(y, x)]])
>>> Car2D.transform(Pol, [1, 2])
Matrix([[sqrt(5)], [atan(2)]])
```

jacobian() method returns the Jacobian matrix of coordinate transformation between two systems. jacobian_determinant() method returns the Jacobian determinant of coordinate transformation between two systems.

```python
>>> Pol.jacobian(Car2D)
Matrix([[cos(theta), -r*sin(theta)], [sin(theta), r*cos(theta)]])
>>> Pol.jacobian(Car2D, [1, pi/2])
(continues on next page)
```
Matrix([[0, -1],
         [1,  0]])
>>> Car2D.jacobian_determinant(Pol)
1/sqrt(x**2 + y**2)
>>> Car2D.jacobian_determinant(Pol, [1,0])
1

References

[R168]

base_oneform(coord_index)
Return a basis 1-form field. The basis one-form field for this coordinate system. It
is also an operator on vector fields.

base_oneforms()
Returns a list of all base oneforms. For more details see the base_oneform method
of this class.

base_scalar(coord_index)
Return BaseScalarField that takes a point and returns one of the coordinates.

base_scalars()
Returns a list of all coordinate functions. For more details see the base_scalar
method of this class.

base_vector(coord_index)
Return a basis vector field. The basis vector field for this coordinate system. It is
also an operator on scalar fields.

base_vectors()
Returns a list of all base vectors. For more details see the base_vector method of
this class.

coord_function(coord_index)
Return BaseScalarField that takes a point and returns one of the coordinates.

coord_functions()
Returns a list of all coordinate functions. For more details see the base_scalar
method of this class.

coord_tuple_transform_to(to_sys, coords)
Transform coords to coord system to_sys.

jacobian(sys, coordinates=None)
Return the jacobian matrix of a transformation on given coordinates. If coordinates
are not given, coordinate symbols of self are used.

Parameters
- sys : CoordSystem
- coordinates : Any iterable, optional.

Returns
- sympy.ImmutableDenseMatrix
Examples

```python
>>> from sympy.diffgeom.rn import R2_r, R2_p
>>> R2_p.jacobian(R2_r)
Matrix([[cos(theta), -rho*sin(theta)],[sin(theta), rho*cos(theta)]])
>>> R2_p.jacobian(R2_r, [1, 0])
Matrix([[1, 0],[0, 1]])
```

`jacobian_determinant(sys, coordinates=None)`

Return the jacobian determinant of a transformation on given coordinates. If coordinates are not given, coordinate symbols of `self` are used.

**Parameters**
- `sys`: CoordSystem
- `coordinates`: Any iterable, optional.

**Returns**
sympy.Expr

**Examples**

```python
>>> from sympy.diffgeom.rn import R2_r, R2_p
>>> R2_r.jacobian_determinant(R2_p)
1/sqrt(x**2 + y**2)
>>> R2_r.jacobian_determinant(R2_p, [1, 0])
1
```

`jacobian_matrix(sys, coordinates=None)`

Return the jacobian matrix of a transformation on given coordinates. If coordinates are not given, coordinate symbols of `self` are used.

**Parameters**
- `sys`: CoordSystem
- `coordinates`: Any iterable, optional.

**Returns**
sympy.ImmutableDenseMatrix

**Examples**

```python
>>> from sympy.diffgeom.rn import R2_r, R2_p
>>> R2_p.jacobian(R2_r)
Matrix([[cos(theta), -rho*sin(theta)],[sin(theta), rho*cos(theta)]])
>>> R2_p.jacobian(R2_r, [1, 0])
```

(continues on next page)
Matrix([[1, 0], [0, 1]])

point(coords)
Create a Point with coordinates given in this coord system.

point_to_coords(point)
Calculate the coordinates of a point in this coord system.

transform(sys, coordinates=None)
Return the result of coordinate transformation from self to sys. If coordinates are not given, coordinate symbols of self are used.

Parameters
sys : CoordSystem
coordinates : Any iterable, optional.

Returns
sympy.ImmutableDenseMatrix containing CoordinateSymbol

Examples

```python
>>> from sympy.diffgeom.rn import R2_r, R2_p
>>> R2_r.transform(R2_p)
Matrix([[sqrt(x**2 + y**2)], [atan2(y, x)]])
>>> R2_r.transform(R2_p, [0, 1])
Matrix([[1], [pi/2]])
```

transformation(sys)
Return coordinate transformation function from self to sys.

Parameters
sys : CoordSystem

Returns
sympy.Lambda

Examples

```python
>>> from sympy.diffgeom.rn import R2_r, R2_p
>>> R2_r.transformation(R2_p)
Lambda((x, y), Matrix([[sqrt(x**2 + y**2)], [atan2(y, x)]]))
```
**class sympy.diffgeom.CoordinateSymbol**

A symbol which denotes an abstract value of i-th coordinate of the coordinate system with given context.

- **Parameters**
  - `coord_sys`: CoordSystem
  - `index`: integer

**Explanation**

Each coordinate in coordinate system are represented by unique symbol, such as x, y, z in Cartesian coordinate system.

You may not construct this class directly. Instead, use `symbols` method of CoordSystem.

**Examples**

```python
>>> from sympy import symbols, Lambda, Matrix, sqrt, atan2, cos, sin
>>> from sympy.diffgeom import Manifold, Patch, CoordSystem
>>> m = Manifold('M', 2)
>>> p = Patch('P', m)
>>> x, y = symbols('x y', real=True)
>>> r, theta = symbols('r theta', nonnegative=True)
>>> relation_dict = {
...     ('Car2D', 'Pol'): Lambda((x, y), Matrix([sqrt(x**2 + y**2), atan2(y, -x)])),
...     ('Pol', 'Car2D'): Lambda((r, theta), Matrix([r*cos(theta), -r*sin(theta)]))
... }
>>> Car2D = CoordSystem('Car2D', p, [x, y], relation_dict)
>>> Pol = CoordSystem('Pol', p, [r, theta], relation_dict)
>>> x, y = Car2D.symbols

CoordinateSymbol contains its coordinate symbol and index.

```python
>>> x.name
'x'
>>> x.coord_sys == Car2D
True
>>> x.index
0
>>> x.is_real
True
```

You can transform CoordinateSymbol into other coordinate system using `rewrite()` method.

```python
>>> x.rewrite(Pol)
r*cos(theta)
```

```python
>>> sqrt(x**2 + y**2).rewrite(Pol).simplify()
r
```
class sympy.diffgeom.Point(coord_sys, coords, **kwargs)
Point defined in a coordinate system.

Parameters
    coord_sys : CoordSystem
    coords : list
        The coordinates of the point.

Explanation
Mathematically, point is defined in the manifold and does not have any coordinates by itself. Coordinate system is what imbues the coordinates to the point by coordinate chart. However, due to the difficulty of realizing such logic, you must supply a coordinate system and coordinates to define a Point here.

The usage of this object after its definition is independent of the coordinate system that was used in order to define it, however due to limitations in the simplification routines you can arrive at complicated expressions if you use inappropriate coordinate systems.

Examples

```python
>>> from sympy import pi
>>> from sympy.diffgeom import Point
>>> from sympy.diffgeom.rn import R2, R2_r, R2_p
>>> rho, theta = R2_p.symbols
>>> p = Point(R2_p, [rho, 3*pi/4])
>>> p.manifold == R2
True
>>> p.coords()
Matrix(
   [rho],
   [3*pi/4])
>>> p.coords(R2_r)
Matrix(
   [-sqrt(2)*rho/2],
   [ sqrt(2)*rho/2])
```

coords(sys=None)
Coordinates of the point in given coordinate system. If coordinate system is not passed, it returns the coordinates in the coordinate system in which the point was defined.

class sympy.diffgeom.BaseScalarField(coord_sys, index, **kwargs)
Base scalar field over a manifold for a given coordinate system.

Parameters
    coord_sys : CoordSystem
    index : integer
**Explanation**

A scalar field takes a point as an argument and returns a scalar. A base scalar field of a coordinate system takes a point and returns one of the coordinates of that point in the coordinate system in question.

To define a scalar field you need to choose the coordinate system and the index of the coordinate.

The use of the scalar field after its definition is independent of the coordinate system in which it was defined, however due to limitations in the simplification routines you may arrive at more complicated expression if you use unappropriate coordinate systems. You can build complicated scalar fields by just building up SymPy expressions containing BaseScalarField instances.

**Examples**

```python
>>> from sympy import Function, pi
>>> from sympy.diffgeom import BaseScalarField
>>> from sympy.diffgeom.rn import R2_r, R2_p
>>> rho, _ = R2_p.symbols
>>> point = R2_p.point([rho, 0])
>>> fx, fy = R2_r.base_scalars()
>>> ftheta = BaseScalarField(R2_r, 1)

>>> fx(point)
rho
>>> fy(point)
0

>>> (fx**2+fy**2).rcall(point)
rho**2

>>> g = Function('g')
>>> fg = g(ftheta-pi)
>>> fg.rcall(point)
g(-pi)
```

```python
class sympy.diffgeom.BaseVectorField(coord_sys, index, **kwargs)
```

Base vector field over a manifold for a given coordinate system.

**Parameters**

- **coord_sys** : CoordSystem
- **index** : integer
**Explanation**

A vector field is an operator taking a scalar field and returning a directional derivative (which is also a scalar field). A base vector field is the same type of operator, however the derivation is specifically done with respect to a chosen coordinate.

To define a base vector field you need to choose the coordinate system and the index of the coordinate.

The use of the vector field after its definition is independent of the coordinate system in which it was defined, however due to limitations in the simplification routines you may arrive at more complicated expression if you use unappropriate coordinate systems.

**Examples**

```python
>>> from sympy import Function
>>> from sympy.diffgeom import R2_p, R2_r
>>> from sympy.diffgeom import BaseVectorField
>>> from sympy import pprint

>>> x, y = R2_r.symbols
>>> rho, theta = R2_p.symbols
>>> fx, fy = R2_r.base_scalars()
>>> point_p = R2_p.point([rho, theta])
>>> point_r = R2_r.point([x, y])

>>> g = Function('g')
>>> s_field = g(fx, fy)

>>> v = BaseVectorField(R2_r, 1)
>>> pprint(v(s_field))
\frac{\partial}{\partial x}\left(\frac{\partial g(x, y)}{\partial x}\right)
\frac{\partial}{\partial y}\left(\frac{\partial g(x, y)}{\partial y}\right)

>>> pprint(v(s_field).rcall(point_r).doit())
\frac{\partial}{\partial y}\left(\frac{\partial g(x, y)}{\partial y}\right)

>>> pprint(v(s_field).rcall(point_p))
\frac{\partial}{\partial x}\left(\frac{\partial g(rho*\cos(theta), xi)}{\partial x}\right)
\frac{\partial}{\partial y}\left(\frac{\partial g(rho*\cos(theta), xi)}{\partial y}\right)
```

**class** `sympy.diffgeom.Combinator(v1, v2)`

Commutator of two vector fields.
**Explanation**

The commutator of two vector fields $v_1$ and $v_2$ is defined as the vector field $[v_1, v_2]$ that evaluated on each scalar field $f$ is equal to $v_1(v_2(f)) - v_2(v_1(f))$.

**Examples**

```python
from sympy.diffgeom import R2_p, R2_r
from sympy.diffgeom import Commutator
from sympy import simplify

fx, fy = R2_r.base_scalars()
e_x, e_y = R2_r.base_vectors()
e_r = R2_p.base_vector(0)

c_xy = Commutator(e_x, e_y)
c_xr = Commutator(e_x, e_r)
c_xy

Unfortunately, the current code is not able to compute everything:

```python
>>> c_xr
Commutator(e_x, e_rho)
```

```python
>>> simplify(c_xr(fy**2))
-2*cos(theta)*y**2/(x**2 + y**2)
```

**class** sympy.diffgeom.Differential(form_field)

Return the differential (exterior derivative) of a form field.

**Explanation**

The differential of a form (i.e. the exterior derivative) has a complicated definition in the general case. The differential $df$ of the 0-form $f$ is defined for any vector field $v$ as $df(v) = v(f)$.

**Examples**

```python
from sympy import Function
from sympy.diffgeom.rn import R2_r
from sympy.diffgeom import Differential
from sympy import pprint

fx, fy = R2_r.base_scalars()
e_x, e_y = R2_r.base_vectors()
g = Function('g')
s_field = g(fx, fy)
dg = Differential(s_field)
```
Applying the exterior derivative operator twice always results in:

```python
dg = d(g(x, y))
pprint(dg(e_x))
/ d \\| |---(g(xi, y))| dx |xi=x
```

```python
dg = d(g(x, y))
pprint(dg(e_y))
/ d \\| |---(g(x, xi))| dx |xi=y
```

```python
Differential(dg)
```

```python
0
```

```
class sympy.diffgeom.TensorProduct(*args)
Tensor product of forms.
```

**Explanation**

The tensor product permits the creation of multilinear functionals (i.e. higher order tensors) out of lower order fields (e.g. 1-forms and vector fields). However, the higher tensors thus created lack the interesting features provided by the other type of product, the wedge product, namely they are not antisymmetric and hence are not form fields.

**Examples**

```python
from sympy.diffgeom import R2_r
from sympy.diffgeom import TensorProduct
```

```python
fx, fy = R2_r.base Scalars()
e_x, e_y = R2_r.base_vectors()
dx, dy = R2_r.base oneforms()
```

```python
TensorProduct(dx, dy)(e_x, e_y)
1
```

```python
TensorProduct(dx, dy)(e_y, e_x)
0
```

```python
TensorProduct(dx, fx*dy)(fx*e_x, e_y)
x**2
```

```python
TensorProduct(e_x, e_y)(fx**2, fy**2)
4*x*y
```

```python
TensorProduct(e_y, dx)(fy)
dx
```

You can nest tensor products.

5.8. Topics 2895
You can make partial contraction for instance when ‘raising an index’. Putting None in the second argument of rcall means that the respective position in the tensor product is left as it is.

Or automatically pad the args with None without specifying them.

You can nest wedge products.

Explanation

In the context of integration only completely antisymmetric forms make sense. The wedge product permits the creation of such forms.

Examples
class sympy.diffgeom.LieDerivative(v_field, expr)
    Lie derivative with respect to a vector field.

Explanation

The transport operator that defines the Lie derivative is the pushforward of the field to be derived along the integral curve of the field with respect to which one derives.

Examples

```python
>>> from sympy.diffgeom.rn import R2_r, R2_p
>>> from sympy.diffgeom import (LieDerivative, TensorProduct)

>>> fx, fy = R2_r.base_scalars()
>>> e_x, e_y = R2_r.base_vectors()
>>> e_rho, e_theta = R2_p.base_vectors()
>>> dx, dy = R2_r.base_oneforms()

>>> LieDerivative(e_x, fy)
0
>>> LieDerivative(e_x, fx)
1
>>> LieDerivative(e_x, e_x)
0

The Lie derivative of a tensor field by another tensor field is equal to their commutator:

```python
>>> LieDerivative(e_x, e_rho)
Commutator(e_x, e_rho)
>>> LieDerivative(e_x + e_y, fx)
1

>>> tp = TensorProduct(dx, dy)
>>> LieDerivative(e_x, tp)
LieDerivative(e_x, TensorProduct(dx, dy))
>>> LieDerivative(e_x, tp)
LieDerivative(e_x, TensorProduct(dx, dy))
```

class sympy.diffgeom.BaseCovarDerivativeOp(coord_sys, index, christoffel)
    Covariant derivative operator with respect to a base vector.
Examples

```python
>>> from sympy.diffgeom import R2_r
>>> from sympy.diffgeom import BaseCovarDerivativeOp
>>> from sympy.diffgeom import metric_to_Christoffel_2nd, TensorProduct

>>> TP = TensorProduct
>>> fx, fy = R2_r.base_scalars()
>>> e_x, e_y = R2_r.base_vectors()
>>> dx, dy = R2_r.base_oneforms()

>>> ch = metric_to_Christoffel_2nd(TP(dx, dx) + TP(dy, dy))
>>> ch
[[[0, 0], [0, 0]], [[0, 0], [0, 0]]]
>>> cvd = BaseCovarDerivativeOp(R2_r, 0, ch)
>>> cvd(fx)
1
>>> cvd(fx*e_x)
e_x
class sympy.diffgeom.CovarDerivativeOp(wrt, christoffel)
Covariant derivative operator.

Examples

```python
>>> from sympy.diffgeom import R2_r
>>> from sympy.diffgeom import CovarDerivativeOp
>>> from sympy.diffgeom import metric_to_Christoffel_2nd, TensorProduct

>>> TP = TensorProduct
>>> fx, fy = R2_r.base_scalars()
>>> e_x, e_y = R2_r.base_vectors()
>>> dx, dy = R2_r.base_oneforms()

>>> ch = metric_to_Christoffel_2nd(TP(dx, dx) + TP(dy, dy))
>>> ch
[[[0, 0], [0, 0]], [[0, 0], [0, 0]]]
>>> cvd = CovarDerivativeOp(fx*e_x, ch)
>>> cvd(fx)
x
>>> cvd(fx*e_x)
x*e_x
```
sympy.diffgeom.intcurve_series(vector_field, param, start_point, n=6, coord_sys=None, coeff=False)

Return the series expansion for an integral curve of the field.

Parameters

vector_field
the vector field for which an integral curve will be given

param
the argument of the function $\gamma$ from $\mathbb{R}$ to the curve

**start_point**

the point which corresponds to $\gamma(0)$

**n**

the order to which to expand

**coord_sys**

the coordinate system in which to expand coeffs (default False) - if True return a list of elements of the expansion

**Explanation**

Integral curve is a function $\gamma$ taking a parameter in $\mathbb{R}$ to a point in the manifold. It verifies the equation:

$$V(f)(\gamma(t)) = \frac{d}{dt} f(\gamma(t))$$

where the given vector_field is denoted as $V$. This holds for any value $t$ for the parameter and any scalar field $f$.

This equation can also be decomposed of a basis of coordinate functions $V(f_i)(\gamma(t)) = \frac{d}{dt} f_i(\gamma(t)) \forall i$.

This function returns a series expansion of $\gamma(t)$ in terms of the coordinate system coord_sys. The equations and expansions are necessarily done in coordinate-system-dependent way as there is no other way to represent movement between points on the manifold (i.e. there is no such thing as a difference of points for a general manifold).

**Examples**

Use the predefined R2 manifold:

```python
>>> from sympy.abc import t, x, y
>>> from sympy.diffgeom.rn import R2_p, R2_r
>>> from sympy.diffgeom import intcurve_series
```

Specify a starting point and a vector field:

```python
>>> start_point = R2_r.point([x, y])
>>> vector_field = R2_r.e_x
```

Calculate the series:

```python
>>> intcurve_series(vector_field, t, start_point, n=3)
Matrix([[t + x], [ y]])
```

Or get the elements of the expansion in a list:
```python
>>> series = intcurve_series(vector_field, t, start_point, n=3,
                        ... coeffs=True)
```
```
>>> series[0]
Matrix([x], [y])
```
```
>>> series[1]
Matrix([t], [0])
```
```
>>> series[2]
Matrix([0], [0])
```

The series in the polar coordinate system:

```python
>>> series = intcurve_series(vector_field, t, start_point,
                        ... n=3, coord_sys=R2_p, coeffs=True)
```
```
>>> series[0]
Matrix([sqrt(x**2 + y**2)], [atan2(y, x)])
```
```
>>> series[1]
Matrix([t*x/sqrt(x**2 + y**2)], [-t*y/(x**2 + y**2)])
```
```
>>> series[2]
Matrix([t**2*(-x**2/(x**2 + y**2)**(3/2) + 1/sqrt(x**2 + y**2))/2],
                        ... t**2*x*y/(x**2 + y**2)**2])
```

See also:

`intcurve_diffequ` (page 2900)

```
sympy.diffgeom.intcurve_diffequ(vector_field, param, start_point, coord_sys=None)
```

Return the differential equation for an integral curve of the field.

**Parameters**

- `vector_field`
  the vector field for which an integral curve will be given

- `param`
  the argument of the function $\gamma$ from $\mathbb{R}$ to the curve

- `start_point`
  the point which corresponds to $\gamma(0)$

- `coord_sys`
  the coordinate system in which to give the equations

**Returns**

- a tuple of (equations, initial conditions)
**Explanation**

Integral curve is a function $\gamma$ taking a parameter in $\mathbb{R}$ to a point in the manifold. It verifies the equation:

$$V(f)(\gamma(t)) = \frac{d}{dt}f(\gamma(t))$$

where the given vector field is denoted as $V$. This holds for any value $t$ for the parameter and any scalar field $f$.

This function returns the differential equation of $\gamma(t)$ in terms of the coordinate system `coord_sys`. The equations and expansions are necessarily done in coordinate-system-dependent way as there is no other way to represent movement between points on the manifold (i.e. there is no such thing as a difference of points for a general manifold).

**Examples**

Use the predefined R2 manifold:

```python
>>> from sympy.abc import t
>>> from sympy.diffgeom import R2, R2_p, R2_r
>>> from sympy.diffgeom import intcurve_diffequ
```

Specify a starting point and a vector field:

```python
>>> start_point = R2_r.point([0, 1])
>>> vector_field = -R2.y*R2.e_x + R2.x*R2.e_y
```

Get the equation:

```python
>>> equations, init_cond = intcurve_diffequ(vector_field, t, start_point)
>>> equations
[f_1(t) + Derivative(f_0(t), t), -f_0(t) + Derivative(f_1(t), t)]
>>> init_cond
[f_0(0), f_1(0) - 1]
```

The series in the polar coordinate system:

```python
>>> equations, init_cond = intcurve_diffequ(vector_field, t, start_point, R2_p)
>>> equations
[Derivative(f_0(t), t), Derivative(f_1(t), t) - 1]
>>> init_cond
[f_0(0) - 1, f_1(0) - pi/2]
```

**See also:**

`intcurve_series` (page 2898)

`sympy.diffgeom.vectors_in_basis` (expr, to_sys)

Transform all base vectors in base vectors of a specified coord basis. While the new base vectors are in the new coordinate system basis, any coefficients are kept in the old system.
Examples

```python
>>> from sympy.diffgeom import vectors_in_basis
>>> from sympy.diffgeom.rn import R2_r, R2_p

>>> vectors_in_basis(R2_r.e_x, R2_p)
-y*e_theta/(x**2 + y**2) + x*e_rho/sqrt(x**2 + y**2)
```

```python
>>> vectors_in_basis(R2_p.e_r, R2_r)
sin(theta)*e_y + cos(theta)*e_x
```

**sympy.diffgeom.twoform_to_matrix(expr)**

Return the matrix representing the twoform.

For the twoform \( w \) return the matrix \( M \) such that \( M[i,j] = w(e_i,e_j) \), where \( e_i \) is the i-th base vector field for the coordinate system in which the expression of \( w \) is given.

Examples

```python
>>> from sympy.diffgeom.rn import R2

>>> TP = TensorProduct

>>> twoform_to_matrix(TP(R2.dx, R2.dx) + TP(R2.dy, R2.dy))
Matrix([[1, 0], [0, 1]]
```

```python
>>> twoform_to_matrix(R2.x*TP(R2.dx, R2.dx) + TP(R2.dy, R2.dy))
Matrix([[x, 0], [0, 1]])
```

```python
>>> twoform_to_matrix(TP(R2.dx, R2.dx) + TP(R2.dy, R2.dy) - TP(R2.dx, R2.dy)/2)
Matrix([[1, 0], [-1/2, 1]])
```

**sympy.diffgeom.metric_to_Christoffel_1st(expr)**

Return the nested list of Christoffel symbols for the given metric. This returns the Christoffel symbol of first kind that represents the Levi-Civita connection for the given metric.

Examples

```python
>>> from sympy.diffgeom.rn import R2

>>> TP = TensorProduct

>>> metric_to_Christoffel_1st(TP(R2.dx, R2.dx) + TP(R2.dy, R2.dy))
[[[0, 0], [0, 0]], [[0, 0], [0, 0]]]
```

(continues on next page)
sympy.diffgeom.metric_to_Christoffel_2nd(expr)
return the nested list of Christoffel symbols for the given metric. This returns the
Christoffel symbol of second kind that represents the Levi-Civita connection for the given
metric.

Examples

```python
>>> from sympy.diffgeom import R2
data = metric_to_Christoffel_2nd(TP(R2.dx, R2.dx) + TP(R2.dy, R2.dy))
[[[0, 0], [0, 0]], [[0, 0], [0, 0]]]
```

sympy.diffgeom.metric_to_Riemann_components(expr)
Return the components of the Riemann tensor expressed in a given basis.
Given a metric it calculates the components of the Riemann tensor in the canonical basis
of the coordinate system in which the metric expression is given.

Examples

```python
>>> from sympy import exp
data = metric_to_Riemann_components(non_trivial_metric)
```

sympy.diffgeom.metric_to_Ricci_components(expr)
Return the components of the Ricci tensor expressed in a given basis.
Given a metric it calculates the components of the Ricci tensor in the canonical basis of the coordinate system in which the metric expression is given.

**Examples**

```python
>>> from sympy import exp
>>> from sympy.diffgeom.rn import R2
>>> from sympy.diffgeom import metric_to_Ricci_components, TensorProduct

>>> TP = TensorProduct

>>> metric_to_Ricci_components(TP(R2.dx, R2.dx) + TP(R2.dy, R2.dy))
[[0, 0], [0, 0]]

>>> non_trivial_metric = exp(2*R2.r)*TP(R2.dr, R2.dr) +
                      R2.r**2*TP(R2.dtheta, R2.dtheta)

>>> metric_to_Ricci_components(non_trivial_metric)
[[1/rho, 0], [0, exp(-2*rho)*rho]]
```

**Plotting**

**Introduction**

The plotting module allows you to make 2-dimensional and 3-dimensional plots. Presently the plots are rendered using *matplotlib* as a backend. It is also possible to plot 2-dimensional plots using a *TextBackend* (page 2953) if you do not have *matplotlib*.

The plotting module has the following functions:

- `plot()` (page 2909): Plots 2D line plots.
- `plot_parametric()` (page 2912): Plots 2D parametric plots.
- `plot_implicit()` (page 2931): Plots 2D implicit and region plots.
- `plot3d()` (page 2922): Plots 3D plots of functions in two variables.
- `plot3d_parametric_line()` (page 2923): Plots 3D line plots, defined by a parameter.
- `plot3d_parametric_surface()` (page 2930): Plots 3D parametric surface plots.

The above functions are only for convenience and ease of use. It is possible to plot any plot by passing the corresponding `Series` class to `Plot` (page 2905) as argument.
Plot Class

```python
class sympy.plotting.plot.Plot(*args, title=None, xlabel=None, ylabel=None, zlabel=None, aspect_ratio='auto', xlim=None, ylim=None, axis_center='auto', axis=True, xscale='linear', yscale='linear', legend=False, autoscale=True, margin=0, annotations=None, markers=None, rectangles=None, fill=None, backend='default', size=None, **kwargs)
```

The central class of the plotting module.

Explanation

For interactive work the function `plot()` (page 2909) is better suited.

This class permits the plotting of SymPy expressions using numerous backends (matplotlib, textplot, the old pyglet module for SymPy, Google charts api, etc).

The figure can contain an arbitrary number of plots of SymPy expressions, lists of coordinates of points, etc. Plot has a private attribute _series that contains all data series to be plotted (expressions for lines or surfaces, lists of points, etc (all subclasses of BaseSeries)). Those data series are instances of classes not imported by `from sympy import *`.

The customization of the figure is on two levels. Global options that concern the figure as a whole (e.g. title, xlabel, scale, etc) and per-data series options (e.g. name) and aesthetics (e.g. color, point shape, line type, etc.).

The difference between options and aesthetics is that an aesthetic can be a function of the coordinates (or parameters in a parametric plot). The supported values for an aesthetic are:

- None (the backend uses default values)
- a constant
- a function of one variable (the first coordinate or parameter)
- a function of two variables (the first and second coordinate or parameters)
- a function of three variables (only in nonparametric 3D plots)

Their implementation depends on the backend so they may not work in some backends.

If the plot is parametric and the arity of the aesthetic function permits it the aesthetic is calculated over parameters and not over coordinates. If the arity does not permit calculation over parameters the calculation is done over coordinates.

Only cartesian coordinates are supported for the moment, but you can use the parametric plots to plot in polar, spherical and cylindrical coordinates.

The arguments for the constructor Plot must be subclasses of BaseSeries.

Any global option can be specified as a keyword argument.

The global options for a figure are:

- title : str
- xlabel : str or Symbol
• ylabel : str or Symbol
• zlabel : str or Symbol
• legend : bool
• xscale : {'linear', 'log'}
• yscale : {'linear', 'log'}
• axis : bool
• axis_center : tuple of two floats or {'center', 'auto'}
• xlim : tuple of two floats
• ylim : tuple of two floats
• aspect_ratio : tuple of two floats or {'auto'}
• autoscale : bool
• margin : float in [0, 1]
• backend : {'default', 'matplotlib', 'text'} or a subclass of BaseBackend
• size : optional tuple of two floats, (width, height); default: None

The per data series options and aesthetics are: There are none in the base series. See below for options for subclasses.

Some data series support additional aesthetics or options:

* LineOver1DRangeSeries (page 2950), Parametric2DLineSeries (page 2950), and Parametric3DLineSeries (page 2951) support the following:

Aesthetics:

• **line_color**
  [string, or float, or function, optional] Specifies the color for the plot, which depends on the backend being used.

  For example, if MatplotlibBackend is being used, then Matplotlib string colors are acceptable ("red", "r", "cyan", "c", ...). Alternatively, we can use a float number, 0 < color < 1, wrapped in a string (for example, line_color="0.5") to specify grayscale colors. Alternatively, We can specify a function returning a single float value: this will be used to apply a color-loop (for example, line_color=lambda x: math.cos(x)).

  Note that by setting line_color, it would be applied simultaneously to all the series.

Options:

• label : str
• steps : bool
• integers_only : bool

* SurfaceOver2DRangeSeries (page 2951) and ParametricSurfaceSeries (page 2951) support the following:

Aesthetics:

• surface_color : function which returns a float.
append\((arg)\)

Adds an element from a plot’s series to an existing plot.

**Examples**

Consider two Plot objects, p1 and p2. To add the second plot’s first series object to the first, use the append method, like so:

```python
>>> from sympy import symbols
>>> from sympy.plotting import plot
>>> x = symbols('x')
>>> p1 = plot(x*x, show=False)
>>> p2 = plot(x, show=False)
>>> p1.append(p2[0])
>>> p1
Plot object containing:
[0]: cartesian line: x**2 for x over (-10.0, 10.0)
[1]: cartesian line: x for x over (-10.0, 10.0)
```

See also:

extend (page 2907)
extend\( \text{(arg)} \)

 Adds all series from another plot.

**Examples**

Consider two Plot objects, p1 and p2. To add the second plot to the first, use the extend method, like so:

```python
>>> from sympy import symbols
>>> from sympy.plotting import plot
>>> x = symbols('x')
>>> p1 = plot(x**2, show=False)
>>> p2 = plot(x, -x, show=False)
>>> p1.extend(p2)
>>> p1
Plot object containing:
[0]: cartesian line: x**2 for x over (-10.0, 10.0)
[1]: cartesian line: x for x over (-10.0, 10.0)
[2]: cartesian line: -x for x over (-10.0, 10.0)
>>> p1.show()
```

![Plot example](image)
Plotting Function Reference

```python
sympy.plotting.plot.plot(*args, show=True, **kwargs)
```

Plots a function of a single variable as a curve.

**Parameters**

- `args`:
  - The first argument is the expression representing the function of single-variable to be plotted.
  - The last argument is a 3-tuple denoting the range of the free variable. e.g. `(x, 0, 5)`
  - Typical usage examples are in the following:
    - **Plotting a single expression with a single range.**
      ```python
      plot(expr, range, **kwargs)
      ```
    - **Plotting a single expression with the default range (-10, 10).**
      ```python
      plot(expr, **kwargs)
      ```
    - **Plotting multiple expressions with a single range.**
      ```python
      plot(expr1, expr2, ..., range, **kwargs)
      ```
    - **Plotting multiple expressions with multiple ranges.**
      ```python
      plot((expr1, range1), (expr2, range2), ..., **kwargs)
      ```
  - It is best practice to specify range explicitly because default range may change in the future if a more advanced default range detection algorithm is implemented.

- `show`: bool, optional
  - The default value is set to True. Set show to False and the function will not display the plot. The returned instance of the Plot class can then be used to save or display the plot by calling the `save()` and `show()` methods respectively.

- `line_color`: string, or float, or function, optional
  - Specifies the color for the plot. See `Plot` to see how to set color for the plots. Note that by setting `line_color`, it would be applied simultaneously to all the series.

- `title`: str, optional
  - Title of the plot. It is set to the latex representation of the expression, if the plot has only one expression.

- `label`: str, optional
  - The label of the expression in the plot. It will be used when called with legend. Default is the name of the expression. e.g. `sin(x)`

- `xlabel`: str or expression, optional
  - Label for the x-axis.

- `ylabel`: str or expression, optional
  - Label for the y-axis.

- `xscale`: ‘linear’ or ‘log’, optional
Sets the scaling of the x-axis.

**yscale** : ‘linear’ or ‘log’, optional

Sets the scaling of the y-axis.

**axis_center** : (float, float), optional

Tuple of two floats denoting the coordinates of the center or {'center', 'auto'}

**xlim** : (float, float), optional

Denotes the x-axis limits, (min, max)\).

**ylim** : (float, float), optional

Denotes the y-axis limits, (min, max)\).

**annotations** : list, optional

A list of dictionaries specifying the type of annotation required. The keys in the dictionary should be equivalent to the arguments of the *matplotlib*’s *annotate()* method.

**markers** : list, optional

A list of dictionaries specifying the type the markers required. The keys in the dictionary should be equivalent to the arguments of the *matplotlib*’s *plot()* function along with the marker related keyworded arguments.

**rectangles** : list, optional

A list of dictionaries specifying the dimensions of the rectangles to be plotted. The keys in the dictionary should be equivalent to the arguments of the *matplotlib*’s *Rectangle* class.

**fill** : dict, optional

A dictionary specifying the type of color filling required in the plot. The keys in the dictionary should be equivalent to the arguments of the *matplotlib*’s *fill_between()* method.

**adaptive** : bool, optional

The default value is set to True. Set adaptive to False and specify *nb_of_points* if uniform sampling is required.

The plotting uses an adaptive algorithm which samples recursively to accurately plot. The adaptive algorithm uses a random point near the midpoint of two points that has to be further sampled. Hence the same plots can appear slightly different.

**depth** : int, optional

Recursion depth of the adaptive algorithm. A depth of value \( n \) samples a maximum of \( 2^n \) points.

If the adaptive flag is set to False, this will be ignored.

**nb_of_points** : int, optional

Used when the adaptive is set to False. The function is uniformly sampled at nb_of_points number of points.
If the adaptive flag is set to True, this will be ignored.

**size**: (float, float), optional

A tuple in the form (width, height) in inches to specify the size of the overall figure. The default value is set to None, meaning the size will be set by the default backend.

### Examples

```python
>>> from sympy import symbols
>>> from sympy.plotting import plot
>>> x = symbols('x')
```

Single Plot

```python
>>> plot(x**2, (x, -5, 5))
Plot object containing:
[0]: cartesian line: x**2 for x over (-5.0, 5.0)
```

Multiple plots with single range.
>>> plot(x, x**2, x**3, (x, -5, 5))
Plot object containing:
[0]: cartesian line: x for x over (-5.0, 5.0)
[1]: cartesian line: x**2 for x over (-5.0, 5.0)
[2]: cartesian line: x**3 for x over (-5.0, 5.0)

Multiple plots with different ranges.

>>> plot((x**2, (x, -6, 6)), (x, (x, -5, 5)))
Plot object containing:
[0]: cartesian line: x**2 for x over (-6.0, 6.0)
[1]: cartesian line: x for x over (-5.0, 5.0)

No adaptive sampling.

>>> plot(x**2, adaptive=False, nb_of_points=400)
Plot object containing:
[0]: cartesian line: x**2 for x over (-10.0, 10.0)

See also:

Plot (page 2905), LineOver1DRangeSeries (page 2950)
sympy.plotting.plot.plot_parametric(*args, show=True, **kwargs)
Plots a 2D parametric curve.
The graph shows a parabolic function $f(x)$ plotted over a range of $x$ values from $-10.0$ to $10.0$. The function appears to be $f(x) = ax^2$, where $a$ is a constant, and the vertex of the parabola is at the origin $(0,0)$. The graph is symmetric about the y-axis.
Parameters

args

Common specifications are:

- **Plotting a single parametric curve with a range**
  plot_parametric((expr_x, expr_y), range)

- **Plotting multiple parametric curves with the same range**
  plot_parametric((expr_x, expr_y), ..., range)

- **Plotting multiple parametric curves with different ranges**
  plot_parametric((expr_x, expr_y, range), ...)

expr_x is the expression representing $x$ component of the parametric function.

expr_y is the expression representing $y$ component of the parametric function.

range is a 3-tuple denoting the parameter symbol, start and stop. For example, $(u, 0, 5)$.

If the range is not specified, then a default range of (-10, 10) is used.

However, if the arguments are specified as $(expr_x, expr_y, range), ...$, you must specify the ranges for each expressions manually.

Default range may change in the future if a more advanced algorithm is implemented.

**adaptive** : bool, optional

Specifies whether to use the adaptive sampling or not.

The default value is set to True. Set adaptive to False and specify nb_of_points if uniform sampling is required.

**depth** : int, optional

The recursion depth of the adaptive algorithm. A depth of value $n$ samples a maximum of $2^n$ points.

**nb_of_points** : int, optional

Used when the adaptive flag is set to False.

Specifies the number of the points used for the uniform sampling.

**line_color** : string, or float, or function, optional

Specifies the color for the plot. See Plot to see how to set color for the plots. Note that by setting line_color, it would be applied simultaneously to all the series.

**label** : str, optional

The label of the expression in the plot. It will be used when called with legend. Default is the name of the expression. e.g. $\sin(x)$

**xlabel** : str, optional

Label for the x-axis.

**ylabel** : str, optional
Label for the y-axis.

**xscale**: ‘linear’ or ‘log’, optional
Sets the scaling of the x-axis.

**yscale**: ‘linear’ or ‘log’, optional
Sets the scaling of the y-axis.

**axis_center**: (float, float), optional
Tuple of two floats denoting the coordinates of the center or {'center', 'auto'}

**xlim**: (float, float), optional
Denotes the x-axis limits, (min, max).

**ylim**: (float, float), optional
Denotes the y-axis limits, (min, max).

**size**: (float, float), optional
A tuple in the form (width, height) in inches to specify the size of the overall figure. The default value is set to None, meaning the size will be set by the default backend.

**Examples**

```python
code
from sympy import plot_parametric, symbols, cos, sin

u = symbols('u')

Plot object containing:
[0]: parametric cartesian line: (cos(u), sin(u)) for u over (-5.0, 5.0)

Plot object containing:
[0]: parametric cartesian line: (cos(u), sin(u)) for u over (-10.0, 10.0)
[1]: parametric cartesian line: (u, cos(u)) for u over (-10.0, 10.0)

Plot object containing:
[0]: parametric cartesian line: (cos(u), sin(u)) for u over (-5.0, 5.0)
[1]: parametric cartesian line: (cos(u), u) for u over (-5.0, 5.0)
```
Notes

The plotting uses an adaptive algorithm which samples recursively to accurately plot the curve. The adaptive algorithm uses a random point near the midpoint of two points that has to be further sampled. Hence, repeating the same plot command can give slightly different results because of the random sampling.

If there are multiple plots, then the same optional arguments are applied to all the plots drawn in the same canvas. If you want to set these options separately, you can index the returned `Plot` object and set it.

For example, when you specify `line_color` once, it would be applied simultaneously to both series.

```python
>>> from sympy import pi
>>> expr1 = (u, cos(2*pi*u)/2 + 1/2)
>>> expr2 = (u, sin(2*pi*u)/2 + 1/2)
>>> p = plot_parametric(expr1, expr2, (u, 0, 1), line_color='blue')
```

If you want to specify the line color for the specific series, you should index each item and apply the property manually.

```python
>>> p[0].line_color = 'red'
>>> p.show()
```
See also:

*Plot* (page 2905), *Parametric2DLineSeries* (page 2950)

```
sympy.plotting.plot.plot3d(*args, show=True, **kwargs)
```

Plots a 3D surface plot.

**Usage**

Single plot

```
plot3d(expr, range_x, range_y, **kwargs)
```

If the ranges are not specified, then a default range of (-10, 10) is used.

Multiple plot with the same range.

```
plot3d(expr1, expr2, range_x, range_y, **kwargs)
```

If the ranges are not specified, then a default range of (-10, 10) is used.

Multiple plots with different ranges.

```
plot3d((expr1, range_x, range_y), (expr2, range_x, range_y), ..., **kwargs)
```

Ranges have to be specified for every expression.

Default range may change in the future if a more advanced default range detection algorithm is implemented.

**Arguments**

`expr` : Expression representing the function along `x`.

`range_x` : A 3-tuple denoting the range of the `x` variable, e.g. `(x, 0, 5)`.  

`range_y` : A 3-tuple denoting the range of the `y` variable, e.g. `(y, 0, 5)`.

**Keyword Arguments**

Arguments for `SurfaceOver2DRangeSeries` class:

`nb_of_points_x` : [int] The `x` range is sampled uniformly at `nb_of_points_x` of points.

`nb_of_points_y` : [int] The `y` range is sampled uniformly at `nb_of_points_y` of points.

Aesthetics:

`surface_color` : [Function which returns a float] Specifies the color for the surface of the plot. See *Plot* (page 2905) for more details.
If there are multiple plots, then the same series arguments are applied to all the plots. If you want to set these options separately, you can index the returned `Plot` object and set it.

Arguments for `Plot` class:

- **title**
  
  [str] Title of the plot.

- **size**
  
  [(float, float), optional] A tuple in the form (width, height) in inches to specify the size of the overall figure. The default value is set to `None`, meaning the size will be set by the default backend.

**Examples**

```python
>>> from sympy import symbols
>>> from sympy.plotting import plot3d
>>> x, y = symbols('x y')
```

Single plot

```python
>>> plot3d(x*y, (x, -5, 5), (y, -5, 5))
```

Plot object containing:

- `[0]`: cartesian surface: \(x*y\) for \(x\) over \((-5.0, 5.0)\) and \(y\) over \((-5.0, 5.0)\)

Multiple plots with same range

```python
>>> plot3d(x*y, -x*y, (x, -5, 5), (y, -5, 5))
```

Plot object containing:

- `[0]`: cartesian surface: \(x*y\) for \(x\) over \((-5.0, 5.0)\) and \(y\) over \((-5.0, 5.0)\)
- `[1]`: cartesian surface: \(-x*y\) for \(x\) over \((-5.0, 5.0)\) and \(y\) over \((-5.0, 5.0)\)

Multiple plots with different ranges.

```python
>>> plot3d((x**2 + y**2, (x, -5, 5), (y, -5, 5)),
... (x*y, (x, -3, 3), (y, -3, 3)))
```

Plot object containing:

- `[0]`: cartesian surface: \(x^2 + y^2\) for \(x\) over \((-5.0, 5.0)\) and \(y\) over \((-5.0, 5.0)\)
- `[1]`: cartesian surface: \(x*y\) for \(x\) over \((-3.0, 3.0)\) and \(y\) over \((-3.0, 3.0)\)

See also:

- `Plot` (page 2905), `SurfaceOver2DRangeSeries` (page 2951)
- `sympy.plotting.plot.plot3d_parametric_line(*args, show=True, **kwargs)`
  
  Plots a 3D parametric line plot.
$f(x, y)$
Usage

Single plot:

```python
plot3d_parametric_line(expr_x, expr_y, expr_z, range, **kwargs)
```

If the range is not specified, then a default range of (-10, 10) is used.

Multiple plots.

```python
plot3d_parametric_line((expr_x, expr_y, expr_z, range), ..., **kwargs)
```

Ranges have to be specified for every expression.

Default range may change in the future if a more advanced default range detection algorithm is implemented.

Arguments

- `expr_x`: Expression representing the function along `x`.
- `expr_y`: Expression representing the function along `y`.
- `expr_z`: Expression representing the function along `z`.
- `range`: A 3-tuple denoting the range of the parameter variable, e.g., `(u, 0, 5)`.

Keyword Arguments

Arguments for `Parametric3DLineSeries` class.

- `nb_of_points`: The range is uniformly sampled at `nb_of_points` number of points.

Aesthetics:

- `line_color`: Specifies the color for the plot. See Plot to see how to set color for the plots. Note that by setting `line_color`, it would be applied simultaneously to all the series.

- `label`: The label to the plot. It will be used when called with `legend=True` to denote the function with the given label in the plot.

If there are multiple plots, then the same series arguments are applied to all the plots. If you want to set these options separately, you can index the returned `Plot` object and set it.

Arguments for `Plot` class.

- `title`: Title of the plot.
- `size`: A tuple in the form `(width, height)` in inches to specify the size of the overall figure. The default value is set to `None`, meaning the size will be set by the default backend.
Examples

```python
>>> from sympy import symbols, cos, sin
>>> from sympy.plotting import plot3d_parametric_line
>>> u = symbols('u')

Single plot.

```python
>>> plot3d_parametric_line(cos(u), sin(u), u, (u, -5, 5))
```
Plot object containing:
[0]: 3D parametric cartesian line: (cos(u), sin(u), u) for u over (-5.0, →5.0)

Multiple plots.

```python
>>> plot3d_parametric_line((cos(u), sin(u), u, (u, -5, 5)), ...
  ...  (sin(u), u**2, u, (u, -5, 5)))
```
Plot object containing:
[0]: 3D parametric cartesian line: (cos(u), sin(u), u) for u over (-5.0, →5.0)
[1]: 3D parametric cartesian line: (sin(u), u**2, u) for u over (-5.0, 5. →0)
See also:

*Plot (page 2905), Parametric3DLineSeries (page 2951)*

sympy.plotting.plot.plot3d_parametric_surface(*args, show=True, **kwargs)

Plots a 3D parametric surface plot.

**Explanation**

Single plot.

```
plot3d_parametric_surface(expr_x, expr_y, expr_z, range_u, range_v, **kwargs)
```

If the ranges is not specified, then a default range of (-10, 10) is used.

Multiple plots.

```
plot3d_parametric_surface((expr_x, expr_y, expr_z, range_u, range_v), ..., **kwargs)
```

Ranges have to be specified for every expression.

Default range may change in the future if a more advanced default range detection algorithm is implemented.

**Arguments**

`expr_x` : Expression representing the function along $x$.
`expr_y` : Expression representing the function along $y$.
`expr_z` : Expression representing the function along $z$.

`range_u`  

```
[(Symbol (page 1028), float, float)] A 3-tuple denoting the range of the u variable, e.g. (u, 0, 5).
```

`range_v`  

```
[(Symbol (page 1028), float, float)] A 3-tuple denoting the range of the v variable, e.g. (v, 0, 5).
```

**Keyword Arguments**

Arguments for ParametricSurfaceSeries class:

`nb_of_points_u`  

```
[int] The u range is sampled uniformly at nb_of_points_v of points
```

`nb_of_points_v`  

```
[int] The v range is sampled uniformly at nb_of_points_y of points
```

Aesthetics:

`surface_color`  

```
[Function which returns a float] Specifies the color for the surface of the plot. See Plot (page 2905) for more details.
```
If there are multiple plots, then the same series arguments are applied for all the plots. If you want to set these options separately, you can index the returned Plot object and set it.

Arguments for Plot class:

- **title**: [str] Title of the plot.
- **size**: [(float, float), optional] A tuple in the form (width, height) in inches to specify the size of the overall figure. The default value is set to None, meaning the size will be set by the default backend.

**Examples**

```python
>>> from sympy import symbols, cos, sin
>>> from sympy.plotting import plot3d_parametric_surface
>>> u, v = symbols('u v')
```

Single plot.

```python
>>> plot3d_parametric_surface(cos(u + v), sin(u - v), u - v,
...                           (u, -5, 5), (v, -5, 5))
```

Plot object containing:

- [0]: parametric cartesian surface: (cos(u + v), sin(u - v), u - v) for u over (-5.0, 5.0) and v over (-5.0, 5.0)

**See also:**

- `Plot` (page 2905), `ParametricSurfaceSeries` (page 2951)
- `sympy.plotting.plot_implicit.plot_implicit`:
  ```python
  expr, x_var=None, y_var=None, adaptive=True, depth=0, points=300, line_color='blue', show=True, **kwargs
  ```

A plot function to plot implicit equations / inequalities.

**Arguments**

- **expr**: The equation / inequality that is to be plotted.
- **x_var** (optional): symbol to plot on x-axis or tuple giving symbol and range as (symbol, xmin, xmax)
- **y_var** (optional): symbol to plot on y-axis or tuple giving symbol and range as (symbol, ymin, ymax)

If neither x_var nor y_var are given then the free symbols in the expression will be assigned in the order they are sorted.

The following keyword arguments can also be used:

- **adaptive**: Boolean. The default value is set to True. It has to be set to False if you want to use a mesh grid.
- **depth**: integer. The depth of recursion for adaptive mesh grid.
  Default value is 0. Takes value in the range (0, 4).
• **points** integer. The number of points if adaptive mesh grid is not used. Default value is 300.

• **show** Boolean. Default value is True. If set to False, the plot will not be shown. See Plot for further information.

• **title** string. The title for the plot.

• **xlabel** string. The label for the x-axis

• **ylabel** string. The label for the y-axis

Aesthetics options:

• **line_color**: float or string. Specifies the color for the plot. See Plot to see how to set color for the plots. Default value is “Blue”

plot_implicit, by default, uses interval arithmetic to plot functions. If the expression cannot be plotted using interval arithmetic, it defaults to a generating a contour using a mesh grid of fixed number of points. By setting adaptive to False, you can force plot_implicit to use the mesh grid. The mesh grid method can be effective when adaptive plotting using interval arithmetic, fails to plot with small line width.

### Examples

Plot expressions:

```python
>>> from sympy import plot_implicit, symbols, Eq, And
>>> x, y = symbols('x y')
```

Without any ranges for the symbols in the expression:

```python
>>> p1 = plot_implicit(Eq(x**2 + y**2, 5))
```

With the range for the symbols:

```python
>>> p2 = plot_implicit(Eq(x**2 + y**2, 3), (x, -3, 3), (y, -3, 3))
```

With depth of recursion as argument:

```python
>>> p3 = plot_implicit(Eq(x**2 + y**2, 5), (x, -4, 4), (y, -4, 4), depth=2)
```

Using mesh grid and not using adaptive meshing:

```python
>>> p4 = plot_implicit(Eq(x**2 + y**2, 5), (x, -5, 5), (y, -2, 2), adaptive=False)
```

Using mesh grid without using adaptive meshing with number of points specified:

```python
>>> p5 = plot_implicit(Eq(x**2 + y**2, 5), (x, -5, 5), (y, -2, 2), adaptive=False, points=400)
```

Plotting regions:
5.8. Topics
Plotting Using boolean conjuctions:

```python
>>> p7 = plot_implicit(And(y > x, y > -x))
```

When plotting an expression with a single variable (y - 1, for example), specify the x or the y variable explicitly:

```python
>>> p8 = plot_implicit(y - 1, y_var=y)
>>> p9 = plot_implicit(x - 1, x_var=x)
```

**PlotGrid Class**

```python
class sympy.plotting.plot.PlotGrid(nrows, ncolumns, *args, show=True, size=None, **kwargs)
```

This class helps to plot subplots from already created SymPy plots in a single figure.
Examples

```python
>>> from sympy import symbols
>>> from sympy.plotting import plot, plot3d, PlotGrid
>>> x, y = symbols('x, y')
>>> p1 = plot(x, x**2, x**3, (x, -5, 5))
>>> p2 = plot((x**2, (x, -6, 6)), (x, (x, -5, 5)))
>>> p3 = plot(x**3, (x, -5, 5))
>>> p4 = plot3d(x*y, (x, -5, 5), (y, -5, 5))

Plotting vertically in a single line:

```python
>>> PlotGrid(2, 1, p1, p2)
PlotGrid object containing:
Plot[0]: Plot object containing:
    [0]: cartesian line: x for x over (-5.0, 5.0)
    [1]: cartesian line: x**2 for x over (-5.0, 5.0)
    [2]: cartesian line: x**3 for x over (-5.0, 5.0)
Plot[1]: Plot object containing:
    [0]: cartesian line: x**2 for x over (-6.0, 6.0)
    [1]: cartesian line: x for x over (-5.0, 5.0)
```

Plotting horizontally in a single line:
5.8. Topics
>>> PlotGrid(1, 3, p2, p3, p4)
PlotGrid object containing:
Plot[0]: Plot object containing:
 [0]: cartesian line: x**2 for x over (-6.0, 6.0)
 [1]: cartesian line: x for x over (-5.0, 5.0)
Plot[1]: Plot object containing:
 [0]: cartesian line: x**3 for x over (-5.0, 5.0)
Plot[2]: Plot object containing:
 [0]: cartesian surface: x*y for x over (-5.0, 5.0) and y over (-5.0, 5.0)

Plotting in a grid form:

>>> PlotGrid(2, 2, p1, p2, p3, p4)
PlotGrid object containing:
Plot[0]: Plot object containing:
 [0]: cartesian line: x for x over (-5.0, 5.0)
 [1]: cartesian line: x**2 for x over (-5.0, 5.0)
 [2]: cartesian line: x**3 for x over (-5.0, 5.0)
Plot[1]: Plot object containing:
 [0]: cartesian line: x**2 for x over (-6.0, 6.0)
 [1]: cartesian line: x for x over (-5.0, 5.0)
Plot[2]: Plot object containing:
 [0]: cartesian line: x**3 for x over (-5.0, 5.0)
Plot[3]: Plot object containing:
[0]: cartesian surface: x*y for x over (-5.0, 5.0) and y over (-5.0, 5.0)

---

Series Classes

class sympy.plotting.plot.BaseSeries

Base class for the data objects containing stuff to be plotted.

Explanation

The backend should check if it supports the data series that is given. (e.g. TextBackend supports only LineOver1DRangeSeries). It is the backend responsibility to know how to use the class of data series that is given.

Some data series classes are grouped (using a class attribute like is_2Dline) according to the api they present (based only on convention). The backend is not obliged to use that api (e.g. LineOver1DRangeSeries belongs to the is_2Dline group and presents the get_points method, but the TextBackend does not use the get_points method).
class sympy.plotting.plot.Line2DBaseSeries
A base class for 2D lines.
  • adding the label, steps and only_integers options
  • making is_2Dline true
  • defining get_segments and get_color_array

get_data()
  Return lists of coordinates for plotting the line.

  Returns
  x : list
      List of x-coordinates

  y
      [list] List of y-coordinates

  z
      [list] List of z-coordinates in case of Parametric3DLineSeries

class sympy.plotting.plot.LineOver1DRangeSeries(expr, var_start_end, **kwargs)
Representation for a line consisting of a SymPy expression over a range.

get_points()
  Return lists of coordinates for plotting. Depending on the adaptive option, this function will either use an adaptive algorithm or it will uniformly sample the expression over the provided range.

  Returns
  x : list
      List of x-coordinates

  y
      [list] List of y-coordinates

Explanation
The adaptive sampling is done by recursively checking if three points are almost collinear. If they are not collinear, then more points are added between those points.

References
[R711]
class sympy.plotting.plot.Parametric2DLineSeries(expr_x, expr_y, var_start_end, **kwargs)
Representation for a line consisting of two parametric SymPy expressions over a range.
get_points()

Return lists of coordinates for plotting. Depending on the adaptive option, this function will either use an adaptive algorithm or it will uniformly sample the expression over the provided range.

**Returns**

- **x**: list
  - List of x-coordinates

- **y**: list
  - List of y-coordinates

**Explanation**

The adaptive sampling is done by recursively checking if three points are almost collinear. If they are not collinear, then more points are added between those points.

**References**

[R712]

class sympy.plotting.plot.Line3DBaseSeries

A base class for 3D lines.

Most of the stuff is derived from Line2DBaseSeries.

class sympy.plotting.plot_Parametric3DLineSeries(expr_x, expr_y, expr_z, var_start_end, **kwargs)

Representation for a 3D line consisting of three parametric SymPy expressions and a range.

class sympy.plotting.plot_SurfaceBaseSeries

A base class for 3D surfaces.

class sympy.plotting.plot_SurfaceOver2DRangeSeries(expr, var_start_end_x, var_start_end_y, **kwargs)

Representation for a 3D surface consisting of a SymPy expression and 2D range.

class sympy.plotting.plot_ParametricSurfaceSeries(expr_x, expr_y, expr_z, var_start_end_u, var_start_end_v, **kwargs)

Representation for a 3D surface consisting of three parametric SymPy expressions and a range.

class sympy.plotting.plot_implicit.ImplicitSeries(expr, var_start_end_x, var_start_end_y, has_equality, use_interval_math, depth, nb_of_points, line_color)

Representation for Implicit plot
Backends

class symy.plotting.plot.BaseBackend(parent)

Base class for all backends. A backend represents the plotting library, which implements the necessary functionalities in order to use SymPy plotting functions.

How the plotting module works:

1. Whenever a plotting function is called, the provided expressions are processed and a list of instances of the BaseSeries (page 2949) class is created, containing the necessary information to plot the expressions (e.g. the expression, ranges, series name, ...). Eventually, these objects will generate the numerical data to be plotted.

2. A Plot (page 2905) object is instantiated, which stores the list of series and the main attributes of the plot (e.g. axis labels, title, ...).

3. When the show command is executed, a new backend is instantiated, which loops through each series object to generate and plot the numerical data. The backend is also going to set the axis labels, title, ..., according to the values stored in the Plot instance.

The backend should check if it supports the data series that it is given (e.g. TextBackend (page 2953) supports only LineOver1DRangeSeries (page 2950)).

It is the backend responsibility to know how to use the class of data series that it’s given. Note that the current implementation of the *Series classes is “matplotlib-centric”: the numerical data returned by the get_points and get_meshes methods is meant to be used directly by Matplotlib. Therefore, the new backend will have to pre-process the numerical data to make it compatible with the chosen plotting library. Keep in mind that future SymPy versions may improve the *Series classes in order to return numerical data “non-matplotlib-centric”, hence if you code a new backend you have the responsibility to check if its working on each SymPy release.

Please explore the MatplotlibBackend (page 2952) source code to understand how a backend should be coded.

See also:

MatplotlibBackend (page 2952)

class symy.plotting.plot.MatplotlibBackend(parent)

This class implements the functionalities to use Matplotlib with SymPy plotting functions.

static get_segments(x, y, z=None)

Convert two list of coordinates to a list of segments to be used with Matplotlib’s LineCollection.

Parameters

- x : list
  
  List of x-coordinates

- y
  
  [list] List of y-coordinates

- z
  
  [list] List of z-coordinates for a 3D line.
process_series()
Iterates over every Plot object and further calls_process_series()

class sympy.plotting.plot.TextBackend(parent)

Pyglet Plotting

This is the documentation for the old plotting module that uses pyglet. This module has some limitations and is not actively developed anymore. For an alternative you can look at the new plotting module.

The pyglet plotting module can do nice 2D and 3D plots that can be controlled by console commands as well as keyboard and mouse, with the only dependency being pyglet.

Here is the simplest usage:

```python
>>> from sympy import var
>>> from sympy.plotting.pygletplot import PygletPlot as Plot
>>> var('x y z')
>>> Plot(x*y**3-y*x**3)
```

To see lots of plotting examples, see examples/pyglet_plotting.py and try running it in interactive mode (python -i plotting.py):

```
$ python -i examples/pyglet_plotting.py
```

And type for instance example(7) or example(11).

See also the Plotting Module wiki page for screenshots.

The mouse can be used to rotate, zoom, and translate by dragging the left, middle, and right mouse buttons respectively.

**Coordinate Modes**

Plot supports several curvilinear coordinate modes, and they are independent for each plotted function. You can specify a coordinate mode explicitly with the ‘mode’ named argument, but it can be automatically determined for cartesian or parametric plots, and therefore must only be specified for polar, cylindrical, and spherical modes.

Specifically, `Plot(function arguments)` and `Plot._setitem_(i, function arguments)` (accessed using array-index syntax on the `Plot` instance) will interpret your arguments as a cartesian plot if you provide one function and a parametric plot if you provide two or three functions. Similarly, the arguments will be interpreted as a curve is one variable is used, and a surface if two are used.

Supported mode names by number of variables:

- 1 (curves): parametric, cartesian, polar
- 2 (surfaces): parametric, cartesian, cylindrical, spherical

```python
>>> Plot(1, 'mode=spherical; color=zsfade4')
```

Note that function parameters are given as option strings of the form "key1=value1; key2 = value2" (spaces are truncated). Keyword arguments given directly to `plot` apply to the `plot` itself.

**Specifying Intervals for Variables**

The basic format for variable intervals is [var, min, max, steps]. However, the syntax is quite flexible, and arguments not specified are taken from the defaults for the current coordinate mode:

```python
>>> Plot(x**2) # implies [x,-5,5,100]
>>> Plot(x**2, [], []) # [x,-1,1,40], [y,-1,1,40]
>>> Plot(x**2-y**2, [100], [100]) # [x,-1,1,100], [y,-1,1,100]
>>> Plot(x**2, [x,-13,13,100])
>>> Plot(x**2, [-13,13]) # [x,-13,13,100]
>>> Plot(x**2, [x,-13,13]) # [x,-13,13,100]
>>> Plot(1*x, [], [x], 'mode=cylindrical') # [unbound_theta,0,2*Pi,40], [x,-1, -1,20]
```
Using the Interactive Interface

```python
>>> p = Plot(visible=False)
>>> f = x**2
>>> p[1] = f
>>> p[2] = f.diff(x)
>>> p[3] = f.diff(x).diff(x)
``` 

When not specified explicitly, the default color gradient is $f(0.0) = (0.4, 0.4, 0.4) \to f(1.0) = (0.9, 0.9, 0.9)$. In our case, everything is gray-scale because we have applied the default color gradient uniformly for each color component. When defining a color scheme in this way, you might want to supply a color gradient as well:

```python
>>> p[1].color = (Fx**2 + Fy**2 + Fz**2)**(0.5), (0.1,0.1,0.9), (0.9,0.1,0.1)
``` 

5.8. Topics
The other way to specify a color scheme is to give a separate function for each component r, g, b. With this syntax, the default color scheme is defined:

```python
>>> p[1].color = z, y, x, (0.4, 0.4, 0.4), (0.9, 0.9, 0.9)
```

This maps z->red, y->green, and x->blue. In some cases, you might prefer to use the following alternative syntax:

```python
>>> p[1].color = z, (0.4, 0.9), y, (0.4, 0.9), x, (0.4, 0.9)
```

You can still use multi-step gradients with three-function color schemes.

**Plotting Geometric Entities**

The plotting module is capable of plotting some 2D geometric entities like line, circle and ellipse. The following example plots a circle centred at origin and of radius 2 units.

```python
>>> from sympy import *
>>> x, y = symbols('x y')
>>> plot_implicit(Eq(x**2 + y**2, 4))
```

Similarly, `plot_implicit()` (page 2931) may be used to plot any 2-D geometric structure from its implicit equation.

Plotting polygons (Polygon, RegularPolygon, Triangle) are not supported directly.

**Plotting with ASCII art**

`sympy.plotting.textplot.textplot(expr, a, b, W=55, H=21)`

Print a crude ASCII art plot of the SymPy expression `expr` (which should contain a single symbol, e.g. x or something else) over the interval [a, b].

**Examples**

```python
>>> from sympy import Symbol, sin
>>> from sympy.plotting import textplot
>>> t = Symbol('t')
>>> textplot(sin(t)*t, 0, 15)
```

(continues on next page)
Stats

SymPy statistics module

Introduces a random variable type into the SymPy language.

Random variables may be declared using prebuilt functions such as Normal, Exponential, Coin, Die, etc... or built with functions like FiniteRV.

Queries on random expressions can be made using the functions

<table>
<thead>
<tr>
<th>Expression</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>P(condition)</td>
<td>Probability</td>
</tr>
<tr>
<td>E(expression)</td>
<td>Expected value</td>
</tr>
<tr>
<td>H(expression)</td>
<td>Entropy</td>
</tr>
<tr>
<td>variance(expression)</td>
<td>Variance</td>
</tr>
<tr>
<td>density(expression)</td>
<td>Probability Density Function</td>
</tr>
<tr>
<td>sample(expression)</td>
<td>Produce a realization</td>
</tr>
<tr>
<td>where(condition)</td>
<td>Where the condition is true</td>
</tr>
</tbody>
</table>

Examples

```python
>>> from sympy.stats import P, E, variance, Die, Normal
>>> from sympy import simplify
>>> X, Y = Die('X', 6), Die('Y', 6)  # Define two six sided dice
>>> Z = Normal('Z', 0, 1)  # Declare a Normal random variable with mean 0, std 1

>>> P(X>3)  # Probability X is greater than 3
1/2

>>> E(X+Y)  # Expectation of the sum of two dice
7

>>> variance(X+Y)  # Variance of the sum of two dice
35/6

>>> simplify(P(Z>1))  # Probability of Z being greater than 1
1/2 - erf(sqrt(2)/2)/2
```

One could also create custom distribution and define custom random variables as follows:

1. If you want to create a Continuous Random Variable:
```python
from sympy.stats import ContinuousRV, P, E
from sympy import exp, Symbol, Interval, oo

x = Symbol('x')
pdf = exp(-x)  # pdf of the Continuous Distribution
Z = ContinuousRV(x, pdf, set=Interval(0, oo))
E(Z)
1
P(Z > 5)
ex(-5)
```

1.1 To create an instance of Continuous Distribution:

```python
from sympy.stats import ContinuousDistributionHandmade
from sympy import Lambda

dist = ContinuousDistributionHandmade(Lambda(x, pdf), set=Interval(0, oo))
dist.pdf(x)
ex(-x)
```

2. If you want to create a Discrete Random Variable:

```python
from sympy.stats import DiscreteRV, P, E
from sympy import Symbol, S

p = S(1)/2
x = Symbol('x', integer=True, positive=True)
pdf = p*(1 - p)**(x - 1)
D = DiscreteRV(x, pdf, set=S.Naturals)
E(D)
2
P(D > 3)
1/8
```

2.1 To create an instance of Discrete Distribution:

```python
from sympy.stats import DiscreteDistributionHandmade
from sympy import Lambda

dist = DiscreteDistributionHandmade(Lambda(x, pdf), set=S.Naturals)
dist.pdf(x)
2**(1 - x)/2
```

3. If you want to create a Finite Random Variable:

```python
from sympy.stats import FiniteRV, P, E
from sympy import Rational, Eq

pmf = {1: Rational(1, 3), 2: Rational(1, 6), 3: Rational(1, 4), 4: Rational(1, 4)}
X = FiniteRV('X', pmf)
E(X)
29/12
P(X > 3)
1/4
```

3.1 To create an instance of Finite Distribution:
Random Variable Types

Finite Types

sympy.stats.DiscreteUniform(name, items)
Create a Finite Random Variable representing a uniform distribution over the input set.

Parameters
items : list/tuple
Items over which Uniform distribution is to be made

Returns
RandomSymbol

Examples

```python
>>> from sympy.stats import DiscreteUniform, density
>>> from sympy import symbols

>>> X = DiscreteUniform('X', symbols('a b c'))  # equally likely over a, b, c
>>> density(X).dict
{a: 1/3, b: 1/3, c: 1/3}

>>> Y = DiscreteUniform('Y', list(range(5)))  # distribution over a range
>>> density(Y).dict
{0: 1/5, 1: 1/5, 2: 1/5, 3: 1/5, 4: 1/5}
```

References

[R828], [R829]

sympy.stats.Die(name, sides=6)
Create a Finite Random Variable representing a fair die.

Parameters
sides : Integer
Represents the number of sides of the Die, by default is 6

Returns
RandomSymbol
Examples

```python
>>> from sympy.stats import Die, density
>>> from sympy import Symbol

>>> D6 = Die('D6', 6) # Six sided Die
>>> density(D6).dict
{1: 1/6, 2: 1/6, 3: 1/6, 4: 1/6, 5: 1/6, 6: 1/6}

>>> D4 = Die('D4', 4) # Four sided Die
>>> density(D4).dict
{1: 1/4, 2: 1/4, 3: 1/4, 4: 1/4}

>>> n = Symbol('n', positive=True, integer=True)
>>> Dn = Die('Dn', n) # n sided Die
>>> density(Dn).dict
Density(DieDistribution(n))
>>> density(Dn).dict.subs(n, 4).doit()
{1: 1/4, 2: 1/4, 3: 1/4, 4: 1/4}
```

**sympy.stats.Bernoulli**(name, p, succ=1, fail=0)

Create a Finite Random Variable representing a Bernoulli process.

**Parameters**

- **p**: Rational number between 0 and 1
  - Represents probability of success
- **succ**: Integer/symbol/string
  - Represents event of success
- **fail**: Integer/symbol/string
  - Represents event of failure

**Returns**

RandomSymbol

Examples

```python
>>> from sympy.stats import Bernoulli, density
>>> from sympy import S

>>> X = Bernoulli('X', S(3)/4) # 1-0 Bernoulli variable, probability = 3/4
>>> density(X).dict
{0: 1/4, 1: 3/4}

>>> X = Bernoulli('X', S.Half, 'Heads', 'Tails') # A fair coin toss
>>> density(X).dict
{Heads: 1/2, Tails: 1/2}
```
References

[R830], [R831]
sympy.stats.Coin(name, p=1/2)
Create a Finite Random Variable representing a Coin toss.

Parameters
- **p**: Rational Number between 0 and 1
  Represents probability of getting “Heads”, by default is Half

Returns
RandomSymbol

Examples

```python
>>> from sympy.stats import Coin, density
>>> from sympy import Rational

>>> C = Coin('C') # A fair coin toss
>>> density(C).dict
{H: 1/2, T: 1/2}

>>> C2 = Coin('C2', Rational(3, 5)) # An unfair coin
>>> density(C2).dict
{H: 3/5, T: 2/5}
```

See also:
sympy.stats.Binomial (page 2961)

References

[R832]
sympy.stats.Binomial(name, n, p, succ=1, fail=0)
Create a Finite Random Variable representing a binomial distribution.

Parameters
- **n**: Positive Integer
  Represents number of trials
- **p**: Rational Number between 0 and 1
  Represents probability of success
- **succ**: Integer/symbol/string
  Represents event of success, by default is 1
- **fail**: Integer/symbol/string
  Represents event of failure, by default is 0

Returns
RandomSymbol
Examples

```python
>>> from sympy.stats import Binomial, density
>>> from sympy import S, Symbol

>>> X = Binomial('X', 4, S.Half)  # Four “coin flips”
>>> density(X).dict
{0: 1/16, 1: 1/4, 2: 3/8, 3: 1/4, 4: 1/16}

>>> n = Symbol('n', positive=True, integer=True)
>>> p = Symbol('p', positive=True)
>>> X = Binomial('X', n, S.Half)  # n ”coin flips”
>>> density(X).dict
Density(BinomialDistribution(n, 1/2, 1, 0))
>>> density(X).dict.subs(n, 4).doit()
{0: 1/16, 1: 1/4, 2: 3/8, 3: 1/4, 4: 1/16}
```

References

[R833], [R834]

sympy.stats.BetaBinomial(name, n, alpha, beta)

Create a Finite Random Variable representing a Beta-binomial distribution.

Parameters

- **n**: Positive Integer
  - Represents number of trials
- **alpha**: Real positive number
- **beta**: Real positive number

Returns

RandomSymbol

Examples

```python
>>> from sympy.stats import BetaBinomial, density

>>> X = BetaBinomial('X', 2, 1, 1)
>>> density(X).dict
{0: 1/3, 1: 2*beta(2, 2), 2: 1/3}
```
**References**

[R835], [R836]

sympy.stats.Hypergeometric(name, N, m, n)
Create a Finite Random Variable representing a hypergeometric distribution.

**Parameters**

- **N**: Positive Integer
  Represents finite population of size N.
- **m**: Positive Integer
  Represents number of trials with required feature.
- **n**: Positive Integer
  Represents numbers of draws.

**Returns**

RandomSymbol

**Examples**

```python
>>> from sympy.stats import Hypergeometric, density

>>> X = Hypergeometric('X', 10, 5, 3)  # 10 marbles, 5 white (success), 3 draws
>>> density(X).dict
{0: 1/12, 1: 5/12, 2: 5/12, 3: 1/12}
```

**References**

[R837], [R838]

sympy.stats.FiniteRV(name, density, **kwargs)
Create a Finite Random Variable given a dict representing the density.

**Parameters**

- **name**: Symbol
  Represents name of the random variable.
- **density**: dict
  Dictionary containing the pdf of finite distribution
- **check**: bool
  If True, it will check whether the given density integrates to 1 over the given set. If False, it will not perform this check. Default is False.

**Returns**

RandomSymbol
Examples

```python
>>> from sympy.stats import FiniteRV, P, E

>>> density = {0: .1, 1: .2, 2: .3, 3: .4}
>>> X = FiniteRV('X', density)

>>> E(X)
2.00000000000000
>>> P(X >= 2)
0.700000000000000
```

sympy.stats.Rademacher(name)

Create a Finite Random Variable representing a Rademacher distribution.

Returns
RandomSymbol

Examples

```python
>>> from sympy.stats import Rademacher, density

>>> X = Rademacher('X')
>>> density(X).dict
{-1: 1/2, 1: 1/2}
```

See also:

sympy.stats.Bernoulli (page 2960)

References

[R839]

Discrete Types

sympy.stats.Geometric(name, p)

Create a discrete random variable with a Geometric distribution.

Parameters
   p : A probability between 0 and 1

Returns
RandomSymbol
Explanation

The density of the Geometric distribution is given by

\[ f(k) := p(1 - p)^{k-1} \]

Examples

```python
>>> from sympy.stats import Geometric, density, E, variance
>>> from sympy import Symbol, S

>>> p = S.One / 5
>>> z = Symbol("z")

>>> X = Geometric("x", p)

>>> density(X)(z)
(5/4)**(1 - z)/5

>>> E(X)
5

>>> variance(X)
20
```

References

[R840], [R841]

`sympy.stats.Hermite(name, a1, a2)`

Create a discrete random variable with a Hermite distribution.

**Parameters**

- `a1` : A Positive number greater than equal to 0.
- `a2` : A Positive number greater than equal to 0.

**Returns**

RandomSymbol

Explanation

The density of the Hermite distribution is given by

\[ f(x) := e^{-a_1-a_2} \sum_{j=0}^{[x/2]} \frac{a_{1}^{x-2j}a_{2}^{j}}{(x-2j)!j!} \]
Examples

```python
>>> from sympy.stats import Hermite, density, E, variance
>>> from sympy import Symbol

>>> a1 = Symbol("a1", positive=True)
>>> a2 = Symbol("a2", positive=True)
>>> x = Symbol("x")

>>> H = Hermite("H", a1=5, a2=4)

>>> density(H)(2)
33*exp(-9)/2

>>> E(H)
13

>>> variance(H)
21
```

References

[R842] sympy.stats.Poisson(name, lamda)

Create a discrete random variable with a Poisson distribution.

Parameters

- lamda : Positive number, a rate

Returns

RandomSymbol

Explanation

The density of the Poisson distribution is given by

\[ f(k) := \frac{\lambda^k e^{-\lambda}}{k!} \]

Examples

```python
>>> from sympy.stats import Poisson, density, E, variance
>>> from sympy import Symbol, simplify

>>> rate = Symbol("lambda", positive=True)
>>> z = Symbol("z")
```
SymPy Documentation, Release 1.12.1

```python
>>> X = Poisson("x", rate)

>>> density(X)(z)
lambda**z*exp(-lambda)/factorial(z)

>>> E(X)
lambda

>>> simplify(variance(X))
lambda
```

References

[R843], [R844]

sympy.stats.Logarithmic(name, p)
Create a discrete random variable with a Logarithmic distribution.

**Parameters**
- p : A value between 0 and 1

**Returns**
- RandomSymbol

**Explanation**

The density of the Logarithmic distribution is given by

\[ f(k) := \frac{-p^k}{k \ln(1 - p)} \]

**Examples**

```python
>>> from sympy.stats import Logarithmic, density, E, variance
>>> from sympy import Symbol, S

>>> p = S.One / 5
>>> z = Symbol("z")

>>> X = Logarithmic("x", p)

>>> density(X)(z)
-1/(5**z*z*log(4/5))

>>> E(X)
-1/(-4*log(5) + 8*log(2))
```
sympy.stats.NegativeBinomial(name, r, p)
Create a discrete random variable with a Negative Binomial distribution.

Parameters
- **r**: A positive value
- **p**: A value between 0 and 1

Returns
RandomSymbol

Explanation
The density of the Negative Binomial distribution is given by

\[ f(k) := \binom{k + r - 1}{k} (1 - p)^r p^k \]

Examples

```python
>>> from sympy.stats import NegativeBinomial, density, E, variance
>>> from sympy import Symbol, S

>>> r = 5
>>> p = S.One / 5
>>> z = Symbol("z")

>>> X = NegativeBinomial("x", r, p)

>>> density(X)(z)
1024*binomial(z + 4, z)/(3125*5**z)

>>> E(X)
5/4

>>> variance(X)
25/16
```
References

[R847], [R848]
sympy.stats.Skellam(name, mu1, mu2)
Create a discrete random variable with a Skellam distribution.

Parameters

- mu1 : A non-negative value
- mu2 : A non-negative value

Returns

RandomSymbol

Explanation

The Skellam is the distribution of the difference $N_1 - N_2$ of two statistically independent random variables $N_1$ and $N_2$ each Poisson-distributed with respective expected values $\mu_1$ and $\mu_2$.

The density of the Skellam distribution is given by

$$f(k) := e^{-\frac{\mu_1 + \mu_2}{\mu_2}} \frac{(\frac{\mu_1}{\mu_2})^{k/2}}{I_k(2\sqrt{\mu_1 \mu_2})}$$

Examples

```python
>>> from sympy.stats import Skellam, density, E, variance
>>> from sympy import Symbol, pprint

>>> z = Symbol("z", integer=True)
>>> mu1 = Symbol("mu1", positive=True)
>>> mu2 = Symbol("mu2", positive=True)
>>> X = Skellam("x", mu1, mu2)

>>> pprint(density(X)(z), use_unicode=False)
    z - 2
   / \ -mu1 - mu2 /---\ *e *besseli[z, 2*\ mu1 */ mu2 / \
  \mu2/
>>> E(X)
mu1 - mu2
>>> variance(X).expand()
mu1 + mu2
```
sympy.stats.YuleSimon(name, rho)
Create a discrete random variable with a Yule-Simon distribution.

Parameters
rho : A positive value

Returns
RandomSymbol

Explanation
The density of the Yule-Simon distribution is given by

\[ f(k) := \rho B(k, \rho + 1) \]

Examples

```python
>>> from sympy.stats import YuleSimon, density, E, variance
>>> from sympy import Symbol, simplify

>>> p = 5
>>> z = Symbol("z")

>>> X = YuleSimon("x", p)

>>> density(X)(z)
5*beta(z, 6)

>>> simplify(E(X))
5/4

>>> simplify(variance(X))
25/48
```

References

[R849] sympy.stats.Zeta(name, s)
Create a discrete random variable with a Zeta distribution.

Parameters
s : A value greater than 1

Returns
RandomSymbol
**Explanation**

The density of the Zeta distribution is given by

\[ f(k) := \frac{1}{k^s \zeta(s)} \]

**Examples**

```python
>>> from sympy.stats import Zeta, density, E, variance
>>> from sympy import Symbol

>>> s = 5
>>> z = Symbol("z")

>>> X = Zeta("x", s)

>>> density(X)(z)
1/(z**5*zeta(5))

>>> E(X)
pi**4/(90*zeta(5))

>>> variance(X)
-pi**8/(8100*zeta(5)**2) + zeta(3)/zeta(5)
```

**References**

[R851]

**Continuous Types**

`sympy.stats.Arcsin(name, a=0, b=1)`

Create a Continuous Random Variable with an arcsin distribution.

The density of the arcsin distribution is given by

\[ f(x) := \frac{1}{\pi \sqrt{(x-a)(b-x)}} \]

with \( x \in (a, b) \). It must hold that \(-\infty < a < b < \infty\).

**Parameters**

- **a**: Real number, the left interval boundary
- **b**: Real number, the right interval boundary

**Returns**

RandomSymbol
Examples

```python
>>> from sympy.stats import Arcsin, density, cdf
>>> from sympy import Symbol

>>> a = Symbol("a", real=True)
>>> b = Symbol("b", real=True)
>>> z = Symbol("z")

>>> X = Arcsin("x", a, b)

>>> density(X)(z)
1/(pi*sqrt((-a + z)*(b - z)))

>>> cdf(X)(z)
Piecewise((0, a > z),
(2*asin(sqrt((-a + z)/(-a + b)))/pi, b >= z),
(1, True))
```

References

[R852] sympy.stats.Benini(name, alpha, beta, sigma)
Create a Continuous Random Variable with a Benini distribution.

The density of the Benini distribution is given by

\[ f(x) := e^{-\alpha \log x - \beta \log^2 x} \left( \frac{\alpha}{x} + \frac{2\beta \log x}{x^2} \right) \]

This is a heavy-tailed distribution and is also known as the log-Rayleigh distribution.

Parameters
- **alpha**: Real number, \( \alpha > 0 \), a shape
- **beta**: Real number, \( \beta > 0 \), a shape
- **sigma**: Real number, \( \sigma > 0 \), a scale

Returns
RandomSymbol

Examples

```python
>>> from sympy.stats import Benini, density, cdf
>>> from sympy import Symbol, pprint

>>> alpha = Symbol("alpha", positive=True)
>>> beta = Symbol("beta", positive=True)
>>> sigma = Symbol("sigma", positive=True)
>>> z = Symbol("z")
```
>>> X = Benini("x", alpha, beta, sigma)

```python
>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
```

\[
\frac{\alpha - 1}{\sigma^2} \log\frac{z}{\sigma} - \frac{\beta - 1}{\sigma^2} \log\left(\frac{z}{\sigma}\right)^2 + \left(1 - \exp\left(-\alpha \log\frac{z}{\sigma} - \beta \log\left(\frac{z}{\sigma}\right)^2\right), \sigma \leq \frac{z}{\sigma}, \left(0, \text{True})\right)
```

### References

[R853], [R854]

`sympy.stats.Beta(name, alpha, beta)`

Create a Continuous Random Variable with a Beta distribution.

The density of the Beta distribution is given by

\[
f(x) := \frac{x^{\alpha - 1}(1-x)^{\beta - 1}}{B(\alpha, \beta)}
\]

with \( x \in [0, 1] \).

**Parameters**

- `alpha` : Real number, \( \alpha > 0 \), a shape
- `beta` : Real number, \( \beta > 0 \), a shape

**Returns**

RandomSymbol

### Examples

```python
>>> from sympy.stats import Beta, density, E, variance
>>> from sympy import Symbol, simplify, pprint, factor

>>> alpha = Symbol("alpha", positive=True)
>>> beta = Symbol("beta", positive=True)
>>> z = Symbol("z")

>>> X = Beta("x", alpha, beta)

>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
```

(continues on next page)
z * (1 - z) ---------------------- B(alpha, beta)

>>> simplify(E(X))
alpha/(alpha + beta)

>>> factor(simplify(variance(X)))
alpha*beta/((alpha + beta)**2*(alpha + beta + 1))

References

[R855], [R856]
sympy.stats.BetaNoncentral(name, alpha, beta, lamda)
Create a Continuous Random Variable with a Type I Noncentral Beta distribution.
The density of the Noncentral Beta distribution is given by

\[ f(x) := \sum_{k=0}^{\infty} e^{-\lambda/2} \left(\frac{\lambda}{2}\right)^k \frac{x^{\alpha+k-1}(1-x)^{\beta-1}}{k! B(\alpha + k; \beta)} \]

with \( x \in [0, 1] \).

Parameters
- **alpha**: Real number, \( \alpha > 0 \), a shape
- **beta**: Real number, \( \beta > 0 \), a shape
- **lamda**: Real number, \( \lambda \geq 0 \), noncentrality parameter

Returns
RandomSymbol

Examples

```python
>>> from sympy.stats import BetaNoncentral, density, cdf
>>> from sympy import Symbol, pprint

>>> alpha = Symbol("alpha", positive=True)
>>> beta = Symbol("beta", positive=True)
>>> lamda = Symbol("lamda", nonnegative=True)
>>> z = Symbol("z")

>>> X = BetaNoncentral("x", alpha, beta, lamda)

>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
```

(continues on next page)
Compute cdf with specific ‘x’, ‘alpha’, ‘beta’ and ‘lamda’ values as follows:

```python
>>> cdf(BetaNoncentral("x", 1, 1, 1), evaluate=False)(2).doit()
2*exp(1/2)
```

The argument `evaluate=False` prevents an attempt at evaluation of the sum for general `x`, before the argument 2 is passed.

### References

[R857], [R858]

`sympy.stats.BetaPrime(name, alpha, beta)`

Create a continuous random variable with a Beta prime distribution.

The density of the Beta prime distribution is given by

\[
f(x) = \frac{x^{\alpha-1}(1+x)^{-\alpha-\beta}}{B(\alpha, \beta)}
\]

with \(x > 0\).

**Parameters**

- `alpha`: Real number, \(\alpha > 0\), a shape
- `beta`: Real number, \(\beta > 0\), a shape

**Returns**

RandomSymbol

### Examples

```python
>>> from sympy.stats import BetaPrime, density
>>> from sympy import Symbol, pprint

>>> alpha = Symbol("alpha", positive=True)
>>> beta = Symbol("beta", positive=True)
>>> z = Symbol("z")

>>> X = BetaPrime("x", alpha, beta)
```
D = density(X)(z)
pprint(D, use_unicode=False)

\[
\frac{\alpha - 1}{\zeta (\alpha - \beta) z (z + 1)}
\]

References

[R859], [R860]

sympy.stats.BoundedPareto(name, alpha, left, right)

Create a continuous random variable with a Bounded Pareto distribution.

The density of the Bounded Pareto distribution is given by

\[
f(x) := \frac{\alpha L^x - \alpha - 1}{1 - (\frac{L}{H})^\alpha}
\]

Parameters

alpha : Real Number, \( \alpha > 0 \)
Shape parameter
left : Real Number, \( \text{left} > 0 \)
Location parameter
right : Real Number, \( \text{right} > \text{left} \)
Location parameter

Returns

RandomSymbol

Examples

>>> from sympy.stats import BoundedPareto, density, cdf, E
>>> from sympy import symbols
>>> L, H = symbols('L, H', positive=True)
>>> X = BoundedPareto('X', 2, L, H)
>>> x = symbols('x')
>>> density(X)(x)
\(2*L^2/(x**3*(1 - L**2/H**2))\)
>>> cdf(X)(x)
Piecewise((-H**2*L**2/(x**2*(H**2 - L**2)) + H**2/(H**2 - L**2), L <= x), (-\infty, True))
>>> E(X).simplify()
\(2*H*L/(H + L)\)
References

[R861]
sympy.stats.Cauchy(name, x0, gamma)

Create a continuous random variable with a Cauchy distribution.

The density of the Cauchy distribution is given by

$$f(x) := \frac{1}{\pi \gamma \left[1 + \left(\frac{x-x_0}{\gamma}\right)^2\right]}$$

Parameters

- \(x_0\) : Real number, the location
- \(\text{gamma}\) : Real number, \(\gamma > 0\), a scale

Returns

RandomSymbol

Examples

```python
>>> from sympy.stats import Cauchy, density
>>> from sympy import Symbol

>>> x0 = Symbol("x0")
>>> gamma = Symbol("gamma", positive=True)
>>> z = Symbol("z")

>>> X = Cauchy("x", x0, gamma)

>>> density(X)(z)
1/(pi*gamma*(1 + (-x0 + z)**2/gamma**2))
```

References

[R862], [R863]
sympy.stats.Chi(name, k)

Create a continuous random variable with a Chi distribution.

The density of the Chi distribution is given by

$$f(x) := \frac{2^{k/2} x^{k-1} e^{-x^2/2}}{\Gamma(k/2)}$$

with \(x \geq 0\).

Parameters

- \(k\) : Positive integer, The number of degrees of freedom

Returns

RandomSymbol
Examples

```python
>>> from sympy.stats import Chi, density, E
>>> from sympy import Symbol, simplify

>>> k = Symbol("k", integer=True)
>>> z = Symbol("z")

>>> X = Chi("x", k)

>>> density(X)(z)
2**(1 - k/2)*z**(k - 1)*exp(-z**2/2)/gamma(k/2)

>>> simplify(E(X))
sqrt(2)*gamma(k/2 + 1/2)/gamma(k/2)
```

References

[R864], [R865]
sympy.stats.ChNoncentral(name, k, l)
Create a continuous random variable with a non-central Chi distribution.

Parameters

- **k**: A positive Integer, \(k > 0\)
  - The number of degrees of freedom.
- **lambda**: Real number, \(\lambda > 0\)
  - Shift parameter.

Returns

RandomSymbol

Explanation

The density of the non-central Chi distribution is given by

\[
f(x) = \frac{e^{-(x^2+\lambda^2)/2}x^k\lambda}{(\lambda x)^{k/2}}I_{k/2-1}(\lambda x)
\]

with \(x \geq 0\). Here, \(I_\nu(x)\) is the modified Bessel function of the first kind (page 556).
Examples

```python
>>> from sympy.stats import ChiNoncentral, density
>>> from sympy import Symbol

>>> k = Symbol("k", integer=True)
>>> l = Symbol("l")
>>> z = Symbol("z")

>>> X = ChiNoncentral("x", k, l)

>>> density(X)(z)
l*z**k*exp(-l**2/2 - z**2/2)*besseli(k/2 - 1, l*z)/(l*z)**(k/2)
```

References

[R866] sympy.stats.Chisquared(name, k)
Create a continuous random variable with a Chi-squared distribution.

**Parameters**

- **k**: Positive integer

  The number of degrees of freedom.

**Returns**

RandomSymbol

**Explanation**

The density of the Chi-squared distribution is given by

\[
f(x) := \frac{1}{2^{k/2}\Gamma(k/2)} x^{k/2 - 1} e^{-x/2}
\]

with \( x \geq 0 \).

Examples

```python
>>> from sympy.stats import Chisquared, density, E, variance, moment
>>> from sympy import Symbol

>>> k = Symbol("k", integer=True, positive=True)
>>> z = Symbol("z")

>>> X = Chisquared("x", k)

>>> density(X)(z)
z**(k/2 - 1)*exp(-z/2)/(2**(k/2)*gamma(k/2))
```
>>> E(X)

k

>>> variance(X)

2*k

>>> moment(X, 3)

k**3 + 6*k**2 + 8*k

References

[R867], [R868]
sympy.stats.Dagum(name, p, a, b)
Create a continuous random variable with a Dagum distribution.

Parameters

- `p`: Real number
  
  $p > 0$, a shape.

- `a`: Real number
  
  $a > 0$, a shape.

- `b`: Real number
  
  $b > 0$, a scale.

Returns

RandomSymbol

Explanation

The density of the Dagum distribution is given by

$$f(x) := \frac{ap}{x} \left( \frac{\left( \frac{x}{b} \right)^a}{\left( \frac{x}{b} \right)^a + 1} \right)^{p+1}$$

with $x > 0$.

Examples

```python
>>> from sympy.stats import Dagum, density, cdf
>>> from sympy import Symbol

>>> p = Symbol("p", positive=True)
>>> a = Symbol("a", positive=True)
>>> b = Symbol("b", positive=True)
>>> z = Symbol("z")
```
\[
X = \text{Dagum}("x", p, a, b)
\]

\[
density(X)(z)
= a \cdot p \cdot (z/b)^{(a \cdot p)} \cdot ((z/b)^{a} + 1)^{(-p - 1)}/z
\]

\[
cdf(X)(z)
= \text{Piecewise}(((1 + (z/b)^{-a})^{(-p)}, z \geq 0), (0, \text{True}))
\]

**References**

[R869]
sympy.stats.Erlang(name, k, l)
Create a continuous random variable with an Erlang distribution.

**Parameters**

- \(k\) : Positive integer
- \(l\) : Real number, \(\lambda > 0\), the rate

**Returns**

RandomSymbol

**Explanation**

The density of the Erlang distribution is given by

\[
f(x) := \frac{\lambda^{k} x^{k-1} e^{-\lambda x}}{(k-1)!}
\]

with \(x \in [0, \infty)\).

**Examples**

```python
>>> from sympy.stats import Erlang, density, cdf, E, variance
>>> from sympy import Symbol, simplify, pprint

>>> k = Symbol("k", integer=True, positive=True)
>>> l = Symbol("l", positive=True)
>>> z = Symbol("z")

>>> X = Erlang("x", k, l)

>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
\[\frac{\lambda^{k} \cdot x^{k-1} \cdot e^{-\lambda x}}{(k-1)!}\]

>>> Gamma(k)
```
SymPy Documentation, Release 1.12.1

```python
>>> C = cdf(X)(z)
>>> pprint(C, use_unicode=False)
/\lowergamma(k, l*z)
\|------------------ for z > 0
\| \Gamma(k)
\| \0 otherwise

>>> E(X)
k/l

>>> simplify(variance(X))
k/l**2
```

References

sympy.stats.ExGaussian(name, mean, std, rate)

Create a continuous random variable with an Exponentially modified Gaussian (EMG) distribution.

**Parameters**

- `name` : A string giving a name for this distribution
- `mean` : A Real number, the mean of Gaussian component
- `std` : A positive Real number,
  - `math` \( \sigma^2 > 0 \) the variance of Gaussian component
- `rate` : A positive Real number,
  - `math` \( \lambda > 0 \) the rate of Exponential component

**Returns**

RandomSymbol

**Explanation**

The density of the exponentially modified Gaussian distribution is given by

\[
f(x) := \frac{\lambda}{2} e^{\frac{1}{2}(2\mu + \lambda \sigma^2 - 2x)} \text{erfc}\left(\frac{\mu + \lambda \sigma^2 - x}{\sqrt{2\sigma}}\right)
\]

with \( x > 0 \). Note that the expected value is \( 1/\lambda \).
Examples

```python
>>> from sympy.stats import ExGaussian, density, cdf, E
>>> from sympy.stats import variance, skewness
>>> from sympy import Symbol, pprint, simplify

>>> mean = Symbol("mu")
>>> std = Symbol("sigma", positive=True)
>>> rate = Symbol("lamda", positive=True)
>>> z = Symbol("z")
>>> X = ExGaussian("x", mean, std, rate)

>>> pprint(density(X)(z), use_unicode=False)
2
\lamda*\lamda*sigma + 2*mu - 2*z/
--------------------------------- / ___ / 2
\lamda*e \erfc|---------------------------| 2
\lamda*sigma + mu - z/2*sigma

>>> cdf(X)(z)
-(erf(sqrt(2)*(-lamda**2*sigma**2 + lamda*(-mu + z))/(2*lamda*sigma))/2
+ 1/2)*exp(lamda**2*sigma**2/2 - lamda*(-mu + z)) + erf(sqrt(2)*(-mu +
-z)/(2*sigma))/2 + 1/2

>>> E(X)
(lamda*mu + 1)/lamda

>>> simplify(variance(X))
sigma**2 + lamda**(-2)

>>> simplify(skewness(X))
2/(lamda**2*sigma**2 + 1)**(3/2)
```
**SymPy Documentation, Release 1.12.1**

**References**

[R872]
sympy.stats.**Exponential**(name, rate)

Create a continuous random variable with an Exponential distribution.

**Parameters**

rate : A positive Real number, \( \lambda > 0 \), the rate (or inverse scale/inverse mean)

**Returns**

RandomSymbol

**Explanation**

The density of the exponential distribution is given by

\[
f(x) := \lambda \exp(-\lambda x)
\]

with \( x > 0 \). Note that the expected value is \( 1/\lambda \).

**Examples**

```python
>>> from sympy.stats import Exponential, density, cdf, E
>>> from sympy.stats import variance, std, skewness, quantile
>>> from sympy import Symbol

>>> l = Symbol("lambda", positive=True)
>>> z = Symbol("z")
>>> p = Symbol("p")
>>> X = Exponential("x", l)

>>> density(X)(z)
lambda*exp(-lambda*z)

>>> cdf(X)(z)
Piecewise((1 - exp(-lambda*z), z >= 0), (0, True))

>>> quantile(X)(p)
-log(1 - p)/lambda

>>> E(X)
1/lambda

>>> variance(X)
lambda**(-2)

>>> skewness(X)
2
```
```python
>>> X = Exponential('x', 10)
```
```python
>>> density(X)(z)
10*exp(-10*z)
```
```python
>>> E(X)
1/10
```
```python
>>> std(X)
1/10
```

References

sympy.stats.FDistribution(name, d1, d2)
Create a continuous random variable with a F distribution.

Parameters

d1 : $d_1 > 0$, where $d_1$ is the degrees of freedom $(n_1 - 1)$
d2 : $d_2 > 0$, where $d_2$ is the degrees of freedom $(n_2 - 1)$

Returns

RandomSymbol

Explanation

The density of the F distribution is given by

$$f(x) := \frac{(d_1 x)^{d_1/2} (d_2 x)^{-d_2/2}}{x B\left(\frac{d_1}{2}, \frac{d_2}{2}\right)}$$

with $x > 0$.

Examples

```python
>>> from sympy.stats import FDistribution, density
>>> from sympy import Symbol, pprint
```
```python
>>> d1 = Symbol("d1", positive=True)
>>> d2 = Symbol("d2", positive=True)
>>> z = Symbol("z")
```
```python
>>> X = FDistribution("x", d1, d2)
```
>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
   2  /d1 -d1 - d2
   d2 *\ (d1*z) *(d1*z + d2)
--------------------------------------
           /d1  d2\                     
           z*B|--, --|                     
            \2  2 /                     

References

[R875], [R876]
sympy.stats.FisherZ(name, d1, d2)
Create a Continuous Random Variable with an Fisher's Z distribution.

Parameters

- **d1**: \( d_1 \gt 0 \)
  Degree of freedom.
- **d2**: \( d_2 \gt 0 \)
  Degree of freedom.

Returns

RandomSymbol

Explanation

The density of the Fisher's Z distribution is given by

\[
f(x) := \frac{2^{d_1/2} d_2^{d_2/2} e^{d_1 z}}{B(d_1/2, d_2/2) (d_1 e^{2z} + d_2)^{(d_1+d_2)/2}}
\]

Examples

```python
>>> from sympy.stats import FisherZ, density
>>> from sympy import Symbol, pprint

>>> d1 = Symbol("d1", positive=True)
>>> d2 = Symbol("d2", positive=True)
>>> z = Symbol("z")

>>> X = FisherZ("x", d1, d2)
```
>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
\[
\frac{d1 \cdot d2}{-d1 - d2} - \frac{\frac{2}{2} \cdot 2}{d1 \cdot 2^2} - \frac{2}{2} \cdot 2^2 \\
\frac{2 \cdot d1 \cdot d2}{-d1 \cdot d2} - \frac{\frac{2}{d1 \cdot 2^2} \cdot \frac{2}{2} + d2}{e} - \frac{1}{d1 \cdot d2} - \frac{\frac{2}{2} \cdot 2}{d1 \cdot 2^2} - \frac{2}{d1 \cdot d2}
\]

References

**sympy.stats.Frechet(name, a, s=1, m=0)**

Create a continuous random variable with a Frechet distribution.

**Parameters**

- **a**: Real number, \( a \in (0, \infty) \) the shape
- **s**: Real number, \( s \in (0, \infty) \) the scale
- **m**: Real number, \( m \in (-\infty, \infty) \) the minimum

**Returns**

RandomSymbol

**Explanation**

The density of the Frechet distribution is given by

\[
f(x) := \frac{\alpha}{s} \left( \frac{x - m}{s} \right)^{-1-\alpha} e^{-\left( \frac{x - m}{s} \right)^{-\alpha}}
\]

with \( x \geq m \).

**Examples**

```python
>>> from sympy.stats import Frechet, density, cdf
>>> from sympy import Symbol

>>> a = Symbol("a", positive=True)
>>> s = Symbol("s", positive=True)
>>> m = Symbol("m", real=True)
>>> z = Symbol("z")

>>> X = Frechet("x", a, s, m)
```
>>> density(X)(z)
a*((-m + z)/s)**(-a - 1)*exp(-1/((-m + z)/s)**a)/s

>>> cdf(X)(z)
Piecewise((exp(-1/((-m + z)/s)**a), m <= z), (0, True))

References

[R879]  
`sympy.stats.Gamma(name, k, theta)`  
Create a continuous random variable with a Gamma distribution.

**Parameters**

- **k**: Real number, \( k > 0 \), a shape
- **theta**: Real number, \( \theta > 0 \), a scale

**Returns**

RandomSymbol

**Explanation**

The density of the Gamma distribution is given by

\[
f(x) := \frac{1}{\Gamma(k)\theta^k} x^{k-1} e^{-\frac{x}{\theta}}
\]

with \( x \in [0, 1] \).

**Examples**

```python
>>> from sympy.stats import Gamma, density, cdf, E, variance
>>> from sympy import Symbol, pprint, simplify

>>> k = Symbol("k", positive=True)
>>> theta = Symbol("theta", positive=True)
>>> z = Symbol("z")

>>> X = Gamma("x", k, theta)

>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
- -z
-----
\(-k\) \(k - 1\) \(\theta\)
\(\theta\) *\(z\) *\(e\)
-----------------------------
\(\Gamma(k)\)
```
```python
>>> C = cdf(X, meijerg=True)(z)
>>> pprint(C, use_unicode=False)
| k*lowergamma[k, ----] | z |
| \theta/              |
\---------------------- for z >= 0 | Gamma(k + 1) | 0 otherwise

>>> E(X)
k*theta

>>> V = simplify(variance(X))
>>> pprint(V, use_unicode=False)
2
k*theta
```

`sympy.stats.GammaInverse(name, a, b)`
Create a continuous random variable with an inverse Gamma distribution.

**Parameters**
- a : Real number, $a > 0$, a shape
- b : Real number, $b > 0$, a scale

**Returns**
RandomSymbol

**Explanation**

The density of the inverse Gamma distribution is given by

$$f(x) := \frac{\beta^{a}}{\Gamma(a)} x^{-a-1} \exp \left(\frac{-\beta}{x}\right)$$

with $x > 0$.

**Examples**

```python
>>> from sympy.stats import GammaInverse, density, cdf
>>> from sympy import Symbol, pprint

>>> a = Symbol("a", positive=True)
>>> b = Symbol("b", positive=True)
>>> z = Symbol("z")
```
```python
>>> X = GammaInverse("x", a, b)
>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
-b
---
a -a - 1 z
b *z *e
-------------------
Gamma(a)
```

```python
>>> cdf(X)(z)

[R883]
sympy.stats.Gumbel(name, beta, mu, minimum=False)
Create a Continuous Random Variable with Gumbel distribution.

Parameters
  mu : Real number, \( \mu \), a location
  beta : Real number, \( \beta > 0 \), a scale
  minimum : Boolean, by default False, set to True for enabling minimum distribution

Returns
  RandomSymbol

Explanation

The density of the Gumbel distribution is given by

For Maximum

\[ f(x) := \frac{1}{\beta} \exp \left( -\frac{x - \mu}{\beta} - \exp \left( -\frac{x - \mu}{\beta} \right) \right) \]

with \( x \in [-\infty, \infty] \).

For Minimum

\[ f(x) := \exp \left( -\frac{-\mu + x}{\beta} \right) \]

with \( x \in [-\infty, \infty] \).

Examples

```python
>>> from sympy.stats import Gumbel, density, cdf
>>> from sympy import Symbol
>>> x = Symbol("x")
>>> mu = Symbol("mu")
>>> beta = Symbol("beta", positive=True)
>>> X = Gumbel("x", beta, mu)
>>> density(X)(x)
exp(-exp(-(-mu + x)/beta) - (-mu + x)/beta)/beta
>>> cdf(X)(x)
exp(-exp(-(-mu + x)/beta))
```
References

sympy.stats.Kumaraswamy(name, a, b)
Create a Continuous Random Variable with a Kumaraswamy distribution.

Parameters
- a : Real number, \( a > 0 \), a shape
- b : Real number, \( b > 0 \), a shape

Returns
RandomSymbol

Explanation
The density of the Kumaraswamy distribution is given by
\[
    f(x) := abx^{a-1}(1 - x^a)^{b-1}
\]
with \( x \in [0, 1] \).

Examples

```python
>>> from sympy.stats import Kumaraswamy, density, cdf
>>> from sympy import Symbol, pprint

>>> a = Symbol("a", positive=True)
>>> b = Symbol("b", positive=True)
>>> z = Symbol("z")

>>> X = Kumaraswamy("x", a, b)

>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
    b - 1
a - 1 / a\n    a*b*z *\1 - z /

>>> cdf(X)(z)
Piecewise((0, z < 0), (1 - (1 - z**a)**b, z <= 1), (1, True))
```
References

[R888]
sympy.stats.Laplace(name, mu, b)
Create a continuous random variable with a Laplace distribution.

Parameters
- **mu**: Real number or a list/matrix, the location (mean) or the location vector
- **b**: Real number or a positive definite matrix, representing a scale or the covariance matrix.

Returns
RandomSymbol

Explanation

The density of the Laplace distribution is given by

\[ f(x) := \frac{1}{2b} \exp\left( - \frac{|x - \mu|}{b} \right) \]

Examples

```python
>>> from sympy.stats import Laplace, density, cdf
>>> from sympy import Symbol, pprint

>>> mu = Symbol("\textcolor{mu}")
>>> b = Symbol("\textcolor{b}", positive=True)
>>> z = Symbol("\textcolor{z}")

>>> X = Laplace("x", mu, b)

>>> density(X)(z)
exp(-Abs(mu - z)/b)/(2*b)

>>> cdf(X)(z)
Piecewise((exp((-mu + z)/b)/2, mu > z), (1 - exp((mu - z)/b)/2, True))

>>> L = Laplace('L', [1, 2], [[1, 0], [0, 1]])
>>> pprint(density(L)(1, 2), use_unicode=False)
5 / e *besselk\0, \sqrt{35} / \pi
```

5.8. Topics 2993
References

[R889], [R890]

\texttt{sympy.stats.Levy(name, mu, c)}

Create a continuous random variable with a Levy distribution.

The density of the Levy distribution is given by

\[
f(x) := \sqrt{\frac{c}{2\pi}} \frac{\exp\left(-\frac{c}{2(x-\mu)}\right)}{(x-\mu)^{3/2}}
\]

**Parameters**

- \texttt{mu} : Real number
  - The location parameter.
- \texttt{c} : Real number, \( c > 0 \)
  - A scale parameter.

**Returns**

RandomSymbol

**Examples**

```python
>>> from sympy.stats import Levy, density, cdf
>>> from sympy import Symbol

>>> mu = Symbol("mu", real=True)
>>> c = Symbol("c", positive=True)
>>> z = Symbol("z")

>>> X = Levy("x", mu, c)

>>> density(X)(z)
sqrt(2)*sqrt(c)*exp(-c/(-2*mu + 2*z))/(2*sqrt(pi)*(-mu + z)**(3/2))

>>> cdf(X)(z)
erfc(sqrt(c)*sqrt(1/(-2*mu + 2*z)))
```

References

[R891], [R892]

\texttt{sympy.stats.Logistic(name, mu, s)}

Create a continuous random variable with a logistic distribution.

**Parameters**

- \texttt{mu} : Real number, the location (mean)
- \texttt{s} : Real number, \( s > 0 \), a scale

**Returns**

RandomSymbol
**Explanation**

The density of the logistic distribution is given by

\[
f(x) := \frac{e^{-(x-\mu)/s}}{s \left(1 + e^{-(x-\mu)/s}\right)^2}
\]

**Examples**

```python
>>> from sympy.stats import Logistic, density, cdf
>>> from sympy import Symbol

>>> mu = Symbol("mu", real=True)
>>> s = Symbol("s", positive=True)
>>> z = Symbol("z")

>>> X = Logistic("x", mu, s)

>>> density(X)(z)
exp((mu - z)/s)/(s*(exp((mu - z)/s) + 1)**2)

>>> cdf(X)(z)
1/(exp((mu - z)/s) + 1)
```

**References**

[R893], [R894]  

sympy.stats.LogLogistic(name, alpha, beta)

Create a continuous random variable with a log-logistic distribution. The distribution is unimodal when beta > 1.

**Parameters**
- `alpha`: Real number, \( \alpha > 0 \), scale parameter and median of distribution
- `beta`: Real number, \( \beta > 0 \), a shape parameter

**Returns**
- RandomSymbol

**Explanation**

The density of the log-logistic distribution is given by

\[
f(x) := \frac{(\frac{\beta}{\alpha})(\frac{x}{\alpha})^{\beta-1}}{(1+(\frac{x}{\alpha})^{\beta})^2}
\]
**Examples**

```python
>>> from sympy.stats import LogLogistic, density, cdf, quantile
>>> from sympy import Symbol, pprint

>>> alpha = Symbol("alpha", positive=True)
>>> beta = Symbol("beta", positive=True)
>>> p = Symbol("p")
>>> z = Symbol("z", positive=True)

>>> X = LogLogistic("x", alpha, beta)

>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
\[ \frac{\beta - 1}{\beta^{2} \alpha^{\frac{\beta\left(1 + \frac{z}{\alpha}\right)^{-\beta}}{\alpha^{\beta} + 1}}} \]

>>> cdf(X)(z)
\[ \frac{1}{1 + \left(\frac{z}{\alpha}\right)^{-\beta}} \]

>>> quantile(X)(p)
\[ \alpha \left(\frac{p}{1 - p}\right)^{\frac{1}{\beta}} \]
```

**References**

[R895]  
`sympy.stats.LogNormal(name, mean, std)`  
Create a continuous random variable with a log-normal distribution.

**Parameters**

- `mu` : Real number  
  The log-scale.

- `sigma` : Real number  
  A shape. \((\sigma^2 > 0)\)

**Returns**

- RandomSymbol
Explanation

The density of the log-normal distribution is given by

\[ f(x) := \frac{1}{x\sqrt{2\pi\sigma^2}} e^{-\frac{(\ln x - \mu)^2}{2\sigma^2}} \]

with \( x \geq 0 \).

Examples

```python
given
>>> from sympy.stats import LogNormal, density
>>> from sympy import Symbol, pprint

>>> mu = Symbol("mu", real=True)
>>> sigma = Symbol("sigma", positive=True)
>>> z = Symbol("z")

>>> X = LogNormal("x", mu, sigma)

>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
  2
-(-mu + log(z))
    ____________
   \___________
   \  2*sigma
    \___________
      \  2*e
       \  \\
     ____________
    2*\sqrt{2*\pi*sigma*z}

>>> X = LogNormal('x', 0, 1) # Mean 0, standard deviation 1

>>> density(X)(z)
sqrt(2)*exp(-log(z)**2/2)/(2*sqrt(pi)*z)
```

References

[R896], [R897]

`sympy.stats.Lomax(name, alpha, lamda)`

Create a continuous random variable with a Lomax distribution.

**Parameters**

- **alpha** : Real Number, \( \alpha > 0 \)
  
  Shape parameter

- **lamda** : Real Number, \( \lambda > 0 \)
  
  Scale parameter
Returns
RandomSymbol

Explanation

The density of the Lomax distribution is given by

\[ f(x) := \frac{\alpha}{\lambda} \left[ 1 + \frac{x}{\lambda} \right]^{-(\alpha+1)} \]

Examples

```python
>>> from sympy.stats import Lomax, density, cdf, E
>>> from sympy import symbols
>>> a, l = symbols('a, l', positive=True)
>>> X = Lomax('X', a, l)
>>> x = symbols('x')
>>> density(X)(x)
a*(1 + x/l)**(-a - 1)/l
>>> cdf(X)(x)
Piecewise((1 - 1/(1 + x/l)**a, x >= 0), (0, True))
>>> a = 2
>>> X = Lomax('X', a, l)
>>> E(X)
l
References

[R898]
sympy.stats.Maxwell(name, a)
Create a continuous random variable with a Maxwell distribution.

Parameters
a: Real number, \( a > 0 \)

Returns
RandomSymbol

Explanation

The density of the Maxwell distribution is given by

\[ f(x) := \sqrt{\frac{2}{\pi}} \frac{x^2 e^{-x^2/(2a^2)}}{a^3} \]

with \( x \geq 0 \).
Examples

```python
>>> from sympy.stats import Maxwell, density, E, variance
>>> from sympy import Symbol, simplify

>>> a = Symbol("a", positive=True)
>>> z = Symbol("z")

>>> X = Maxwell("x", a)

>>> density(X)(z)
sqrt(2)*z**2*exp(-z**2/(2*a**2))/(sqrt(pi)*a**3)

>>> E(X)
2*sqrt(2)*a/sqrt(pi)

>>> simplify(variance(X))
a**2*(-8 + 3*pi)/pi
```

References

[R899], [R900]
sympy.stats.Moyal(name, mu, sigma)
Create a continuous random variable with a Moyal distribution.

**Parameters**

- **mu**: Real number
  Location parameter
- **sigma**: Real positive number
  Scale parameter

**Returns**

RandomSymbol

**Explanation**

The density of the Moyal distribution is given by

\[ f(x) := \exp \left( \frac{1}{2} \exp \left( -\frac{x-\mu}{\sigma} - \frac{x-\mu}{2\sigma} \right) \right) \]

with \( x \in \mathbb{R} \).
Examples

```python
>>> from sympy.stats import Moyal, density, cdf
>>> from sympy import Symbol, simplify

>>> mu = Symbol("mu", real=True)
>>> sigma = Symbol("sigma", positive=True, real=True)
>>> z = Symbol("z")
>>> X = Moyal("x", mu, sigma)

>>> density(X)(z)
sqrt(2)*exp(-exp((mu - z)/sigma)/2 - (-mu + z)/(2*sigma))/(
    2*sqrt(pi)*sigma)

>>> simplify(cdf(X)(z))
1 - erf(sqrt(2)*exp((mu - z)/(2*sigma))/2)
```

References

[R901], [R902]

sympy.stats.Nakagami(name, mu, omega)

Create a continuous random variable with a Nakagami distribution.

Parameters

- **mu**: Real number, \( \mu \geq \frac{1}{2} \), a shape
- **omega**: Real number, \( \omega > 0 \), the spread

Returns

RandomSymbol

Explanation

The density of the Nakagami distribution is given by

\[
f(x) := \frac{2^{\mu} \mu^\mu}{\Gamma(\mu)\omega^\mu} x^{2\mu-1} \exp\left(-\frac{\mu}{\omega} x^2\right)
\]

with \( x > 0 \).

Examples

```python
>>> from sympy.stats import Nakagami, density, E, variance, cdf
>>> from sympy import Symbol, simplify, pprint

>>> mu = Symbol("mu", positive=True)
>>> omega = Symbol("omega", positive=True)
>>> z = Symbol("z")

>>> X = Nakagami("x", mu, omega)
```
>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
\[
\frac{-\mu z}{\mu^2 - 2\mu \omega - 1} \frac{1}{\Gamma(\mu)}
\]

>>> simplify(E(X))
\[
\sqrt{\mu} \sqrt{\omega} \frac{\Gamma(\mu + \frac{1}{2})}{\Gamma(\mu + 1)}
\]

>>> V = simplify(variance(X))
>>> pprint(V, use_unicode=False)
\[
\frac{\omega \Gamma(\mu + \frac{1}{2})}{\Gamma(\mu) \Gamma(\mu + 1)}
\]

>>> cdf(X)(z)
Piecewise((lowergamma(mu, mu*z**2/omega)/gamma(mu), z > 0), (0, True))

References

[R903]
sympy.stats.Normal(name, mean, std)
Create a continuous random variable with a Normal distribution.

Parameters

mu : Real number or a list representing the mean or the mean vector

sigma : Real number or a positive definite square matrix, \(\sigma^2 > 0\), the variance

Returns

RandomSymbol

Explanation

The density of the Normal distribution is given by
\[
f(x) := \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}}
\]
Examples

```python
from sympy.stats import Normal, density, E, std, cdf, skewness, quantile, marginal_distribution
from sympy import Symbol, simplify, pprint

mu = Symbol("mu")
sigma = Symbol("sigma", positive=True)
z = Symbol("z")
y = Symbol("y")
p = Symbol("p")
X = Normal("x", mu, sigma)

density(X)(z)
sqrt(2)*exp(-(-mu + z)**2/(2*sigma**2))/(2*sqrt(pi)*sigma)

C = simplify(cdf(X))(z) # it needs a little more help...
pprint(C, use_unicode=False)
/ ___ 
|\ 2 *(-mu + z)|
| erf-------------|
\ 2*sigma / 1
------------------- + -
 2 2

quantile(X)(p)
mu + sqrt(2)*sigma*erfinv(2*p - 1)

simplify(skewness(X))

sympy.stats.Pareto(name, xm, alpha)
Create a continuous random variable with the Pareto distribution.

Parameters
xm : Real number, \( x_m > 0 \), a scale
alpha : Real number, \( \alpha > 0 \), a shape

Returns
RandomSymbol

Explanation

The density of the Pareto distribution is given by

\[ f(x) := \frac{\alpha x_m^\alpha}{x^\alpha + 1} \]

with \( x \in [x_m, \infty] \).

Examples

```python
>>> from sympy.stats import Pareto, density
>>> from sympy import Symbol

>>> xm = Symbol("xm", positive=True)
>>> beta = Symbol("beta", positive=True)
>>> z = Symbol("z")

>>> X = Pareto("x", xm, beta)

>>> density(X)(z)
beta*xm**beta*z**(-beta - 1)
```

References

[R906], [R907]
sympy.stats.PowerFunction(name, alpha, a, b)
Create a continuous random variable with a Power Function Distribution.
**Parameters**

- **alpha**: Positive number, $0 < \alpha$, the shape parameter
- **a**: Real number, $-\infty < a$, the left boundary
- **b**: Real number, $a < b < \infty$, the right boundary

**Returns**

RandomSymbol

**Explanation**

The density of PowerFunction distribution is given by

$$f(x) := \frac{\alpha (x-a)^{\alpha-1}}{(b-a)^\alpha}$$

with $x \in [a,b]$.

**Examples**

```python
>>> from sympy.stats import PowerFunction, density, cdf, E, variance
>>> from sympy import Symbol
>>> alpha = Symbol("alpha", positive=True)
>>> a = Symbol("a", real=True)
>>> b = Symbol("b", real=True)
>>> z = Symbol("z")

>>> X = PowerFunction("X", 2, a, b)

>>> density(X)(z)
(-2*a + 2*z)/(-a + b)**2

>>> cdf(X)(z)
Piecewise((a**2/(a**2 - 2*a*b + b**2) - 2*a*z/(a**2 - 2*a*b + b**2) + z**2/(a**2 - 2*a*b + b**2), a <= z), (0, True))

>>> alpha = 2
>>> a = 0

>>> Y = PowerFunction("Y", alpha, a, b)

>>> E(Y)
2/3

>>> variance(Y)
1/18
```
References

[R908]
sympy.stats.QuadraticU(name, a, b)
Create a Continuous Random Variable with a U-quadratic distribution.

Parameters
- a : Real number
- b : Real number, \( a < b \)

Returns
RandomSymbol

Explanation
The density of the U-quadratic distribution is given by

\[
f(x) := \alpha(x - \beta)^2
\]

with \( x \in [a, b] \).

Examples

```python
>>> from sympy.stats import QuadraticU, density
>>> from sympy import Symbol, pprint

>>> a = Symbol("a", real=True)
>>> b = Symbol("b", real=True)
>>> z = Symbol("z")

>>> X = QuadraticU("x", a, b)

>>> D = density(X)(z)

sympy.stats.RaisedCosine(name, mu, s)
Create a Continuous Random Variable with a raised cosine distribution.

Parameters

mu : Real number
s : Real number, s > 0

Returns

RandomSymbol

Explanation

The density of the raised cosine distribution is given by

\[ f(x) := \frac{1}{2s} \left( 1 + \cos \left( \frac{x - \mu}{s} \pi \right) \right) \]

with \( x \in [\mu - s, \mu + s] \).

Examples

```python
>>> from sympy.stats import RaisedCosine, density
>>> from sympy import Symbol, pprint

>>> mu = Symbol("mu", real=True)
>>> s = Symbol("s", positive=True)
>>> z = Symbol("z")

>>> X = RaisedCosine("x", mu, s)

>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
/ \pi*(-mu + z)\n|cos|-------------| + 1
| \ s /

sympy.stats.Rayleigh(name, sigma)
Create a continuous random variable with a Rayleigh distribution.

- **Parameters**
  - `sigma`: Real number, $\sigma > 0$

- **Returns**
  - RandomSymbol

**Explanation**

The density of the Rayleigh distribution is given by

$$f(x) := \frac{x}{\sigma^2} e^{-x^2/2\sigma^2}$$

with $x > 0$.

**Examples**

```python
>>> from sympy.stats import Rayleigh, density, E, variance
>>> from sympy import Symbol

>>> sigma = Symbol("sigma", positive=True)
>>> z = Symbol("z")

>>> X = Rayleigh("x", sigma)

>>> density(X)(z)
z*exp(-z**2/(2*sigma**2))/sigma**2

>>> E(X)
sqrt(2)*sqrt(pi)*sigma/2

>>> variance(X)
-pi*sigma**2/2 + 2*sigma**2
```

sympy.stats.Reciprocal(name, a, b)
Creates a continuous random variable with a reciprocal distribution.

- **Parameters**
  - `a`: Real number, $0 < a$
  - `b`: Real number, $a < b`
Returns
RandomSymbol

Examples

```python
>>> from sympy.stats import Reciprocal, density, cdf
>>> from sympy import symbols

>>> a, b, x = symbols('a, b, x', positive=True)

>>> R = Reciprocal('R', a, b)

>>> density(R)(x)
1/(x*(-log(a) + log(b)))

>>> cdf(R)(x)
Piecewise((log(a)/(log(a) - log(b)) - log(x)/(log(a) - log(b)), a <= x), (0, True))
```

Reference

sympy.stats.StudentT(name, nu)

Create a continuous random variable with a student’s t distribution.

Parameters

- **nu**: Real number, \( \nu > 0 \), the degrees of freedom

Returns
RandomSymbol

Explanation

The density of the student’s t distribution is given by

\[
f(x) := \frac{\Gamma\left(\frac{\nu + 1}{2}\right)}{\sqrt{\nu\pi}\Gamma\left(\frac{\nu}{2}\right)} \left(1 + \frac{x^2}{\nu}\right)^{-\frac{\nu+1}{2}}
\]

Examples

```python
>>> from sympy.stats import StudentT, density, cdf
>>> from sympy import Symbol, pprint

>>> nu = Symbol("nu", positive=True)

>>> z = Symbol("z")

>>> X = StudentT("x", nu)

>>> D = density(X)(z)

>>> pprint(D, use_unicode=False)

nu  1
```

(continues on next page)
\[
\begin{align*}
&\frac{1}{2 - \sqrt{\nu}} - \frac{1}{2} + z\frac{\sqrt{\pi}}{\sqrt{n}} - \frac{1}{\sqrt{\nu}} \frac{\sqrt{\nu} B\left(\frac{1}{2}, \frac{n + 1}{2}\right)}{\gamma\left(\frac{n}{2}\right)} \\
&\text{CDF} = \frac{1}{2} + z\frac{\sqrt{\pi}}{\sqrt{n}} - \frac{1}{\sqrt{\nu}} \frac{\sqrt{\nu} B\left(\frac{1}{2}, \frac{n + 1}{2}\right)}{\gamma\left(\frac{n}{2}\right)}
\end{align*}
\]

sympy.stats.ShiftedGompertz(name, b, eta)

Create a continuous random variable with a Shifted Gompertz distribution.

Parameters

- **b**: Real number, \(b > 0\), a scale
- **eta**: Real number, \(\eta > 0\), a shape

Returns

RandomSymbol

Explanation

The density of the Shifted Gompertz distribution is given by

\[
f(x) := b e^{-bx} e^{-\eta \exp(-bx)} \left[ 1 + \eta (1 - e^x - bx) \right]
\]

with \(x \in [0, \infty)\).

Examples

```python
>>> from sympy.stats import ShiftedGompertz, density
>>> from sympy import Symbol

>>> b = Symbol("b", positive=True)
>>> eta = Symbol("eta", positive=True)
>>> x = Symbol("x")

>>> X = ShiftedGompertz("x", b, eta)
```
density(X)(x)

\[ b \cdot \eta \cdot (1 - \exp(-b \cdot x)) + 1 \cdot \exp(-b \cdot x) \cdot \exp(-\eta \cdot \exp(-b \cdot x)) \]

References

[R916]

sympy.stats.Trapezoidal(name, a, b, c, d)

Create a continuous random variable with a trapezoidal distribution.

Parameters

- a : Real number, \( a < d \)
- b : Real number, \( a \leq b < c \)
- c : Real number, \( b < c \leq d \)
- d : Real number

Returns

RandomSymbol

Explanation

The density of the trapezoidal distribution is given by

\[
f(x) := \begin{cases} 
0 & \text{for } x < a, \\
\frac{2(x-a)}{(b-a)(d+c-a-b)} & \text{for } a \leq x < b, \\
\frac{2b}{2(d-x)} & \text{for } b \leq x < c, \\
\frac{d+c-a-b}{(d-c)(d+c-a-b)} & \text{for } c \leq x < d, \\
0 & \text{for } d < x.
\end{cases}
\]

Examples

```python
>>> from sympy.stats import Trapezoidal, density
>>> from sympy import Symbol, pprint

>>> a = Symbol("a")
>>> b = Symbol("b")
>>> c = Symbol("c")
>>> d = Symbol("d")
>>> z = Symbol("z")

>>> X = Trapezoidal("x", a,b,c,d)

>>> pprint(density(X)(z), use_unicode=False)
/                       -2*a + 2*z
|------------------------- for And(a <= z, b > z)
|(-a + b)*(-a - b + c + d)```

(continues on next page)
\[
\begin{align*}
\text{for } \text{And}(b \leq z, c > z) & : & 2 \cdot \frac{-a - b + c + d}{-a - b + c + d} \\
\text{for } \text{And}(d \geq z, c \leq z) & : & 2 \cdot \frac{d - 2z}{-c + d} \cdot \frac{-a - b + c + d}{(-c + d) \cdot (-a - b + c + d)} \\
\text{otherwise} & : & 0
\end{align*}
\]

**References**

[R917] sympy.stats.Triangular\(\textit{name}, a, b, c\)  
Create a continuous random variable with a triangular distribution.

**Parameters**  
\begin{itemize}
\item \textit{a} : Real number, \(a \in (-\infty, \infty)\)
\item \textit{b} : Real number, \(a < b\)
\item \textit{c} : Real number, \(a \leq c \leq b\)
\end{itemize}

**Returns**  
RandomSymbol

**Explanation**

The density of the triangular distribution is given by

\[
f(x) := \begin{cases} 
0 & \text{for } x < a, \\
\frac{2(x - a)}{(b - a)(c - a)} & \text{for } a \leq x < c, \\
\frac{2}{b - a} \cdot \frac{2(b - x)}{(b - a)(b - c)} & \text{for } c < x \leq b, \\
0 & \text{for } b < x. 
\end{cases}
\]

**Examples**

```python
>>> from sympy.stats import Triangular, density
>>> from sympy import Symbol, pprint

>>> a = Symbol("a")
>>> b = Symbol("b")
>>> c = Symbol("c")
>>> z = Symbol("z")
```
```python
>>> X = Triangular("x", a, b, c)

>>> pprint(density(X)(z), use_unicode=False)
/  -2*a + 2*z
|----------------- for And(a <= z, c > z)
|((-a + b)*(-a + c)
| 2
| ------ for c = z
< -a + b
| 2*b - 2*z
|---------------- for And(b >= z, c < z)
|(-a + b)*(b - c)
\ 0 otherwise
```

References

`sympy.stats.Uniform(name, left, right)`
Create a continuous random variable with a uniform distribution.

**Parameters**
- **a**: Real number, $-\infty < a$, the left boundary
- **b**: Real number, $a < b < \infty$, the right boundary

**Returns**
- `RandomSymbol`

**Explanation**

The density of the uniform distribution is given by

$$f(x) := \begin{cases} \frac{1}{b-a} & \text{for } x \in [a, b] \\ 0 & \text{otherwise} \end{cases}$$

with $x \in [a, b]$.

**Examples**

```python
>>> from sympy.stats import Uniform, density, cdf, E, variance
>>> from sympy import Symbol, simplify

>>> a = Symbol("a", negative=True)
>>> b = Symbol("b", positive=True)
>>> z = Symbol("z")
```
>>> X = Uniform("x", a, b)

```python
>>> density(X)(z)
Piecewise((1/(-a + b), (b >= z) & (a <= z)), (0, True))
```  
```python
>>> cdf(X)(z)
Piecewise((0, a > z), ((-a + z)/(-a + b), b >= z), (1, True))
```  
```python
>>> E(X)
a/2 + b/2
```  
```python
>>> simplify(variance(X))
a**2/12 - a*b/6 + b**2/12
```  
References

[R920], [R921]
sympy.stats.UniformSum(name, n)

Create a continuous random variable with an Irwin-Hall distribution.

**Parameters**

- `n`: A positive integer, `n > 0`

**Returns**

RandomSymbol

**Explanation**

The probability distribution function depends on a single parameter `n` which is an integer. The density of the Irwin-Hall distribution is given by

\[
f(x) := \frac{1}{(n-1)!} \sum_{k=0}^{\lfloor x \rfloor} (-1)^k \binom{n}{k} (x-k)^{n-1}
\]

**Examples**

```python
>>> from sympy.stats import UniformSum, density, cdf
>>> from sympy import Symbol, pprint
```  
```python
>>> n = Symbol("n", integer=True)
>>> z = Symbol("z")
```  
```python
>>> X = UniformSum("x", n)
```
>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
floor(z)
\[\begin{array}{l}
\quad \, (-1)^{k} (-k + z)^{n} \frac{n - 1}{n} \\
\quad \, \frac{(-1)^{k} (-k + z)^{n} \text{binomial}(n, k)}{(n - 1)!} \\
\end{array}\]

>>> cdf(X)(z)
Piecewise((0, z < 0), (Sum((-1)**_k*(-_k + z)**n*binomial(n, _k), (_k, 0, floor(z)))/factorial(n), n >= z), (1, True))

Compute cdf with specific ‘x’ and ‘n’ values as follows: >>> cdf(UniformSum("x", 5), evaluate=False)(2).doit() 9/40

The argument evaluate=False prevents an attempt at evaluation of the sum for general n, before the argument 2 is passed.

References

[R922], [R923]
sympy.stats.VonMises(name, mu, k)
Create a Continuous Random Variable with a von Mises distribution.

Parameters

mu : Real number
Measure of location.

k : Real number
Measure of concentration.

Returns
RandomSymbol

Explanation
The density of the von Mises distribution is given by

\[f(x) := \frac{e^{\kappa \cos(x-\mu)}}{2\pi I_0(\kappa)}\]

with \(x \in [0, 2\pi]\).
Examples

```python
>>> from sympy.stats import VonMises, density
>>> from sympy import Symbol, pprint

>>> mu = Symbol("\mu")
>>> k = Symbol("k", positive=True)
>>> z = Symbol("z")

>>> X = VonMises("x", mu, k)

>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
\kappa \cos (\mu - z)
\frac{e}{2 \pi \text{besseli}(0, \kappa)}
```

References

[R924], [R925]

sympy.stats.Wald(name, mean, shape)
Create a continuous random variable with an Inverse Gaussian distribution. Inverse Gaussian distribution is also known as Wald distribution.

Parameters

- mu : Positive number representing the mean.
- lambda : Positive number representing the shape parameter.

Returns

RandomSymbol

Explanation

The density of the Inverse Gaussian distribution is given by

\[ f(x) := \frac{\lambda^{\lambda/2} e^{-\lambda(x-\mu)^2/2\mu^2}}{2\pi \mu^3} \]
Examples

```python
>>> from sympy.stats import GaussianInverse, density, E, std, skewness
>>> from sympy import Symbol, pprint

>>> mu = Symbol("mu", positive=True)
>>> lamda = Symbol("lambda", positive=True)
>>> z = Symbol("z", positive=True)
>>> X = GaussianInverse("x", mu, lamda)

>>> D = density(X)(z)
>>> pprint(D, use_unicode=False)
2
-\lambda*(-\mu + z)
---------------------
2\sqrt{2*\mu*z}
\sqrt{2*\lambda*e}

2\sqrt{2*\pi*z}

>>> E(X)
mu

>>> std(X).expand()
mu**(3/2)/sqrt(lamda)

>>> skewness(X).expand()
3*sqrt(mu)/sqrt(lamda)
```

References

[R926], [R927]

sympy.stats.Weibull(name, alpha, beta)
Create a continuous random variable with a Weibull distribution.

Parameters

- **lambda**: Real number, \( \lambda > 0 \), a scale
- **k**: Real number, \( k > 0 \), a shape

Returns

RandomSymbol
**Explanation**

The density of the Weibull distribution is given by

\[
    f(x) := \begin{cases} 
        \left(\frac{z}{\lambda}\right)^{k-1} e^{-(z/\lambda)^k} & x \geq 0 \\
        0 & x < 0 
    \end{cases}
\]

**Examples**

```python
>>> from sympy.stats import Weibull, density, E, variance
>>> from sympy import Symbol, simplify

>>> l = Symbol("lambda", positive=True)
>>> k = Symbol("k", positive=True)
>>> z = Symbol("z")

>>> X = Weibull("x", l, k)

>>> density(X)(z)
\left(\frac{z}{\lambda}\right)^{k - 1} e^{-\left(\frac{z}{\lambda}\right)^k} / \lambda

>>> simplify(E(X))
\lambda \gamma(1 + \frac{1}{k})

>>> simplify(variance(X))
\lambda^2 \left(\gamma\left(1 + \frac{1}{k}\right)^2 - \gamma\left(1 + \frac{2}{k}\right)\right)
```

**References**

[R928], [R929]

`sympy.stats.WignerSemicircle(name, R)`

Create a continuous random variable with a Wigner semicircle distribution.

**Parameters**

- `R`: Real number, \( R > 0 \), the radius

**Returns**

A RandomSymbol.

**Explanation**

The density of the Wigner semicircle distribution is given by

\[
    f(x) := \frac{2}{\pi R^2} \sqrt{R^2 - x^2}
\]

with \( x \in [-R, R] \).
Examples

```python
>>> from sympy.stats import WignerSemicircle, density, E
>>> from sympy import Symbol

>>> R = Symbol("R", positive=True)
>>> z = Symbol("z")

>>> X = WignerSemicircle("x", R)

>>> density(X)(z)
2*sqrt(R**2 - z**2)/(pi*R**2)

>>> E(X)
0
```

[R930], [R931]

`sympy.stats.ContinuousRV(symbol, density, set=Interval(-oo, oo), **kwargs)`
Create a Continuous Random Variable given the following:

Parameters
- **symbol**: Symbol
  Represents name of the random variable.
- **density**: Expression containing symbol
  Represents probability density function.
- **set**: set/Interval
  Represents the region where the pdf is valid, by default is real line.
- **check**: bool
  If True, it will check whether the given density integrates to 1 over the given set. If False, it will not perform this check. Default is False.

Returns
RandomSymbol
Many common continuous random variable types are already implemented.
This function should be necessary only very rarely.
Examples

```python
>>> from sympy import Symbol, sqrt, exp, pi
>>> from sympy.stats import ContinuousRV, P, E

```

```python
>>> x = Symbol("x")
```

```python
>>> pdf = sqrt(2)*exp(-x**2/2)/(2*sqrt(pi)) # Normal distribution
>>> X = ContinuousRV(x, pdf)
```

```python
>>> E(X)
0
>>> P(X>0)
1/2
```

Joint Types

```python
sympy.stats.JointRV(symbol, pdf, _set=None)
``` Create a Joint Random Variable where each of its component is continuous, given the following:

**Parameters**

- **symbol**: Symbol
  Represents name of the random variable.
- **pdf**: A PDF in terms of indexed symbols of the symbol given as the first argument

**Returns**

RandomSymbol

**Note**

As of now, the set for each component for a JointRV is equal to the set of all integers, which cannot be changed.

Examples

```python
>>> from sympy import exp, pi, Indexed, S
>>> from sympy.stats import density, JointRV
>>> x1, x2 = (Indexed('x', i) for i in (1, 2))
>>> pdf = exp(-x1**2/2 + x1 - x2**2/2 - S(1)/2)/(2*pi)
>>> N1 = JointRV('x', pdf) # Multivariate Normal distribution
>>> density(N1)(1, 2)
exp(-2)/(2*pi)
```
sympy.stats.marginal_distribution(rv, *indices)
Marginal distribution function of a joint random variable.

**Parameters**
- **rv**: A random variable with a joint probability distribution.
- **indices**: Component indices or the indexed random symbol for which the joint distribution is to be calculated

**Returns**
A Lambda expression in *sym*.

**Examples**
```python
>>> from sympy.stats import MultivariateNormal, marginal_distribution
>>> m = MultivariateNormal('X', [1, 2], [[2, 1], [1, 2]])
>>> marginal_distribution(m, m[0])(1)
1/(2*sqrt(pi))
```

sympy.stats.MultivariateNormal(name, mu, sigma)
Creates a continuous random variable with Multivariate Normal Distribution.
The density of the multivariate normal distribution can be found at [1].

**Parameters**
- **mu**: List representing the mean or the mean vector
- **sigma**: Positive semidefinite square matrix
  - Represents covariance Matrix. If σ is noninvertible then only sampling is supported currently

**Returns**
RandomSymbol

**Examples**
```python
>>> from sympy.stats import MultivariateNormal, density, marginal_distribution
>>> from sympy import symbols, MatrixSymbol
>>> X = MultivariateNormal('X', [3, 4], [[2, 1], [1, 2]])
>>> y, z = symbols('y z')
>>> density(X)(y, z)
sqrt(3)*exp(-y**2/3 + y*z/3 + 2*y/3 - z**2/3 + 5*z/3 - 13/3)/(6*pi)
>>> density(X)(1, 2)
sqrt(3)*exp(-4/3)/(6*pi)
>>> marginal_distribution(X, X[1])(y)
exp(-(y - 4)**2/4)/(2*sqrt(pi))
>>> marginal_distribution(X, X[0])(y)
exp(-(y - 3)**2/4)/(2*sqrt(pi))
```

The example below shows that it is also possible to use symbolic parameters to define the MultivariateNormal class.
```python
>>> n = symbols('n', integer=True, positive=True)
>>> Sg = MatrixSymbol('Sg', n, n)
>>> mu = MatrixSymbol('mu', n, 1)
>>> obs = MatrixSymbol('obs', n, 1)
>>> X = MultivariateNormal('X', mu, Sg)
```

The density of a multivariate normal can be calculated using a matrix argument, as shown below:

```python
>>> density(X)(obs)
(exp(((1/2)*mu.T - (1/2)*obs.T)*Sg**(-1)*(-mu + obs))/
→sqrt((2*pi)**n*Determinant(Sg)))[0, 0]
```

**References**

[R932] sympy.stats.MultivariateLaplace(name, mu, sigma)

Creates a continuous random variable with Multivariate Laplace Distribution.

The density of the multivariate Laplace distribution can be found at [1].

**Parameters**

- **mu**: List representing the mean or the mean vector
- **sigma**: Positive definite square matrix
  Represents covariance Matrix

**Returns**

RandomSymbol

**Examples**

```python
>>> from sympy.stats import MultivariateLaplace, density
>>> from sympy import symbols
>>> y, z = symbols('y z')
>>> X = MultivariateLaplace('X', [2, 4], [[3, 1], [1, 3]])
>>> density(X)(y, z)
sqrt(2)*exp(y/4 + 5*z/4)*besselk(0, sqrt(15*y*(3*y/8 - z/8)/2 + 15*z*(-y/ →8 + 3*z/8)/2))/(4*pi)
```
References

[R933]
sympy.stats.GeneralizedMultivariateLogGamma(syms, delta, v, lamda, mu)
Creates a joint random variable with generalized multivariate log gamma distribution. The joint pdf can be found at [1].

Parameters
syms : list/tuple/set of symbols for identifying each component
delta : A constant in range [0, 1]
v : Positive real number
lamda : List of positive real numbers
mu : List of positive real numbers

Returns
RandomSymbol

Examples

```python
>>> from sympy.stats import density
>>> from sympy.stats.joint_rv_types import GeneralizedMultivariateLogGamma
>>> from sympy import symbols, S
>>> v = 1
>>> l, mu = [1, 1, 1], [1, 1, 1]
>>> d = S.Half
>>> y = symbols('y_1:4', positive=True)
>>> Gd = GeneralizedMultivariateLogGamma('G', d, v, l, mu)
>>> density(Gd)(y[0], y[1], y[2])
Sum(exp((n + 1)*(y_1 + y_2 + y_3) - exp(y_1) - exp(y_2) - exp(y_3))/(2**n*gamma(n + 1)**3), (n, 0, oo))/2
```

Note

If the GeneralizedMultivariateLogGamma is too long to type use,

```python
>>> from sympy.stats.joint_rv_types import GeneralizedMultivariateLogGamma as GMVLG
>>> Gd = GMVLG('G', d, v, l, mu)
```

If you want to pass the matrix omega instead of the constant delta, then use GeneralizedMultivariateLogGammaOmega.
sympy.stats.\texttt{GeneralizedMultivariateLogGammaOmega}(\texttt{syms}, \texttt{omega}, \texttt{v}, \texttt{lamda}, \texttt{mu})

Extends GeneralizedMultivariateLogGamma.

**Parameters**

- \texttt{syms} : list/tuple/set of symbols
  For identifying each component
- \texttt{omega} : A square matrix
  Every element of square matrix must be absolute value of square root of correlation coefficient
- \texttt{v} : Positive real number
- \texttt{lamda} : List of positive real numbers
- \texttt{mu} : List of positive real numbers

**Returns**

RandomSymbol

**Examples**

```python
>>> from sympy.stats import density
>>> from sympy.stats.joint_rv_types import GeneralizedMultivariateLogGammaOmega
>>> from sympy import Matrix, symbols, S

>>> omega = Matrix([[1, S.Half, S.Half], [S.Half, 1, S.Half], [S.Half, S.Half, 1]])
>>> v = 1
>>> l, mu = [1, 1, 1], [1, 1, 1]
>>> G = GeneralizedMultivariateLogGammaOmega('G', omega, v, l, mu)
>>> y = symbols('y_1:4', positive=True)
>>> density(G)(y[0], y[1], y[2])
\sqrt{2}\sum_{n=0}^{\infty} \frac{(1 - \sqrt{2}/2)^n \exp((n + 1) (y_1 + y_2 + y_3) - \exp(y_1) - \exp(y_2) - \exp(y_3))/\gamma(n + 1)^3, (n, 0, \infty)}/2
```

**Notes**

If the \texttt{GeneralizedMultivariateLogGammaOmega} is too long to type use,

```python
>>> from sympy.stats.joint_rv_types import GeneralizedMultivariateLogGammaOmega as GMVLGO
>>> G = GMVLGO('G', omega, v, l, mu)
```
sympy.stats.Multinomial(syms, n, *p)

Creates a discrete random variable with Multinomial Distribution.

The density of the said distribution can be found at [1].

**Parameters**

- **n**: Positive integer
  - Represents number of trials
- **p**: List of event probabilities
  - Must be in the range of [0, 1].

**Returns**

RandomSymbol

**Examples**

```python
>>> from sympy.stats import density, Multinomial, marginal_distribution
>>> from sympy import symbols
>>> x1, x2, x3 = symbols('x1, x2, x3', nonnegative=True, integer=True)
>>> p1, p2, p3 = symbols('p1, p2, p3', positive=True)
>>> M = Multinomial('M', 3, p1, p2, p3)
>>> density(M)(x1, x2, x3)
Piecewise((6*p1**x1*p2**x2*p3**x3/factorial(x1)*factorial(x2)*factorial(x3),
           Eq(x1 + x2 + x3, 3)), (0, True))
>>> marginal_distribution(M, M[0])(x1).subs(x1, 1)
3*p1*p2**2 + 6*p1*p2*p3 + 3*p1*p3**2
```

**References**

[R938], [R939]

sympy.stats.MultivariateBeta(syms, *alpha)

Creates a continuous random variable with Dirichlet/Multivariate Beta Distribution.

The density of the Dirichlet distribution can be found at [1].

**Parameters**

- **alpha**: Positive real numbers
  - Signifies concentration numbers.

**Returns**

RandomSymbol
Examples

```python
>>> from sympy.stats import density, MultivariateBeta, marginal_distribution
>>> from sympy import Symbol
>>> a1 = Symbol('a1', positive=True)
>>> a2 = Symbol('a2', positive=True)
>>> B = MultivariateBeta('B', [a1, a2])
>>> C = MultivariateBeta('C', a1, a2)
>>> x = Symbol('x')
>>> y = Symbol('y')
>>> density(B)(x, y)

x**(a1 - 1)*y**(a2 - 1)*gamma(a1 + a2)/(gamma(a1)*gamma(a2))
```

```
>>> marginal_distribution(C, C[0])(x)

x**(a1 - 1)*gamma(a1 + a2)/(a2*gamma(a1)*gamma(a2))
```

References

[R940], [R941]
sympy.stats.MultivariateEwens(syms, n, theta)

Creates a discrete random variable with Multivariate Ewens Distribution.

The density of the said distribution can be found at [1].

**Parameters**

- **n**: Positive integer
  
  Size of the sample or the integer whose partitions are considered

- **theta**: Positive real number
  
  Denotes Mutation rate

**Returns**

RandomSymbol

Examples

```python
>>> from sympy.stats import density, marginal_distribution, MultivariateEwens
>>> from sympy import Symbol
>>> a1 = Symbol('a1', positive=True)
>>> a2 = Symbol('a2', positive=True)
>>> ed = MultivariateEwens('E', 2, 1)
>>> density(ed)(a1, a2)

Piecewise((1/(2**a2*factorial(a1)*factorial(a2)), Eq(a1 + 2*a2, 2)), (0, True))
```

```
>>> marginal_distribution(ed, ed[0])(a1)

Piecewise((1/factorial(a1), Eq(a1, 2)), (0, True))
```
References

[R942], [R943]
sympy.stats.MultivariateT(syms, mu, sigma, v)
    Creates a joint random variable with multivariate T-distribution.

    **Parameters**
    - **syms**: A symbol/str
      For identifying the random variable.
    - **mu**: A list/matrix
      Representing the location vector
    - **sigma**: The shape matrix for the distribution

    **Returns**
    RandomSymbol

    **Examples**

```python
>>> from sympy.stats import density, MultivariateT
>>> from sympy import Symbol

>>> x = Symbol("x")
>>> X = MultivariateT("x", [1, 1], [[1, 0], [0, 1]], 2)

>>> density(X)(1, 2)
2/(9*pi)
```

sympy.stats.NegativeMultinomial(syms, k0, *p)
    Creates a discrete random variable with Negative Multinomial Distribution.

    The density of the said distribution can be found at [1].

    **Parameters**
    - **k0**: positive integer
      Represents number of failures before the experiment is stopped
    - **p**: List of event probabilities
      Must be in the range of [0, 1]

    **Returns**
    RandomSymbol
Examples

```python
>>> from sympy.stats import density, NegativeMultinomial, marginal_distribution
>>> from sympy import symbols

>>> x1, x2, x3 = symbols('x1, x2, x3', nonnegative=True, integer=True)
>>> p1, p2, p3 = symbols('p1, p2, p3', positive=True)

>>> N = NegativeMultinomial('M', 3, p1, p2, p3)
>>> N_c = NegativeMultinomial('M', 3, 0.1, 0.1, 0.1)

>>> density(N)(x1, x2, x3)
p1**x1*p2**x2*p3**x3*(-p1 - p2 - p3 + 1)**3*gamma(x1 + x2 + x3 + 3)/(2*factorial(x1)*factorial(x2)*factorial(x3))

>>> marginal_distribution(N_c, N_c[0])(1).evalf().round(2)
0.25
```

References

[R944], [R945]

**sympy.stats.NormalGamma**(*sym*, *mu*, *lamda*, *alpha*, *beta*)

Creates a bivariate joint random variable with multivariate Normal gamma distribution.

**Parameters**

- **sym**: A symbol/str
  - For identifying the random variable.
- **mu**: A real number
  - The mean of the normal distribution
- **lamda**: A positive integer
  - Parameter of joint distribution
- **alpha**: A positive integer
  - Parameter of joint distribution
- **beta**: A positive integer
  - Parameter of joint distribution

**Returns**

RandomSymbol

Examples

```python
>>> from sympy.stats import density, NormalGamma

>>> from sympy import symbols

>>> X = NormalGamma('x', 0, 1, 2, 3)
>>> y, z = symbols('y z')

>>> density(X)(y, z)
9*sqrt(2)*z**(3/2)*exp(-3*z)*exp(-y**2*z/2)/(2*sqrt(pi))
```
References

[R946]

Stochastic Processes

class sympy.stats.DiscreteMarkovChain(sym, state_space=None, trans_probs=None)
 Represents a finite discrete time-homogeneous Markov chain.
 This type of Markov Chain can be uniquely characterised by its (ordered) state space and its one-step transition probability matrix.

Parameters
 sym:
  The name given to the Markov Chain

state_space:
  Optional, by default, Range(n)

trans_probs:
  Optional, by default, MatrixSymbol('_T', n, n)

Examples

```python
>>> from sympy.stats import DiscreteMarkovChain, TransitionMatrixOf, P, E
>>> from sympy import Matrix, MatrixSymbol, Eq, symbols

>>> T = Matrix([[0.5, 0.2, 0.3], [0.2, 0.5, 0.3], [0.2, 0.3, 0.5]])
>>> Y = DiscreteMarkovChain("Y", [0, 1, 2], T)
>>> YS = DiscreteMarkovChain("Y")

>>> Y.state_space
{0, 1, 2}
>>> Y.transition_probabilities
Matrix([0.5, 0.2, 0.3], [0.2, 0.5, 0.3], [0.2, 0.3, 0.5])
>>> TS = MatrixSymbol('T', 3, 3)
>>> P(Eq(YS[3], 2), Eq(YS[1], 1) & TransitionMatrixOf(YS, TS))
T[0, 2]*T[1, 0] + T[1, 1]*T[1, 2] + T[1, 2]*T[2, 2]
>>> P(Eq(Y[3], 2), Eq(Y[1], 1)).round(2)
0.36
```

Probabilities will be calculated based on indexes rather than state names. For example, with the Sunny-Cloudy-Rainy model with string state names:

```python
>>> from sympy.core.symbol import Str
>>> Y = DiscreteMarkovChain("Y", [Str('Sunny'), Str('Cloudy'), Str('Rainy')], T)
>>> P(Eq(Y[3], 2), Eq(Y[1], 1)).round(2)
0.36
```
This gives the same answer as the $[0, 1, 2]$ state space. Currently, there is no support for state names within probability and expectation statements. Here is a work-around using Str:

```python
>>> P(Eq(Str('Rainy'), Y[3]), Eq(Y[1], Str('Cloudy'))).round(2)
0.36
```

Symbol state names can also be used:

```python
>>> sunny, cloudy, rainy = symbols('Sunny, Cloudy, Rainy')
>>> Y = DiscreteMarkovChain("Y", [sunny, cloudy, rainy], T)
>>> P(Eq(Y[3], rainy), Eq(Y[1], cloudy)).round(2)
0.36
```

Expectations will be calculated as follows:

```python
>>> E(Y[3], Eq(Y[1], cloudy))
0.38*Cloudy + 0.36*Rainy + 0.26*Sunny
```

Probability of expressions with multiple RandomIndexedSymbols can also be calculated provided there is only 1 RandomIndexedSymbol in the given condition. It is always better to use Rational instead of floating point numbers for the probabilities in the transition matrix to avoid errors.

```python
>>> from sympy import Gt, Le, Rational
>>> T = Matrix([[Rational(5, 10), Rational(3, 10), Rational(2, 10)],
              [Rational(2, 10), Rational(7, 10), Rational(1, 10)],
              [Rational(3, 10), Rational(4, 10)]])
>>> Y = DiscreteMarkovChain("Y", [0, 1, 2], T)
>>> P(Eq(Y[3], Y[1]), Eq(Y[0], 0)).round(3)
0.409
>>> P(Gt(Y[3], Y[1]), Eq(Y[0], 0)).round(2)
0.36
>>> P(Le(Y[15], Y[10]), Eq(Y[8], 2)).round(7)
0.693328
```

Symbolic probability queries are also supported

```python
>>> a, b, c, d = symbols('a b c d')
>>> T = Matrix([[Rational(1, 10), Rational(4, 10), Rational(5, 10)],
              [Rational(3, 10), Rational(4, 10), Rational(3, 10)],
              [Rational(2, 10), Rational(1, 10)]])
>>> Y = DiscreteMarkovChain("Y", [0, 1, 2], T)
>>> query = P(Eq(Y[a], b), Eq(Y[c], d))
>>> query.subs({a:10, b:2, c:5, d:1}).round(4)
0.3096
>>> P(Eq(Y[10], 2), Eq(Y[5], 1)).evalf().round(4)
0.3096
>>> query_gt = P(Gt(Y[a], b), Eq(Y[c], d))
>>> query_gt.subs({a:21, b:0, c:5, d:0}).evalf().round(5)
0.64705
>>> P(Gt(Y[21], 0), Eq(Y[5], 0)).round(5)
0.64705
```

There is limited support for arbitrarily sized states.
>>> n = symbols('n', nonnegative=True, integer=True)
>>> T = MatrixSymbol('T', n, n)
>>> Y = DiscreteMarkovChain("Y", trans_probs=T)
>>> Y.state_space
Range(0, n, 1)
>>> query = P(Eq(Y[a], b), Eq(Y[c], d))
(T**5)[1, 2]

[R947], [R948]

absorbing_probabilities()

Computes the absorbing probabilities, i.e. the ij-th entry of the matrix denotes the probability of Markov chain being absorbed in state j starting from state i.

canonical_form() → Tuple[List[Basic (page 979)], ImmutableDenseMatrix (page 1413)]

Reorders the one-step transition matrix so that recurrent states appear first and transient states appear last. Other representations include inserting transient states first and recurrent states last.

Returns

states, P_new

states is the list that describes the order of the new states in the matrix so that the ith element in states is the state of the ith row of A. P_new is the new transition matrix in canonical form.

Examples

>>> from sympy.stats import DiscreteMarkovChain
>>> from sympy import Matrix, S

You can convert your chain into canonical form:

>>> T = Matrix([[S(1)/2, S(1)/2, 0, 0, 0],
...              [S(2)/5, S(1)/5, S(2)/5, 0, 0],
...              [0, 0, 1, 0, 0],
...              [0, 0, S(1)/2, S(1)/2, 0],
...              [S(1)/2, 0, 0, 0, S(1)/2]])
>>> X = DiscreteMarkovChain('X', list(range(1, 6)), trans_probs=T)
>>> states, new_matrix = X.canonical_form()
>>> states
[3, 1, 2, 4, 5]

>>> new_matrix
Matrix([[1, 0, 0, 0, 0],
        [0, 1/2, 1/2, 0, 0],
        [0, 0, 0, 1, 0],
        [0, 0, 0, 0, 1],
        [0, 0, 0, 0, 0]], [2, 2, 2, 2, 2], [2, 2, 2, 2, 2])

(continues on next page)
The new states are \([3, 1, 2, 4, 5]\) and you can create a new chain with this and its canonical form will remain the same (since it is already in canonical form).

```python
>>> X = DiscreteMarkovChain('X', states, new_matrix)
>>> states, new_matrix = X.canonical_form()
>>> states
[3, 1, 2, 4, 5]
```

```python
>>> new_matrix
Matrix([ 1, 0, 0, 0, 0],
[ 0, 1/2, 1/2, 0, 0],
[2/5, 2/5, 1/5, 0, 0],
[1/2, 0, 0, 1/2, 0],
[ 0, 1/2, 0, 0, 1/2])
```

This is not limited to absorbing chains:

```python
>>> T = Matrix([[0, 5, 5, 0, 0],
              ...             [0, 0, 0, 10, 0],
              ...             [5, 0, 5, 0, 0],
              ...             [0, 10, 0, 0, 0],
              ...             [0, 3, 3, 0, 4]])/10
>>> X = DiscreteMarkovChain('X', trans_probs=T)
>>> states, new_matrix = X.canonical_form()
>>> states
[1, 3, 0, 2, 4]
```

```python
>>> new_matrix
Matrix([ 0, 1, 0, 0, 0],
[ 1, 0, 0, 0, 0],
[1/2, 0, 0, 1/2, 0],
[ 0, 0, 1/2, 1/2, 0],
[3/10, 3/10, 0, 0, 2/5])
```

See also:

- `sympy.stats.DiscreteMarkovChain.communication_classes` (page 3032)
- `sympy.stats.DiscreteMarkovChain.decompose` (page 3033)
communication_classes() → List[Tuple[List[Basic (page 979)], Boolean (page 1207), Integer (page 1038)]]

Returns the list of communication classes that partition the states of the Markov chain.

A communication class is defined to be a set of states such that every state in that set is reachable from every other state in that set. Due to its properties, this forms a class in the mathematical sense. Communication classes are also known as recurrence classes.

**Returns**

classes

The classes are a list of tuples. Each tuple represents a single communication class with its properties. The first element in the tuple is the list of states in the class, the second element is whether the class is recurrent and the third element is the period of the communication class.

**Examples**

```python
>>> from sympy.stats import DiscreteMarkovChain
>>> from sympy import Matrix
>>> T = Matrix([[0, 1, 0],
              ... [1, 0, 0],
              ... [1, 0, 0]])
>>> X = DiscreteMarkovChain('X', [1, 2, 3], T)
>>> classes = X.communication_classes()
>>> for states, is_recurrent, period in classes:
...     states, is_recurrent, period
([1, 2], True, 2)
([3], False, 1)
```

From this we can see that states 1 and 2 communicate, are recurrent and have a period of 2. We can also see state 3 is transient with a period of 1.

**Notes**

The algorithm used is of order $O(n^2 + 2)$ where $n$ is the number of states in the Markov chain. It uses Tarjan’s algorithm to find the classes themselves and then it uses a breadth-first search algorithm to find each class’s periodicity. Most of the algorithm’s components approach $O(n)$ as the matrix becomes more and more sparse.
decompose() \rightarrow \text{Tuple}[	ext{List}[\text{Basic (page 979)}], \text{ImmutableDenseMatrix (page 1413)}, \\
\text{ImmutableDenseMatrix (page 1413)}, \text{ImmutableDenseMatrix (page 1413)}]

Decomposes the transition matrix into submatrices with special properties.

The transition matrix can be decomposed into 4 submatrices: - A - the submatrix from recurrent states to recurrent states. - B - the submatrix from transient to recurrent states. - C - the submatrix from transient to transient states. - O - the submatrix of zeros for recurrent to transient states.

Returns
states, A, B, C

states - a list of state names with the first being the recurrent states and the last being the transient states in the order of the row names of A and then the row names of C. A - the submatrix from recurrent states to recurrent states. B - the submatrix from transient to recurrent states. C - the submatrix from transient to transient states.

Examples

```python
>>> from sympy.stats import DiscreteMarkovChain
>>> from sympy import Matrix, S
```

One can decompose this chain for example:

```python
>>> T = Matrix([[S(1)/2, S(1)/2, 0, 0, 0],  
...             [S(2)/5, S(1)/5, S(2)/5, 0, 0],  
...             [0, 0, 1, 0, 0],  
...             [0, 0, S(1)/2, S(1)/2, 0],  
...             [S(1)/2, 0, 0, 0, S(1)/2]])
>>> X = DiscreteMarkovChain('X', trans_probs=T)
>>> states, A, B, C = X.decompose()

>>> states
[2, 0, 1, 3, 4]
```

```python
>>> A  # recurrent to recurrent
Matrix([[1]])
```

```python
>>> B  # transient to recurrent
Matrix([  
[0],  
[2/5],  
[1/2],  
[0]])
```

```python
>>> C  # transient to transient
Matrix([  
[1/2, 1/2, 0, 0],  
[2/5, 1/5, 0, 0],  
```

(continues on next page)
This means that state 2 is the only absorbing state (since \(A\) is a 1x1 matrix). \(B\) is a 4x1 matrix since the 4 remaining transient states all merge into recurrent state 2. And \(C\) is the 4x4 matrix that shows how the transient states 0, 1, 3, 4 all interact.

References

[R955], [R956]

**fixed_row_vector()**

A wrapper for stationary_distribution().

**fundamental_matrix()**

Each entry fundamental matrix can be interpreted as the expected number of times the chains is in state \(j\) if it started in state \(i\).

References

[R957]

**property limiting_distribution**

The fixed row vector is the limiting distribution of a discrete Markov chain.

**sample()**

Returns

\(\text{sample}: \text{iterator object}\)

\(\text{iterator object containing the sample}\)

**stationary_distribution()**

\(\text{condition_set= False} \rightarrow \text{ImmutableDenseMatrix}\)

The stationary distribution is any row vector, \(p\), that solves \(p = pP\), is row stochastic and each element in \(p\) must be nonnegative. That means in matrix form: \((P-I)^T p^T = 0\) and \((1, \ldots, 1)p = 1\) where \(P\) is the one-step transition matrix.

All time-homogeneous Markov Chains with a finite state space have at least one stationary distribution. In addition, if a finite time-homogeneous Markov Chain is irreducible, the stationary distribution is unique.

**Parameters**

\(\text{condition_set}\) : bool

If the chain has a symbolic size or transition matrix, it will return a Lambda if False and return a ConditionSet if True.
Examples

```python
>>> from sympy.stats import DiscreteMarkovChain
>>> from sympy import Matrix, S

An irreducible Markov Chain

```python
>>> T = Matrix([[S(1)/2, S(1)/2, 0],
              ...               [S(4)/5, S(1)/5, 0],
              ...               [1, 0, 0]])
>>> X = DiscreteMarkovChain('X', trans_probs=T)
>>> X.stationary_distribution()
Matrix([[8/13, 5/13, 0]])
``` 

A reducible Markov Chain

```python
>>> T = Matrix([[S(1)/2, S(1)/2, 0],
              ...               [S(4)/5, S(1)/5, 0],
              ...               [0, 0, 1]])
>>> X = DiscreteMarkovChain('X', trans_probs=T)
>>> X.stationary_distribution()
Matrix([[8/13 - 8*tau0/13, 5/13 - 5*tau0/13, tau0]])
``` 

```python
>>> Y = DiscreteMarkovChain('Y')
>>> Y.stationary_distribution()
Lambda((wm, _T), Eq(wm*_T, wm))
>>> Y.stationary_distribution(condition_set=True)
ConditionSet(wm, Eq(wm*_T, wm))
```

References

[R958], [R959]

property transition_probabilities

Transition probabilities of discrete Markov chain, either an instance of Matrix or MatrixSymbol.

class sympy.stats.ContinuousMarkovChain(sym, state_space=None, gen_mat=None)

Represents continuous time Markov chain.

Parameters

- `sym`: Symbol/str
- `state_space`: Set
  Optional, by default, S.Reals
- `gen_mat`: Matrix/ImmutableMatrix/MatrixSymbol
  Optional, by default, None
Examples

```python
>>> from sympy.stats import ContinuousMarkovChain, P
>>> from sympy import Matrix, S, Eq, Gt

>>> G = Matrix([[-S(1), S(1)], [S(1), -S(1)]])
>>> C = ContinuousMarkovChain('C', state_space=[0, 1], gen_mat=G)
>>> C.limiting_distribution()
Matrix([[1/2, 1/2]])

>>> C.state_space
{0, 1}

>>> C.generator_matrix
Matrix([[1, -1], [-1, 1]])

Probability queries are supported

```python
>>> P(Eq(C(1.96), 0), Eq(C(0.78), 1)).round(5)
0.45279

>>> P(Gt(C(1.7), 0), Eq(C(0.82), 1)).round(5)
0.58602
```

Probability of expressions with multiple RandomIndexedSymbols can also be calculated provided there is only 1 RandomIndexedSymbol in the given condition. It is always better to use Rational instead of floating point numbers for the probabilities in the generator matrix to avoid errors.

```python
>>> from sympy import Gt, Le, Rational

>>> G = Matrix([[-S(1), Rational(1, 10), Rational(9, 10)], [Rational(2, 5), S(1), Rational(3, 5)], [Rational(1, 2), Rational(1, 2), -S(1)]])
>>> C = ContinuousMarkovChain('C', state_space=[0, 1, 2], gen_mat=G)
>>> P(Eq(C(3.92), C(1.75)), Eq(C(0.46), 0)).round(5)
0.37933

>>> P(Gt(C(3.92), C(1.75)), Eq(C(0.46), 0)).round(5)
0.34211

>>> P(Le(C(1.57), C(3.14)), Eq(C(1.22), 1)).round(4)
0.7143
```

Symbolic probability queries are also supported

```python
>>> from sympy import symbols

>>> a, b, c, d = symbols('a b c d')

>>> G = Matrix([[-S(1), Rational(1, 10), Rational(9, 10)], [Rational(2, 5), S(1), Rational(3, 5)], [Rational(1, 2), Rational(1, 2), -S(1)]])
>>> C = ContinuousMarkovChain('C', state_space=[0, 1, 2], gen_mat=G)

>>> query = P(Eq(C(a), b), Eq(C(c), d))
>>> query.subs({a:3.65, b:2, c:1.78, d:1}).evalf().round(10)
0.4002723175

>>> P(Eq(C(3.65), 2), Eq(C(1.78), 1)).round(10)
0.4002723175
>>> query.gt = P(Gt(C(a), b), Eq(C(c), d))
>>> query.gt.subs({a:43.2, b:0, c:3.29, d:2}).evalf().round(10)
0.6832579186
```

(continues on next page)

class sympy.stats.BernoulliProcess(sym, p, success=1, failure=0)
The Bernoulli process consists of repeated independent Bernoulli process trials with the same parameter p. It’s assumed that the probability p applies to every trial and that the outcomes of each trial are independent of all the rest. Therefore Bernoulli Process is Discrete State and Discrete Time Stochastic Process.

Parameters

- **sym**: Symbol/str

- **success**: Integer/str
  
The event which is considered to be success. Default: 1.

- **failure**: Integer/str
  
The event which is considered to be failure. Default: 0.

- **p**: Real Number between 0 and 1
  
  Represents the probability of getting success.

Examples

```python
>>> from sympy.stats import BernoulliProcess, P, E
>>> from sympy import Eq, Gt
>>> B = BernoulliProcess("B", p=0.7, success=1, failure=0)
>>> B.state_space
{0, 1}
>>> (B.p).round(2)
0.70
>>> B.success
1
>>> B.failure
0
>>> P(Eq(X, 0)).round(2)
0.03
>>> P(Eq(X, 2)).round(2)
0.44
>>> P(Eq(X, 4)).round(2)
0
>>> P(Gt(X, 1)).round(2)
0.78
>>> P(Eq(B[1], 0) & Eq(B[2], 1) & Eq(B[3], 0) & Eq(B[4], 1)).round(2)
0.04
>>> B.joint_distribution(B[1], B[2])
```
JointDistributionHandmade(Lambda((B[1], B[2]), Piecewise((0.7, Eq(B[1], 1)), (0.3, Eq(B[1], 0)), (0, True))*Piecewise((0.7, Eq(B[2], 1)), (0.3, Eq(B[2], 0)), (0, True))))

2.10

>>> P(B[1] < 1).round(2)
0.30

References

[R962], [R963]

**expectation**(expr, condition=None, evaluate=True, **kwargs)
Computes expectation.

Parameters

- **expr**: RandomIndexedSymbol, Relational, Logic
  Condition for which expectation has to be computed. Must contain a
  RandomIndexedSymbol of the process.

- **condition**: Relational, Logic
  The given conditions under which computations should be done.

Returns

Expectation of the RandomIndexedSymbol.

**probability**(condition, given_condition=None, evaluate=True, **kwargs)
Computes probability.

Parameters

- **condition**: Relational
  Condition for which probability has to be computed. Must contain a
  RandomIndexedSymbol of the process.

- **given_condition**: Relational, Logic
  The given conditions under which computations should be done.

Returns

Probability of the condition.

class sympy.stats.PoissonProcess(sym, lamda)
The Poisson process is a counting process. It is usually used in scenarios where we are
counting the occurrences of certain events that appear to happen at a certain rate, but
completely at random.

Parameters

- **sym**: Symbol/str

- **lamda**: Positive number
  Rate of the process, lamda > 0
Examples

```python
>>> from sympy.stats import PoissonProcess, P, E
>>> from sympy import symbols, Eq, Ne, Contains, Interval

>>> X = PoissonProcess("X", lamda=3)
>>> X.state_space
Naturals0
>>> X.lamda
3
>>> t1, t2 = symbols('t1 t2', positive=True)
>>> P(X(t1) < 4)
(9*t1**3/2 + 9*t1**2/2 + 3*t1 + 1)*exp(-3*t1)
>>> P(Eq(X(t1), 2) | Ne(X(t1), 4), Contains(t1, Interval.Ropen(2, 4)))
1 - 36*exp(-6)
>>> P(Eq(X(t1), 2) & Eq(X(t2), 3), Contains(t1, Interval.Lopen(0, 2)) & Contains(t2, Interval.Lopen(2, 4)))
648*exp(-12)
>>> E(X(t1))
3*t1
>>> E(X(t1)**2 + 2*X(t2), Contains(t1, Interval.Lopen(0, 1)) & Contains(t2, Interval.Lopen(1, 2)))
18
>>> P(X(3) < 1, Eq(X(1), 0))
exp(-6)
>>> P(Eq(X(4), 3), Eq(X(2), 3))
exp(-6)
>>> P(X(2) <= 3, X(1) > 1)
5*exp(-3)
```

Merging two Poisson Processes

```python
>>> Y = PoissonProcess("Y", lamda=4)
>>> Z = X + Y
>>> Z.lamda
7
```

Splitting a Poisson Process into two independent Poisson Processes

```python
>>> N, M = Z.split(l1=2, l2=5)
>>> N.lamda, M.lamda
(2, 5)
```

References

class sympy.stats.WienerProcess(sym)

The Wiener process is a real valued continuous-time stochastic process. In physics it is used to study Brownian motion and it is often also called Brownian motion due to its historical connection with physical process of the same name originally observed by Scottish botanist Robert Brown.
Parameters

**sym**: Symbol/str

Examples

```python
>>> from sympy.stats import WienerProcess, P, E
>>> from sympy import symbols, Contains, Interval
>>> X = WienerProcess("X")
>>> X.state_space
Reals
>>> t1, t2 = symbols('t1 t2', positive=True)
>>> P(X(t1) < 7).simplify()  
    erf(7*sqrt(2)/(2*sqrt(t1)))/2 + 1/2
>>> P((X(t1) > 2) | (X(t1) < 4), Contains(t1, Interval.Ropen(2, 4))).simplify()
    -erf(1)/2 + erf(2)/2 + 1
>>> E(X(t1))
0
>>> E(X(t1) + 2*X(t2), Contains(t1, Interval.Lopen(0, 1)) & Contains(t2, Interval.Lopen(1, 2)))
0
```

References

[R966], [R967]

class sympy.stats.GammaProcess(sym, lamda, gamma)
A Gamma process is a random process with independent gamma distributed increments. It is a pure-jump increasing Levy process.

Parameters

**sym**: Symbol/str

**lamda**: Positive number

Jump size of the process, lamda > 0

**gamma**: Positive number

Rate of jump arrivals, γ > 0

Examples

```python
>>> from sympy.stats import GammaProcess, E, P, variance
>>> from sympy import symbols, Contains, Interval, Not
>>> t, d, x, l, g = symbols('t d x l g', positive=True)
>>> X = GammaProcess("X", l, g)
>>> E(X(t))
g*t/l
>>> variance(X(t)).simplify()
g*t/l**2
>>> X = GammaProcess('X', 1, 2)
```

(continues on next page)
>>> P(X(t) < 1).simplify()
lowergamma(2*t, 1)/gamma(2*t)
>>> P(Not((X(t) < 5) & (X(d) > 3)), Contains(t, Interval.Ropen(2, 4)) &
... Contains(d, Interval.Lopen(7, 8))).simplify()
-4*exp(-3) + 472*exp(-8)/3 + 1
>>> E(X(2) + x*E(X(5)))
10*x + 4

Matrix Distributions

sympy.stats.MatrixGamma(symbol, alpha, beta, scale_matrix)

Creates a random variable with Matrix Gamma Distribution.

The density of the said distribution can be found at [1].

Parameters

alpha: Positive Real number

Shape Parameter

beta: Positive Real number

Scale Parameter

scale_matrix: Positive definite real square matrix

Scale Matrix

Returns

RandomSymbol

Examples

>>> from sympy.stats import density, MatrixGamma
>>> from sympy import MatrixSymbol, symbols
>>> a, b = symbols('a b', positive=True)
>>> M = MatrixGamma('M', a, b, [[2, 1], [1, 2]])
>>> X = MatrixSymbol('X', 2, 2)
>>> density(M)(X).doit()
exp(Trace(Matrix([[[-2/3, 1/3],
[1/3, -2/3]])*X])/b)*Determinant(X)**(a - 3/2)/
(-3**a*sqrt(pi)*b**(2*a)*gamma(a)*gamma(a - 1/2))
>>> density(M)([[1, 0], [0, 1]]).doit()
exp(-4/(3*b))/(3**a*sqrt(pi)*b**(2*a)*gamma(a)*gamma(a - 1/2))
References

[R969]
sympy.stats.Wishart(symbol, n, scale_matrix)
creates a random variable with Wishart Distribution.
The density of the said distribution can be found at [1].

Parameters
- **n**: Positive Real number
  - Represents degrees of freedom
- **scale_matrix**: Positive definite real square matrix
  - Scale Matrix

Returns
- RandomSymbol

Examples

```python
>>> from sympy.stats import density, Wishart
>>> from sympy import MatrixSymbol, symbols
>>> n = symbols('n', positive=True)
>>> W = Wishart('W', n, [[2, 1], [1, 2]])
>>> X = MatrixSymbol('X', 2, 2)
>>> density(W)(X).doit()
exp(Trace(Matrix([-1/3, 1/6],
                 [1/6, -1/3])*X))*Determinant(X)**(n/2 - 3/2)/(2**n*3**(n/2)*sqrt(pi)*gamma(n/2)*gamma(n/2 - 1/2))
```

References

[R970]
sympy.stats.MatrixNormal(symbol, location_matrix, scale_matrix_1, scale_matrix_2)
creates a random variable with Matrix Normal Distribution.
The density of the said distribution can be found at [1].

Parameters
- **location_matrix**: Real `n x p` matrix
  - Represents degrees of freedom
- **scale_matrix_1**: Positive definite matrix
  - Scale Matrix of shape n x n
- **scale_matrix_2**: Positive definite matrix
  - Scale Matrix of shape p x p
**Returns**
RandomSymbol

**Examples**

```python
>>> from sympy import MatrixSymbol
>>> from sympy.stats import density, MatrixNormal
>>> M = MatrixNormal('M', [[1, 2]], [1], [[1, 0], [0, 1]])
>>> X = MatrixSymbol('X', 1, 2)
>>> density(M)(X).doit()
exp(-Trace(Matrix([[-1], [-2]]) + X.T)*(Matrix([[-1, -2]]) + X))/2)/(2*pi)
>>> density(M)([[3, 4]]).doit()
exp(-4)/(2*pi)
```

**References**

[R971]

**Compound Distribution**

```python
class sympy.stats.compound_rv.CompoundDistribution(dist)
```
Class for Compound Distributions.

**Parameters**

- **dist**: Distribution
  Distribution must contain a random parameter

**Examples**

```python
>>> from sympy.stats.compound_rv import CompoundDistribution
>>> from sympy.stats.crv_types import NormalDistribution
>>> from sympy.stats import Normal
>>> from sympy.abc import x
>>> X = Normal('X', 2, 4)
>>> N = NormalDistribution(X, 4)
>>> C = CompoundDistribution(N)
>>> C.set(Interval(-oo, oo)
>>> C.pdf(x, evaluate=True).simplify()
exp(-x**2/64 + x/16 - 1/16)/(8*sqrt(pi))
```
Interface

sympy.stats.P(condition, given_condition=None, numsamples=None, evaluate=True, **kwargs)

Probability that a condition is true, optionally given a second condition.

Parameters

condition : Combination of Relationals containing RandomSymbols

The condition of which you want to compute the probability

given_condition : Combination of Relationals containing RandomSymbols

A conditional expression. P(X > 1, X > 0) is expectation of X > 1 given X > 0

numsamples : int

Enables sampling and approximates the probability with this many samples

evaluate : Bool (defaults to True)

In case of continuous systems return unevaluated integral

Examples

```python
>>> from sympy.stats import P, Die
>>> from sympy import Eq
>>> X, Y = Die('X', 6), Die('Y', 6)
>>> P(X > 3)
1/2
>>> P(Eq(X, 5), X > 2)  # Probability that X == 5 given that X > 2
1/4
>>> P(X > Y)
5/12
```

class sympy.stats.Probability(prob, condition=None, **kwargs)

Symbolic expression for the probability.

Examples

```python
>>> from sympy.stats import Probability, Normal
>>> from sympy import Integral
>>> X = Normal("X", 0, 1)
>>> prob = Probability(X > 1)
>>> prob
Probability(X > 1)
```
Integral representation:

```python
>>> prob.rewrite(Integral)
Integral(sqrt(2)*exp(-_z**2/2)/(2*sqrt(pi)), (_z, 1, oo))
```

Evaluation of the integral:

```python
>>> prob.evaluate_integral()
sqrt(2)*(-sqrt(2)*sqrt(pi)*erf(sqrt(2)/2) + sqrt(2)*sqrt(pi))/
->(4*sqrt(pi))
```

```python
sympy.stats.E(expr, condition=None, numsamples=None, evaluate=True, **kwargs)
```

Returns the expected value of a random expression.

**Parameters**

- **expr**: Expr containing RandomSymbols
  The expression of which you want to compute the expectation value
- **given**: Expr containing RandomSymbols
  A conditional expression. \( E(X, X>0) \) is expectation of \( X \) given \( X > 0 \)
- **numsamples**: int
  Enables sampling and approximates the expectation with this many samples
- **evalf**: Bool (defaults to True)
  If sampling return a number rather than a complex expression
- **evaluate**: Bool (defaults to True)
  In case of continuous systems return unevaluated integral

**Examples**

```python
>>> from sympy.stats import E, Die
>>> X = Die('X', 6)
>>> E(X)
7/2
>>> E(2*X + 1)
8
```

```python
>>> E(X, X > 3) # Expectation of X given that it is above 3
5
```

class sympy.stats.Expectation(expr, condition=None, **kwargs)

Symbolic expression for the expectation.
Examples

```python
>>> from sympy.stats import Expectation, Normal, Probability, Poisson
>>> from sympy import symbols, Integral, Sum

>>> mu = symbols("mu")
>>> sigma = symbols("sigma", positive=True)
>>> X = Normal("X", mu, sigma)

>>> Expectation(X)
Expectation(X)

>>> Expectation(X).evaluate_integral().simplify()
mu
```

To get the integral expression of the expectation:

```python
>>> Expectation(X).rewrite(Integral)
Integral(sqrt(2)*X*exp(-(X - mu)**2/(2*sigma**2))/(2*sqrt(pi)*sigma), (X, -oo, oo))
```

The same integral expression, in more abstract terms:

```python
>>> Expectation(X).rewrite(Probability)
Integral(x*Probability(Eq(X, x)), (x, -oo, oo))
```

To get the Summation expression of the expectation for discrete random variables:

```python
>>> lamda = symbols('lamda', positive=True)
>>> Z = Poisson('Z', lamda)
>>> Expectation(Z).rewrite(Sum)
Sum(Z*lamda**Z*exp(-lamda)/factorial(Z), (Z, 0, oo))
```

This class is aware of some properties of the expectation:

```python
>>> from sympy.abc import a

>>> Y = Normal("Y", 1, 2)

>>> Expectation(a*X)
Expectation(a*X)

>>> Expectation(a*X + Y)
Expectation(a*X + Y)

To expand the Expectation into its expression, use expand():
```

```python
>>> Expectation(X + Y).expand()
Expectation(X) + Expectation(Y)
```

```python
>>> Expectation(a*X + Y).expand()
a*Expectation(X) + Expectation(Y)
```

```python
>>> Expectation((X + Y)*(X - Y)).expand()
Expectation(X**2) - Expectation(Y**2)
```

To evaluate the Expectation, use doit():

```python
>>> Expectation(X + Y).doit()
mu + 1
```

(continues on next page)
To prevent evaluating nested \texttt{Expectation}, use \texttt{doit(\text{deep=False})}

\begin{verbatim}
>>> Expectation(X + Expectation(Y)).doit(\text{deep=False})
mu + Expectation(Expectation(Y))

>>> Expectation(X + Expectation(Y + Expectation(2*X))).doit(\text{deep=False})
mu + Expectation(Expectation(Y + Expectation(2*X)))
\end{verbatim}

\textbf{sympy.stats.density} \texttt{(expr, condition=None, evaluate=True, numsamples=None, **kwargs)}

Probability density of a random expression, optionally given a second condition.

\textbf{Parameters}

- \texttt{expr} : \texttt{Expr} containing RandomSymbols
  - The expression of which you want to compute the density value
- \texttt{condition} : \texttt{Relational} containing RandomSymbols
  - A conditional expression. \texttt{density(X > 1, X > 0)} is density of \texttt{X > 1} given \texttt{X > 0}
- \texttt{numsamples} : \texttt{int}
  - Enables sampling and approximates the density with this many samples

\textbf{Explanation}

This density will take on different forms for different types of probability spaces. Discrete variables produce Dicts. Continuous variables produce Lambdas.

\textbf{Examples}

\begin{verbatim}
>>> from sympy.stats import density, Die, Normal
>>> from sympy import Symbol

>>> x = Symbol('x')
>>> D = Die('D', 6)
>>> X = Normal(x, 0, 1)

>>> density(D).dict
{1: 1/6, 2: 1/6, 3: 1/6, 4: 1/6, 5: 1/6, 6: 1/6}

>>> density(2*D).dict
{2: 1/6, 4: 1/6, 6: 1/6, 8: 1/6, 10: 1/6, 12: 1/6}

>>> density(X)(x)
\sqrt{2} \cdot \exp(-x^2/2)/(2\sqrt{\pi})
\end{verbatim}

\textbf{sympy.stats.entropy} \texttt{(expr, condition=None, **kwargs)}

Calculates entropy of a probability distribution.
Parameters

expression : the random expression whose entropy is to be calculated
condition : optional, to specify conditions on random expression
b : base of the logarithm, optional
   By default, it is taken as Euler’s number

Returns

result : Entropy of the expression, a constant

Examples

```python
>>> from sympy.stats import Normal, Die, entropy
>>> X = Normal('X', 0, 1)
>>> entropy(X)
log(2)/2 + 1/2 + log(pi)/2

>>> D = Die('D', 4)
>>> entropy(D)
log(4)
```

References

[R973], [R974], [R975]
sympy.stats.given(expr, condition=None, **kwargs)
Conditional Random Expression.

Explanation

From a random expression and a condition on that expression creates a new probability space from the condition and returns the same expression on that conditional probability space.

Examples

```python
>>> from sympy.stats import given, density, Die
>>> X = Die('X', 6)
>>> Y = given(X, X > 3)
>>> density(Y).dict
{4: 1/3, 5: 1/3, 6: 1/3}
```

Following convention, if the condition is a random symbol then that symbol is considered fixed.
```python
>>> X = Normal('X', 0, 1)
>>> Y = Normal('Y', 0, 1)
>>> pprint(density(X + Y, Y)(z), use_unicode=False)
\frac{2}{\sqrt{2}} \frac{\exp\left(-\frac{1}{2}(-Y + z)^2\right)}{2 \pi}
```

`sympy.stats.where(condition, given_condition=None, **kwargs)`

Returns the domain where a condition is True.

**Examples**

```python
>>> from sympy.stats import where, Die, Normal
>>> from sympy import And

>>> D1, D2 = Die('a', 6), Die('b', 6)
>>> a, b = D1.symbol, D2.symbol
>>> X = Normal('x', 0, 1)

>>> where(X**2<1)
Domain: (-1 < x) & (x < 1)

>>> where(X**2<1).set
Interval.open(-1, 1)

>>> where(And(D1<=D2, D2<3))
Domain: (Eq(a, 1) & Eq(b, 1)) | (Eq(a, 1) & Eq(b, 2)) | (Eq(a, 2) & Eq(b, 2))
```

`sympy.stats.variance(X, condition=None, **kwargs)`

Variance of a random expression.

\[
\text{variance}(X) = \mathbb{E}((X - \mathbb{E}(X))^2)
\]

**Examples**

```python
>>> from sympy.stats import Die, Bernoulli, variance
>>> from sympy import simplify, Symbol

>>> X = Die('X', 6)
>>> p = Symbol('p')
>>> B = Bernoulli('B', p, 1, 0)
```
```python
>>> variance(2*X)
35/3

>>> simplify(variance(B))
p*(1 - p)
```

```python
class sympy.stats.Variance(arg, condition=None, **kwargs)
Symbolic expression for the variance.
```

**Examples**

```python
>>> from sympy import symbols, Integral
>>> from sympy.stats import Normal, Expectation, Variance, Probability
>>> mu = symbols("mu", positive=True)
>>> sigma = symbols("sigma", positive=True)
>>> X = Normal("X", mu, sigma)
>>> Variance(X)
Variance(X)
```

Integral representation of the underlying calculations:

```python
>>> Variance(X).rewrite(Integral)
Integral(sqrt(2)*(X - Integral(sqrt(2)*X*exp(-(X - mu)**2/(2*sigma**2))/
→(2*sqrt(pi)*sigma), (X, -oo, oo)))**2*exp(-(X - mu)**2/(2*sigma**2))/
→(2*sqrt(pi)*sigma), (X, -oo, oo))
```

Integral representation, without expanding the PDF:

```python
>>> Variance(X).rewrite(Probability)
-Integral(x*Probability(Eq(X, x)), (x, -oo, oo))**2 +
→Integral(x**2*Probability(Eq(X, x)), (x, -oo, oo))
```

Rewrite the variance in terms of the expectation

```python
>>> Variance(X).rewrite(Expectation)
-Expectation(X)**2 + Expectation(X**2)
```

Some transformations based on the properties of the variance may happen:

```python
>>> from sympy.abc import a
>>> Y = Normal("Y", 0, 1)
>>> Variance(a*X)
Variance(a*X)
```

To expand the variance in its expression, use expand():

```python
>>> Variance(a*X).expand()
a**2*Variance(X)
```

(continues on next page)
>>> Variance(X + Y).expand()
2*Covariance(X, Y) + Variance(X) + Variance(Y)

sympy.stats.covariance(X, Y, condition=None, **kwargs)
Covariance of two random expressions.

**Explanation**

The expectation that the two variables will rise and fall together

\[ \text{covariance}(X, Y) = E((X - E(X))(Y - E(Y))) \]

**Examples**

```python
>>> from sympy.stats import Exponential, covariance
>>> from sympy import Symbol

>>> rate = Symbol('lambda', positive=True, real=True)
>>> X = Exponential('X', rate)
>>> Y = Exponential('Y', rate)

>>> covariance(X, X)
lambda**(-2)
>>> covariance(X, Y)
0
>>> covariance(X, Y + rate*X)
1/lambda
```

class sympy.stats.Covariance(arg1, arg2, condition=None, **kwargs)
Symbolic expression for the covariance.

**Examples**

```python
>>> from sympy.stats import Covariance
>>> from sympy.stats import Normal

>>> X = Normal("X", 3, 2)
>>> Y = Normal("Y", 0, 1)
>>> Z = Normal("Z", 0, 1)
>>> W = Normal("W", 0, 1)
>>> cexpr = Covariance(X, Y)
```

Evaluate the covariance, \( X \) and \( Y \) are independent, therefore zero is the result:

```python
>>> cexpr.evaluate_integral()
0
```
Rewrite the covariance expression in terms of expectations:

```python
>>> from sympy.stats import Expectation
>>> cexpr.rewrite(Expectation)
Expectation(X*Y) - Expectation(X)*Expectation(Y)
```

In order to expand the argument, use `expand()`:

```python
>>> from sympy.abc import a, b, c, d
>>> Covariance(a*X + b*Y, c*Z + d*W)
Covariance(a*X + b*Y, c*Z + d*W)
>>> Covariance(a*X + b*Y, c*Z + d*W).expand()
a*c*Covariance(X, Z) + a*d*Covariance(W, X) + b*c*Covariance(Y, Z) + b*d*Covariance(W, Y)
```

This class is aware of some properties of the covariance:

```python
>>> Covariance(X, X).expand()
Variance(X)
>>> Covariance(a*X, b*Y).expand()
a*b*Covariance(X, Y)
```

`sympy.stats.coskewness(X, Y, Z, condition=None, **kwargs)`
Calculates the co-skewness of three random variables.

**Parameters**

- **X** : RandomSymbol
  - Random Variable used to calculate coskewness
- **Y** : RandomSymbol
  - Random Variable used to calculate coskewness
- **Z** : RandomSymbol
  - Random Variable used to calculate coskewness
- **condition** : Expr containing RandomSymbols
  - A conditional expression

**Returns**

**coskewness** : The coskewness of the three random variables

**Explanation**

Mathematically Coskewness is defined as

\[
\text{coskewness}(X, Y, Z) = \frac{E[(X - E[X]) \cdot (Y - E[Y]) \cdot (Z - E[Z])]}{\sigma_X \sigma_Y \sigma_Z}
\]
Examples

```python
>>> from sympy.stats import coskewness, Exponential, skewness
>>> from sympy import symbols
>>> p = symbols('p', positive=True)
>>> X = Exponential('X', p)
>>> Y = Exponential('Y', 2*p)
>>> coskewness(X, Y, Y)
0
>>> coskewness(X, Y + X, Y + 2*X)
16*sqrt(5)/85
>>> coskewness(X + 2*Y, Y + X, Y + 2*X, X > 3)
9*sqrt(170)/85
>>> coskewness(Y, Y, Y) == skewness(Y)
True
>>> coskewness(X, Y + p*X, Y + 2*p*X)
4/(sqrt(1 + 1/(4*p**2))*sqrt(4 + 1/(4*p**2)))
```

References

[R976] sympy.stats.median(X, evaluate=True, **kwargs)
Calculates the median of the probability distribution.

**Parameters**

X: The random expression whose median is to be calculated.

**Returns**

The FiniteSet or an Interval which contains the median of the
random expression.

**Explanation**

Mathematically, median of Probability distribution is defined as all those values of \( m \) for
which the following condition is satisfied

\[
P(X \leq m) \geq \frac{1}{2} \text{ and } P(X \geq m) \geq \frac{1}{2}
\]

**Examples**

```python
>>> from sympy.stats import Normal, Die, median
>>> N = Normal('N', 3, 1)
>>> median(N)
{3}
>>> D = Die('D')
>>> median(D)
{3, 4}
```
References

[R977]
sympy.stats.std(X, condition=None, **kwargs)
Standard Deviation of a random expression

\[ \text{std}(X) = \sqrt{E((X - E(X))^2)} \]

Examples

```python
>>> from sympy.stats import Bernoulli, std
>>> from sympy import Symbol, simplify

>>> p = Symbol('p')
>>> B = Bernoulli('B', p, 1, 0)

>>> simplify(std(B))
sqrt(p*(1 - p))
```

sympy.stats.quantile(expr, evaluate=True, **kwargs)
Return the \( p^{th} \) order quantile of a probability distribution.

Explanation

Quantile is defined as the value at which the probability of the random variable is less than or equal to the given probability.

\[ Q(p) = \inf\{x \in (-\infty, \infty) : p \leq F(x)\} \]

Examples

```python
>>> from sympy.stats import quantile, Die, Exponential
>>> from sympy import Symbol, pprint

>>> p = Symbol("p")

>>> l = Symbol("lambda", positive=True)
>>> X = Exponential("x", l)
>>> quantile(X)(p)
-log(1 - p)/lambda

>>> D = Die("d", 6)
>>> pprint(quantile(D)(p), use_unicode=False)
/nan for Or(p > 1, p < 0)
| 1 for p <= 1/6
| 2 for p <= 1/3
```

(continues on next page)
sympy.stats.sample(expr, condition=None, size=(), library='scipy', numsamples=1, seed=None, **kwargs)

A realization of the random expression.

Parameters

- `expr`: Expression of random variables
  Expression from which sample is extracted
- `condition`: Expr containing RandomSymbols
  A conditional expression
- `size`: int, tuple
  Represents size of each sample in numsamples
- `library`: str
  - 'scipy': Sample using scipy
  - 'numpy': Sample using numpy
  - 'pymc': Sample using PyMC
  Choose any of the available options to sample from as string, by default is 'scipy'
- `numsamples`: int
  Number of samples, each with size as `size`.
  Deprecated since version 1.9.

The `numsamples` parameter is deprecated and is only provided for compatibility with v1.8. Use a list comprehension or an additional dimension in `size` instead. See `sympy.stats.sample(numsamples=n)` (page 220) for details.

- `seed`: An object to be used as seed by the given external library for sampling `expr`. Following is the list of possible types of object for the supported libraries,
  - 'scipy': int, numpy.random.RandomState, numpy.random.Generator
  - 'numpy': int, numpy.random.RandomState, numpy.random.Generator
  - 'pymc': int
Optional, by default None, in which case seed settings related to the given library will be used. No modifications to environment’s global seed settings are done by this argument.

**Returns**

- sample: float/list/numpy.ndarray
  - one sample or a collection of samples of the random expression.
  - sample(X) returns float/numpy.float64/numpy.int64 object.
  - sample(X, size=int/tuple) returns numpy.ndarray object.

**Examples**

```python
>>> from sympy.stats import Die, sample, Normal, Geometric
>>> X, Y, Z = Die('X', 6), Die('Y', 6), Die('Z', 6) # Finite Random Variable
>>> die_roll = sample(X + Y + Z)
>>> die_roll
3
>>> N = Normal('N', 3, 4) # Continuous Random Variable
>>> samp = sample(N)
>>> samp in N.pspace.domain.set
True
>>> samp = sample(N, N>0)
>>> samp > 0
True
>>> samp_list = sample(N, size=4)
>>> [sam in N.pspace.domain.set for sam in samp_list]
[True, True, True, True]
>>> sample(N, size = (2,3))
array([[5.42519758, 6.40207856, 4.94991743],
       [1.85819627, 6.83403519, 1.9412172 ]])
>>> G = Geometric('G', 0.5) # Discrete Random Variable
>>> samp_list = sample(G, size=3)
>>> samp_list
[1, 3, 2]
>>> [sam in G.pspace.domain.set for sam in samp_list]
[True, True, True]
>>> MN = Normal("MN", [3, 4], [[2, 1], [1, 2]]) # Joint Random Variable
>>> samp_list = sample(MN, size=4)
>>> samp_list
[array([2.85768055, 3.38954165]),
 array([4.1163337, 4.3176591 ]),
 array([0.79115232, 1.63232916]),
 array([4.01747268, 3.96716083])]
>>> [tuple(sam) in MN.pspace.domain.set for sam in samp_list]
[True, True, True, True]
```

Changed in version 1.7.0: sample used to return an iterator containing the samples instead of value.

Changed in version 1.9.0: sample returns values or array of values instead of an iterator and numsamples is deprecated.
sympy.stats.sample_iter(expr, condition=None, size=(), library='scipy',
numsamples=oo, seed=None, **kwargs)

Returns an iterator of realizations from the expression given a condition.

Parameters
- **expr**: Expr
  Random expression to be realized

- **condition**: Expr, optional
  A conditional expression

- **size**: int, tuple
  Represents size of each sample in numsamples

- **numsamples**: integer, optional
  Length of the iterator (defaults to infinity)

- **seed**: An object to be used as seed by the given external library for sampling
  expr. Following is the list of possible types of object for the supported
  libraries,

  - 'scipy': int, numpy.random.RandomState, numpy.random.Generator
  - 'numpy': int, numpy.random.RandomState, numpy.random.Generator
  - 'pymc': int

  Optional, by default None, in which case seed settings related to the
  given library will be used. No modifications to environment’s global
  seed settings are done by this argument.

Returns
- **sample_iter**: iterator object
  iterator object containing the sample/samples of given expr

Examples

```python
>>> from sympy.stats import Normal, sample_iter
>>> X = Normal('X', 0, 1)
>>> expr = X*X + 3
>>> iterator = sample_iter(expr, numsamples=3)
>>> list(iterator)
[12, 4, 7]
```

See also:

- `sample` (page 3055), `sampling_P` (page 3060), `sampling_E` (page 3060)

sympy.stats.factorial_moment(X, n, condition=None, **kwargs)

The factorial moment is a mathematical quantity defined as the expectation or average
of the falling factorial of a random variable.

\[
factorial-moment(X, n) = E(X(X - 1)(X - 2)...(X - n + 1))
\]
Parameters
- \( n \): A natural number, \( n \)-th factorial moment.
- **condition**: Expr containing RandomSymbols
  A conditional expression.

Examples
```python
>>> from sympy.stats import factorial_moment, Poisson, Binomial
>>> from sympy import Symbol, S
>>> lamda = Symbol('lamda')
>>> X = Poisson('X', lamda)
>>> factorial_moment(X, 2)
lamda**2
>>> Y = Binomial('Y', 2, S.Half)
>>> factorial_moment(Y, 2)
1/2
>>> factorial_moment(Y, 2, Y > 1) # find factorial moment for Y > 1
2
```

References
[R978], [R979]

`sympy.stats.kurtosis`(X, condition=None, **kwargs)
Characterizes the tails/outliers of a probability distribution.

**Parameters**
- **condition**: Expr containing RandomSymbols
  A conditional expression. kurtosis(X, X>0) is kurtosis of X given X > 0

**Explanation**
Kurtosis of any univariate normal distribution is 3. Kurtosis less than 3 means that the distribution produces fewer and less extreme outliers than the normal distribution.

\[
kurtosis(X) = E(((X - E(X))/\sigma_X)^4)
\]

Examples
```python
>>> from sympy.stats import kurtosis, Exponential, Normal
>>> X = Normal('X', 0, 1)
>>> kurtosis(X)
3
>>> kurtosis(X, X > 0) # find kurtosis given X > 0
(-4/pi - 12/pi**2 + 3)/(1 - 2/pi)**2
```
```python
rate = Symbol('lambda', positive=True, real=True)
Y = Exponential('Y', rate)
kurtosis(Y)
9
```

**References**

[R980], [R981]

```python
sympy.stats.skewness(X, condition=None, **kwargs)
Measure of the asymmetry of the probability distribution.

Parameters:
condition : Expr containing RandomSymbols
A conditional expression. skewness(X, X>0) is skewness of X given X > 0

Explanation

Positive skew indicates that most of the values lie to the right of the mean.

\[
skewness(X) = E(((X - E(X))/\sigma_X)^3)
\]

Examples

```python
from sympy.stats import skewness, Exponential, Normal
from sympy import Symbol
X = Normal('X', 0, 1)
skewness(X)
0
skewness(X, X > 0)  # find skewness given X > 0
(-sqrt(2)/sqrt(pi) + 4*sqrt(2)/pi**2/3)/(1 - 2/pi)**2
```

```python
rate = Symbol('lambda', positive=True, real=True)
Y = Exponential('Y', rate)
skewness(Y)
2
```

```python
sympy.stats.correlation(X, Y, condition=None, **kwargs)
Correlation of two random expressions, also known as correlation coefficient or Pearson’s correlation.
```
**Explanation**

The normalized expectation that the two variables will rise and fall together

\[ \text{correlation}(X, Y) = E((X - E(X))(Y - E(Y)))/\sigma_x \sigma_y \]

**Examples**

```python
>>> from sympy.stats import Exponential, correlation
>>> from sympy import Symbol

>>> rate = Symbol('lambda', positive=True, real=True)
>>> X = Exponential('X', rate)
>>> Y = Exponential('Y', rate)

>>> correlation(X, X)
1
>>> correlation(X, Y)
0
>>> correlation(X, Y + rate*X)
1/sqrt(1 + lambda**(-2))
```

`sympy.stats.rv.sampling_density(expr, given_condition=None, library='scipy', numsamples=1, seed=None, **kwargs)`

Sampling version of density.

**See also:**
- `density` (page 3047), `sampling_P` (page 3060), `sampling_E` (page 3060)

`sympy.stats.rv.sampling_P(condition, given_condition=None, library='scipy', numsamples=1, ev alf=True, seed=None, **kwargs)`

Sampling version of P.

**See also:**
- `P` (page 3044), `sampling_E` (page 3060), `sampling_density` (page 3060)

`sympy.stats.rv.sampling_E(expr, given_condition=None, library='scipy', numsamples=1, evalf=True, seed=None, **kwargs)`

Sampling version of E.

**See also:**
- `P` (page 3044), `sampling_P` (page 3060), `sampling_density` (page 3060)

`class sympy.stats.Moment(X, n, c=0, condition=None, **kwargs)`

Symbolic class for Moment
Examples

```python
>>> from sympy import Symbol, Integral
>>> from sympy.stats import Normal, Expectation, Probability, Moment
>>> mu = Symbol('mu', real=True)
>>> sigma = Symbol('sigma', positive=True)
>>> X = Normal('X', mu, sigma)
>>> M = Moment(X, 3, 1)

To evaluate the result of Moment use `doit`:

```python
>>> M.doit()
```

mu**3 - 3*mu**2 + 3*mu*sigma**2 + 3*mu - 3*sigma**2 - 1

Rewrite the Moment expression in terms of Expectation:

```python
>>> M.rewrite(Expectation)
```

Expectation((X - 1)**3)

Rewrite the Moment expression in terms of Probability:

```python
>>> M.rewrite(Probability)
```

Integral((x - 1)**3*Probability(Eq(X, x)), (x, -oo, oo))

Rewrite the Moment expression in terms of Integral:

```python
>>> M.rewrite(Integral)
```

Integral(sqrt(2)*(X - 1)**3*exp(-(X - mu)**2/(2*sigma**2))/
→(2*sqrt(pi)*sigma), (X, -oo, oo))

```

sympy.stats.moment(X, n, c=0, condition=None, *, evaluate=True, **kwargs)
```

Return the nth moment of a random expression about c.

\[
moment(X, n, c) = E((X - c)^n)
\]

Default value of c is 0.

Examples

```python
>>> from sympy.stats import Die, moment, E
>>> X = Die('X', 6)
>>> moment(X, 1, 6)
-5/2
>>> moment(X, 2)
91/6
>>> moment(X, 1) == E(X)
True
```

class sympy.stats.CentralMoment(X, n, condition=None, **kwargs)

Symbolic class Central Moment
Examples

```python
>>> from sympy import Symbol, Integral
>>> from sympy.stats import Normal, Expectation, Probability,
    CentralMoment
>>> mu = Symbol('mu', real=True)
>>> sigma = Symbol('sigma', positive=True)
>>> X = Normal('X', mu, sigma)
>>> CM = CentralMoment(X, 4)

To evaluate the result of CentralMoment use `doit`:

```python
>>> CM.doit().simplify()
```

3*sigma**4

Rewrite the CentralMoment expression in terms of Expectation:

```python
>>> CM.rewrite(Expectation)
```

```
Expectation((X - Expectation(X))**4)
```

Rewrite the CentralMoment expression in terms of Probability:

```python
>>> CM.rewrite(Probability)
```

```
Integral((x - Integral(x*Probability(True), (x, -oo,
    oo))))**4*Probability(Eq(X, x)), (x, -oo, oo))
```

Rewrite the CentralMoment expression in terms of Integral:

```python
>>> CM.rewrite(Integral)
```

```
Integral(sqrt(2)*(X - Integral(sqrt(2)*X*exp(-(X - mu)**2/(2*sigma**2))/
    (2*sqrt(pi)*sigma), (X, -oo, oo)))**4*exp(-(X - mu)**2/(2*sigma**2))/
    (2*sqrt(pi)*sigma), (X, -oo, oo))
```

**sympy.stats.cmoment**(X, n, condition=None, *, evaluate=True, **kwargs)

Return the nth central moment of a random expression about its mean.

\[ cmoment(X, n) = E((X - E(X))^n) \]

Examples

```python
>>> from sympy.stats import Die, cmoment, variance
>>> X = Die('X', 6)
>>> cmoment(X, 3)
0
>>> cmoment(X, 2)
35/12
>>> cmoment(X, 2) == variance(X)
```

```
True
```

**class sympy.stats.ExpectationMatrix**(expr, condition=None)

Expectation of a random matrix expression.
Examples

```python
from sympy.stats import ExpectationMatrix, Normal
from sympy.stats.rv import RandomMatrixSymbol
from sympy import symbols, MatrixSymbol, Matrix

k = symbols("k")
A, B = MatrixSymbol("A", k, k), MatrixSymbol("B", k, k)
X, Y = RandomMatrixSymbol("X", k, 1), RandomMatrixSymbol("Y", k, 1)

ExpectationMatrix(X)
ExpectationMatrix(A*X).shape

>>> ExpectationMatrix(A*X).shape
(k, 1)
```

To expand the expectation in its expression, use `expand()`:

```python
ExpectationMatrix(A*X + B*Y).expand()
```

To evaluate the `ExpectationMatrix`, use `doit()`:

```python
N11, N12 = Normal('N11', 11, 1), Normal('N12', 12, 1)
N21, N22 = Normal('N21', 21, 1), Normal('N22', 22, 1)
M11, M12 = Normal('M11', 1, 1), Normal('M12', 2, 1)
M21, M22 = Normal('M21', 3, 1), Normal('M22', 4, 1)
x1 = Matrix([[N11, N12], [N21, N22]])
x2 = Matrix([[M11, M12], [M21, M22]])
ExpectationMatrix(x1 + x2).doit()
```

```python
Matrix([[12, 14], [24, 26]])
```

**class sympy.stats.VarianceMatrix(arg, condition=None)**

Variance of a random matrix probability expression. Also known as Covariance matrix, auto-covariance matrix, dispersion matrix, or variance-covariance matrix.

Examples

```python
from sympy.stats import VarianceMatrix
from sympy.stats.rv import RandomMatrixSymbol
from sympy import symbols, MatrixSymbol, Matrix

k = symbols("k")
A, B = MatrixSymbol("A", k, k), MatrixSymbol("B", k, k)
X, Y = RandomMatrixSymbol("X", k, 1), RandomMatrixSymbol("Y", k, 1)

VarianceMatrix(X)
VarianceMatrix(X).shape

>>> VarianceMatrix(X).shape
(k, k)
```

To expand the variance in its expression, use `expand()`:
class `sympy.stats.CrossCovarianceMatrix`(arg1, arg2, condition=None)

Covariance of a random matrix probability expression.

Examples

```python
>>> from sympy.stats import CrossCovarianceMatrix
>>> from sympy.stats.rv import RandomMatrixSymbol
>>> from sympy import symbols, MatrixSymbol
>>> k = symbols("k")
>>> A, B = MatrixSymbol("A", k, k), MatrixSymbol("B", k, k)
>>> C, D = MatrixSymbol("C", k, k), MatrixSymbol("D", k, k)
>>> X, Y = RandomMatrixSymbol("X", k, 1), RandomMatrixSymbol("Y", k, 1)
>>> Z, W = RandomMatrixSymbol("Z", k, 1), RandomMatrixSymbol("W", k, 1)
>>> CrossCovarianceMatrix(X, Y)
CrossCovarianceMatrix(X, Y)
>>> CrossCovarianceMatrix(X, Y).shape
(k, k)
```

To expand the covariance in its expression, use `expand()`:

```python
>>> CrossCovarianceMatrix(X + Y, Z).expand()
CrossCovarianceMatrix(X, Z) + CrossCovarianceMatrix(Y, Z)
>>> CrossCovarianceMatrix(A*X, Y).expand()
A*CrossCovarianceMatrix(X, Y)
>>> CrossCovarianceMatrix(A*X, B.T*Y).expand()
A*CrossCovarianceMatrix(X, Y)*B
```

Mechanics

SymPy Stats employs a relatively complex class hierarchy.

RandomDomains are a mapping of variables to possible values. For example, we might say that the symbol `Symbol('x')` can take on the values `{1, 2, 3, 4, 5, 6}`.

```python
class sympy.stats.rv.RandomDomain
```

A PSpace, or Probability Space, combines a RandomDomain with a density to provide probabilistic information. For example the above domain could be enhanced by a finite density `{1:1/6, 2:1/6, 3:1/6, 4:1/6, 5:1/6, 6:1/6}` to fully define the roll of a fair die named `x`.

```python
class sympy.stats.rv.PSpace
```
A RandomSymbol represents the PSpace’s symbol ‘x’ inside of SymPy expressions.

```python
class sympy.stats.rv.RandomSymbol
```

The RandomDomain and PSpace classes are almost never directly instantiated. Instead they are subclassed for a variety of situations.

RandomDomains and PSpaces must be sufficiently general to represent domains and spaces of several variables with arbitrarily complex densities. This generality is often unnecessary. Instead we often build SingleDomains and SinglePSpaces to represent single, univariate events and processes such as a single die or a single normal variable.

```python
class sympy.stats.rv.SinglePSpace
class sympy.stats.rv.SingleDomain
```

Another common case is to collect together a set of such univariate random variables. A collection of independent SinglePSpaces or SingleDomains can be brought together to form a ProductDomain or ProductPSpace. These objects would be useful in representing three dice rolled together for example.

```python
class sympy.stats.rv.ProductDomain
class sympy.stats.rv.ProductPSpace
```

The Conditional adjective is added whenever we add a global condition to a RandomDomain or PSpace. A common example would be three independent dice where we know their sum to be greater than 12.

```python
class sympy.stats.rv.ConditionalDomain
```

We specialize further into Finite and Continuous versions of these classes to represent finite (such as dice) and continuous (such as normals) random variables.

```python
class sympy.stats.frv.FiniteDomain
class sympy.stats.frv.FinitePSpace
class sympy.stats.crv.ContinuousDomain
class sympy.stats.crv.ContinuousPSpace
```

Additionally there are a few specialized classes that implement certain common random variable types. There is for example a DiePSpace that implements SingleFinitePSpace and a NormalPSpace that implements SingleContinuousPSpace.

```python
class sympy.stats.frv_types.DiePSpace
class sympy.stats.crv_types.NormalPSpace
```

RandomVariables can be extracted from these objects using the PSpace.values method.

As previously mentioned SymPy Stats employs a relatively complex class structure. Inheritance is widely used in the implementation of end-level classes. This tactic was chosen to balance between the need to allow SymPy to represent arbitrarily defined random variables and optimizing for common cases. This complicates the code but is structured to only be important to those working on extending SymPy Stats to other random variable types.

Users will not use this class structure. Instead these mechanics are exposed through variable creation functions Die, Coin, FiniteRV, Normal, Exponential, etc.... These build the appropriate SinglePSpaces and return the corresponding RandomVariable. Conditional and Product
spaces are formed in the natural construction of SymPy expressions and the use of interface functions E, Given, Density, etc....

```python
sympy.stats.Die()

sympy.stats.Normal()
```

There are some additional functions that may be useful. They are largely used internally.

```python
sympy.stats.rv.random_symbols(expr)

  Returns all RandomSymbols within a SymPy Expression.

sympy.stats.rv.pspace(expr)

  Returns the underlying Probability Space of a random expression.

  For internal use.
```

**Examples**

```python
>>> from sympy.stats import pspace, Normal

>>> X = Normal('X', 0, 1)

>>> pspace(2*X + 1) == X.pspace
True
```

```python
sympy.stats.rv.rs_swap(a, b)

  Build a dictionary to swap RandomSymbols based on their underlying symbol.

  i.e. if X = ('x', pspace1) and Y = ('x', pspace2) then X and Y match and the key, value pair {X:Y} will appear in the result

  Inputs: collections a and b of random variables which share common symbols  
  Output: dict mapping RVs in a to RVs in b
```
The contributing guide goes over the details necessary to contribute to SymPy. See also the full Development Workflow guide on the SymPy wiki.

Content

6.1 Development Environment Setup

The first step to contributing to the code base is creating your development environment.

6.1.1 Git Setup

SymPy is available on GitHub and uses Git for source control. The workflow is such that code is pulled and pushed to and from the main repository. Install the respective version of Git for your operating system to start development.

Note: Refer to the installation instructions in the Git installation instructions. Learn about the basic git commands in this Git Handbook or any other sources on the internet.

6.1.2 Get the SymPy Code

It is recommended practice to create a fork of the SymPy project for your development purposes. Create your own fork of the SymPy project (if you have not yet). Go to the SymPy GitHub repository:

https://github.com/sympy/sympy

You will now have a fork at <https://github.com/<your-user-name>/sympy>. Then, on your machine browse to where you would like to store SymPy, and clone (download) the latest code from SymPy’s original repository (about 77 MiB):

$ git clone https://github.com/<your-user-name>/sympy

You must configure the remote repositories for collaboration with the upstream project:
$ cd sympy
$ git remote add upstream https://github.com/sympy/sympy

After the configuration, your setup should be similar to this:

$ git remote -v
origin https://github.com/<your-user-name>/sympy (fetch)
origin https://github.com/<your-user-name>/sympy (push)
upstream https://github.com/sympy/sympy (fetch)
upstream https://github.com/sympy/sympy (push)

For further development, it is recommended to create a development branch.

$ git checkout -b dev-branch

The new branch can be of any name.

### 6.1.3 Virtual Environment Setup

You may want to take advantage of using virtual environments to isolate your development version of SymPy from any system wide installed versions, e.g. from `apt-get install python-sympy`.

We recommend using `conda` to create a virtual environment:

$ conda create -n sympy-dev python=3 mpmath flake8 flake8-comprehensions

You now have a environment that you can use for testing your development copy of SymPy. For example, clone your SymPy fork from Github:

$ git clone git@github.com:<your-github-username>/sympy.git
$ cd sympy

Now activate the environment:

$ conda activate sympy-dev

### 6.1.4 Run the Tests

There are several ways of running SymPy tests but the easiest is to use the `bin/test` script, consult the wiki details on running tests.

The script takes a number of options and arguments and then passes them to `sympy.test(*paths, **kwargs)`. Run `bin/test --help` for all supported arguments.

Run all tests by using the command:

$ bin/test

To run tests for a specific file, use:

$ bin/test test_basic
Where test_basic is from file sympy/core/basic.py.

To run tests for modules, use:

$ bin/test /core /utilities

This will run tests for the core and utilities modules.

Similarly, run quality tests with:

$ bin/test code_quality

### 6.2 Dependencies

This page lists the hard and optional dependencies of SymPy.

There are several packages that, when installed, can enable certain additional SymPy functionality. Most users and contributors will not need to install any of the packages mentioned below (except for the hard dependencies), unless they intend to use or contribute to the parts of SymPy that can use those packages.

Every dependency listed below can be installed with conda via conda-forge, and most can also be installed with pip.

This page does not list packages which themselves depend on SymPy, only those packages that SymPy depends on. An incomplete list of packages that depend on SymPy can be found on the [main SymPy webpage](https://docs.sympy.org/latest/install.html), and a more complete list can be found on GitHub or libraries.io.

#### 6.2.1 Hard Dependencies

SymPy only has one hard dependency, which is required for it to work: mpmath.

- **mpmath**: mpmath is a pure Python package for arbitrary precision arithmetic. It is used under the hood whenever SymPy calculates the floating-point value of a function, e.g., when using `evalf` (page 1111).

  SymPy cannot function without mpmath and will fail to import if it is not installed. If you get an error like

  ```
  ImportError: SymPy now depends on mpmath as an external library. See https://docs.sympy.org/latest/install.html#mpmath for more information.
  ```

  this means that you did not install mpmath correctly. *This page* (page 2) explains how to install it.

  Most methods of installing SymPy, such as the ones outlined in the *installation* (page 1) guide, will install mpmath automatically. You typically only need to install mpmath manually if you did not actually install SymPy, e.g., if you are developing directly on SymPy in the git repository.
6.2.2 Optional Dependencies

These dependencies are not required to use SymPy. The vast majority of SymPy functions do not require them, however, a few functions such as plotting and automatic wrapping of code generated functions require additional dependencies to function.

Additionally, as a contributor, when running the SymPy tests, some tests will be skipped if a dependency they require is not installed. The GitHub Actions CI which is run on every SymPy pull request will automatically install these dependencies in the “optional-dependencies” build, but you may wish to install them locally if you are working on a part of SymPy that uses them.

Recommended Optional Dependencies

These dependencies are not required for SymPy to function, but it is recommended that all users install them if they can, as they will improve the general performance of SymPy.

- **gmpy2**: gmpy2 is a Python wrapper for the GMP multiple-precision library. It provides large integers that are faster than the built-in Python int. When gmpy2 is installed, it is used automatically by certain core functions that operate on integers, such as the polys (page 2416). See Reference docs for the Poly Domains (page 2584) for more details. SymPy uses gmpy2 automatically when it is installed. No further action is required to enable it.

  The polys themselves are used by many parts of SymPy, such as the integration algorithms, simplification algorithms like collect() and factor(), the matrices, and some parts of the core. Thus, installing gmpy2 can speed up many parts of SymPy. It is not a required dependency of SymPy because it makes use of a non-Python library (GMP), which is also non-BSD licensed. However, we recommended all users who are able to to install gmpy2 to get a better SymPy experience.

Interactive Use

SymPy is designed to be used both interactively and as a library. When used interactively, SymPy is able to interface with IPython and Jupyter notebooks.

- **IPython**: The init_session() (page 2189) function and isymy command will automatically start IPython if it is installed. In addition to the usual benefits of using IPython, this enables interactive plotting with matplotlib. Also some flags such as auto_symbols and auto_int_to_Integer will only work in IPython.

  The IPython package is required to run some of the tests in sympy/interactive.

- **Jupyter Notebook and Qt Console**: SymPy expressions automatically print using MathJax in the Jupyter Notebook and with LaTeX Qt Console (if LaTeX (page 3071) is installed).
Printing

The `preview()` (page 2256) function automatically converts SymPy expressions into images rendered with LaTeX. `preview()` can either save the image to a file or show it with a viewer.

- **LaTeX**: A LaTeX distributions such as TeXLive or MiKTeX is required for `preview()` (page 2256) to function.

Parsing

Several functions in the `sympy.parsing` (page 2195) submodule require external dependencies to function. Note that not all parsers require external modules at this time. The Python (`parse_expr()` (page 2195)), Mathematca (`parse_mathematica()` (page 2198)), and Maxima (`parse_maxima()` (page 2198)) parsers do not require any external dependencies.

- **antlr-python-runtime**: Antlr is used for the LaTeX parser (page 2202) and Autolev (page 1771) parsers. They both require the Antlr Python runtime to be installed. The package for this is called antlr-python-runtime with conda and antlr4-python3-runtime with pip. Also be aware that the version of the Antlr Python runtime must match the version that was used to compile the LaTeX and Autolev parsers (4.10).

- **Clang Python Bindings**: The C parser (sympy.parsing.c.parse_c) requires the Clang Python bindings. The package for this is called python-clang with conda and clang with pip.

- **lfortran**: The Fortran parser (in sympy.parsing.fortran) requires LFortran.

Logic

The `satisfiable()` (page 1228) function includes a pure Python implementation of the DPLL satisfiability algorithm. But it can optionally use faster C SAT solvers if they are installed. Note that `satisfiable()` is also used by `ask()` (page 249).

- **pycosat**: Pycosat is used automatically if it is installed. The use of pycosat can be forced by using `satisfiable(algorithm='pycosat')`.

- **pysat**: Pysat is a library which wraps many SAT solvers. It can also be used as a backend to `satisfiable()`. Presently, only Minisat is implemented, using `satisfiable(algorithm=minisat22')`.

Plotting

The `sympy.plotting.plot` (page 2904) module makes heavy use of external plotting libraries to render plots. The primarily plotting module that is supported is Matplotlib.

- **matplotlib**: Most plotting functionality requires the Matplotlib plotting library. Without Matplotlib installed, most plotting functions will either fail or give rudimentary text plots (page 2956).

- **pyglet**: SymPy has a submodule `sympy.plotting.pygletplot` (page 2953) that can be used to interface with the pyglet module to do 2D and 3D plotting.
lambdify

`lambdify()` (page 2173) is a function that converts SymPy expressions into functions that can be evaluated numerically using various libraries as backends. `lambdify` is the primary vehicle by which users interface between SymPy and these libraries. It is the standard way to convert a symbolic SymPy expression into an evaluable numeric function.

In principle, `lambdify` can interface with any external library if the user passes in an appropriate namespace dictionary as the third argument, but by default, `lambdify` is aware of several popular numeric Python libraries. These libraries are enabled as backends in `lambdify` with built-in translations to convert SymPy expressions into the appropriate functions for those libraries.

- **NumPy**: By default, if it is installed, `lambdify` creates functions using NumPy (if NumPy is not installed, `lambdify` produces functions using the standard library `math` module, although this behavior is primarily provided for backwards compatibility).
- **SciPy**: If SciPy is installed, `lambdify` will use it automatically. SciPy is needed to `lambdify` certain special functions that are not included in NumPy.
- **CuPy**: CuPy is a library that provides a NumPy compatible interface for CUDA GPUs. `lambdify` can produce CuPy compatible functions using `lambdify(modules='cupy')`.
- **Jax**: JAX is a library that uses XLA to compile and run NumPy programs on GPUs and TPUs. `lambdify` can produce JAX compatibly functions using `lambdify(modules='jax')`.
- **TensorFlow**: TensorFlow is a popular machine learning library. `lambdify` can produce TensorFlow compatible functions using `lambdify(modules='tensorflow')`.
- **NumExpr**: NumExpr is a fast numerical expression evaluator for NumPy. `lambdify` can produce NumExpr compatible functions using `lambdify(modules='numexpr')`.
- **mpmath**: `lambdify` can also produce mpmath compatible functions. Note that mpmath is already a required dependency (page 3069) of SymPy. This functionality is useful for converting a SymPy expression to a function for use with pure mpmath.

**Code Generation**

SymPy can generate code (page 1153) for a large number of languages by converting SymPy expressions into valid code for those languages. It also has functionality for some languages to automatically compile and run the code.

Note that the dependencies below are not a list of supported languages that SymPy can generate code for. Rather it is a list of packages that SymPy can interface with in some way. For most languages that SymPy supports code generation, it simply generates a string representing the code for that language, so no dependency on that language is required to use the code generation functionality. A dependency is typically only required for features that automatically take the generated code and compile it to a function that can be used within Python. Note that `lambdify()` (page 2173) is a special case of this, but its dependencies are listed above (page 3072).
**Autowrap**

- **NumPy**: NumPy and, optionally, its subpackage `f2py`, can be used to generate Python functions using the `autowrap()` (page 2112) or `ufuncify()` (page 2114) functions.
- **Cython**: Cython can be used as a backend for `autowrap()` (page 2112) or `ufuncify()` (page 2114). Cython is also used in some of the `sympy.codegen` tests to compile some examples.
- **Compilers**: `autowrap()` (page 2112), `ufuncify()` (page 2114), and related functions rely on a compiler to compile the generated code to a function. Most standard C, C++, and Fortran compilers are supported, including Clang/LLVM, GCC, and ifort.

**Code Printers**

Most code printers generate Python strings, and therefore do not require the given library or language compiler as a dependency. However, a few code printers generate Python functions instead of strings:

- **Aesara**: The `sympy.printing.aesaracode` (page 2241) module contains functions to convert SymPy expressions into a functions using the Aesara (previously Theano) library. The Aesara code generation functions return Aesara graph objects.
- **llvmlite**: The `sympy.printing.llvmjitcode` module supports generating LLVM Jit from a SymPy expression. The functions make use of `llvmlite`, a Python wrapper around LLVM. The `llvm_callable()` function generates callable functions.
- **TensorFlow**: The `sympy.printing.tensorflow` module supports generating functions using the TensorFlow, a popular machine learning library. Unlike the above two examples, `tensorflow_code()` function does generate Python strings. However, `tensorflow` is imported if available in order to automatically detect the TensorFlow version. If it is not installed, the `tensorflow_code()` function assumes the latest supported version of TensorFlow.

**Testing-Only Dependencies**

- **Wurlitzer**: Wurlitzer is a Python package that allows capturing output from C extensions. It is used by some of the tests in the `sympy.codegen` submodule. It is only used by the test suite. It is not used by any end-user functionality. If it is not installed, some tests will be skipped.
- **Cython**: Cython is also used in some of the `sympy.codegen` tests to compile some examples.
- **Compilers**: The various compilers (page 3073) mentioned above are used in some of the codegen and autowrap tests if they are installed.
Statistics

The `sympy.stats.sample()` function uses an external library to produce samples from the given distribution. At least one of the following libraries is required to use the sampling functionality of `sympy.stats`.

- **SciPy**: `sample(library='scipy')` is the default. This uses `scipy.stats`.
- **NumPy**: `sample(library='numpy')` uses the NumPy random module.
- **pymc**: `sample(library='pymc')` uses PyMC to do sampling.

Optional SymEngine Backend

- **python-symengine**: SymEngine is a fast symbolic manipulation library, written in C++. The SymEngine Python bindings may be used as an optional backend for SymPy core. To do this, first install the SymEngine Python bindings (with `pip install symengine`) and run SymPy with the `USE_SYMENGINE=1` environment variable.

Presently, the SymEngine backend is only used by the `sympy.physics.mechanics` (page 1721) and `sympy.liealgebras` (page 2400) modules, although you can also interface with SymPy’s SymEngine backend directly by importing things from `sympy.core.backend`:

```python
>>> from sympy.core.backend import Symbol
>>> # This will create a SymEngine Symbol object if the USE_SYMENGINE environment variable is configured. Otherwise it will be an ordinary SymPy Symbol object.
>>> x = Symbol('x')
```

SymEngine backend support is still experimental, so certain SymPy functions may not work correctly when it is enabled.

Sage

Sage is an open source mathematics software that incorporates a large number of open source mathematics libraries. SymPy is one of the libraries used by Sage.

Most of the code that interfaces between SymPy and Sage is in Sage itself, but a few `_sage_` methods in SymPy that do some very basic setting up of the Sage/SymPy wrappers. These methods should typically only be called by Sage itself.
6.2.3 Development Dependencies

Typical development on SymPy does not require any additional dependencies beyond Python and mpmath.

Getting the Source Code

- **git**: The SymPy source code uses the git version control system. See the installation guide (page 1) and development workflow for instructions on how to get the development version of SymPy from git.

Running the Tests

The base SymPy tests do not require any additional dependencies, however most of the above dependencies may be required for some tests to run. Tests that depend on optional dependencies should be skipped when they are not installed, either by using the sympy.testing.pytest.skip() function or by setting skip = True to skip the entire test file. Optional modules in tests and SymPy library code should be imported with import_module().

- **pytest**: Pytest is not a required dependency for the SymPy test suite. SymPy has its own test runner, which can be accessed via the bin/test script in the SymPy source directory or the test() (page 2106) function.

  However, if you prefer to use pytest, you can use it to run the tests instead of the SymPy test runner. Tests in SymPy should use the wrappers in sympy.testing.pytest (page 2098) instead of using pytest functions directly.

- **Cloudpickle**: The cloudpickle package can be used to more effectively pickle SymPy objects than the built-in Python pickle. Some tests in sympy.utilities.tests.test_pickling.py depend on cloudpickle to run. It is not otherwise required for any SymPy function.

Building the Documentation

Building the documentation requires several additional dependencies. This page (page 3076) outlines these dependencies and how to install them. It is only necessary to install these dependencies if you are contributing documentation to SymPy and want to check that the HTML or PDF documentation renders correctly. If you only want to view the documentation for the development version of SymPy, development builds of the docs are hosted online at https://docs.sympy.org/dev/index.html.

Running the Benchmarks

The benchmarks for SymPy are hosted at https://github.com/sympy/sympy_benchmarks. The README in that repository explains how to run the benchmarks.

Note that the benchmarks are also run automatically on the GitHub Actions CI, so it is generally not necessary to run them yourself as a contributor unless you want to reproduce the benchmarks results on your computer or add a new benchmark to the suite.

- **asv**: Airspeed Velocity is the package used for running the benchmarks. Note that the package name that you install is called asv.
6.3 Build the Documentation

Start by installing the required dependencies for the documentation.

6.3.1 Required dependencies

You can either install the dependencies locally on your machine, or you can build a Docker image containing them.

**Docker**

If you have Docker, then instead of following the OS-specific installation instructions below, you may choose to build a Docker image:

```bash
cd doc
docker build -f Dockerfile.html -t sympy_html_doc .
```

If you choose this option, you can now skip down to the “Build the Docs” section below.

**Debian/Ubuntu**

For Debian/Ubuntu:

```bash
apt-get install python3-sphinx texlive-latex-recommended dvipng librsvg2-bin imagemagick docbook2x graphviz
```

Install pip using:

```bash
sudo apt install python3-pip
```

However, you can also create a virtual environment and use pip in it using:

```bash
python3 -m venv /path/to/my/venv # create the venv
```

Then activate it using:

```bash
source /path/to/my/venv/bin/activate # need to rerun this each time you open a new terminal
```

After installing pip through either of the two methods given above, run:

```bash
python -m pip install -r doc/requirements.txt
```

If you get mpmath error, install python-mpmath package:

```bash
apt-get install python-mpmath
```

If you get matplotlib error, install python-matplotlib package:
apt-get install python-matplotlib

**Fedora**

For Fedora (and maybe other RPM-based distributions), install the prerequisites:

```bash
dnf install python3-sphinx librsvg2 ImageMagick docbook2X texlive-dvipng-bin
texlive-scheme-medium librsvg2-tools
python -m pip install -r doc/requirements.txt
```

If you get mpmath error, install python3-mpmath package:

```bash
dnf install python3-mpmath
```

If you get matplotlib error, install python3-matplotlib package:

```bash
dnf install python3-matplotlib
```

**Mac**

For Mac, first install homebrew: https://brew.sh/

Then install these packages with homebrew:

```bash
brew install imagemagick graphviz docbook librsvg
```

Install the docs dependencies with either pip or conda:

```bash
python -m pip install -r requirements.txt
```

Or:

```bash
conda install -c conda-forge --file requirements.txt
```

Making your Sphinx build successful on the Windows system is tricky because some dependencies like dvipng or docbook2x are not available.

**Windows 10**

For Windows 10, however, the Windows Subsystem for Linux can be a possible workaround solution, and you can install Ubuntu shell on your Windows system after following the tutorial below:

In your command prompt, run ubuntu to transfer to Linux terminal, and follow the Debian/Ubuntu tutorial above to install the dependencies, and then you can run make html to build. (Note that you also have to install make via apt-get install make.)
If you want to change the directory in your prompt to your working folder of SymPy in the Windows file system, you can prepend `cd /mnt/` to your file path in Windows, and run in your shell to navigate to the folder. (Also note that Linux uses `/` instead of `\` for file paths.)

This method provides better compatibility than Cygwin or MSYS2 and more convenience than a virtual machine if you partially need a Linux environment for your workflow, however this method is only viable for Windows 10 64-bit users.

or

Follow instruction to install Chocolatey

Install make and other dependencies:

```
choco install make graphviz rsvg-convert imagemagick
```

Install python dependencies:

```
pip install -r doc/requirements.txt
```

## 6.3.2 Build the Docs

### Docker

If you chose to build using Docker, and followed the instructions above to build the `sympy_htmldoc` image, then you can build the docs with:

```
docker run --rm -v /absolute/path/to/sympy:/sympy sympy_htmldoc
```

(Be sure to substitute the actual absolute filesystem path to sympy!) This command can be run from any directory.

### Local Installation

If you chose to follow OS-specific instructions above and installed the required dependencies locally, the documentation can be built by running the `makefile` in the `doc` subdirectory:

```
cd doc
make html
```

### SymPy Logos

SymPy has a collection of official logos, which can be generated from `sympy.svg` in your local copy of SymPy by:

```
$ cd doc
$ make logo # will be stored in the _build/logo subdirectory
```

The license of all the logos is the same as SymPy: BSD. See the LICENSE file for more information.
### 6.3.3 View the Docs

Once you have built the docs, the generated files will be found under `doc/_build/html`. To view them in your preferred web browser, use the drop down menu and select “open file”, navigate into the `sympy/doc/_build/html` folder, and open the `index.html` file.

### 6.3.4 Auto-Rebuild with the Live Server

The instructions given above told you how to build the docs once, and load them in the browser. After you make changes to the document sources, you’ll have to manually repeat the build step, and reload the pages in the browser.

There is an alternative approach that sets up a live server, which will monitor the docs directory, automatically rebuild when changes are detected, and automatically reload the page you are viewing in the browser.

If you want to use this option, the procedure again depends on whether you are using Docker, or a local installation.

**Docker**

To start the live server with Docker, you can use:

```
docker run --rm -it \
  -v /absolute/path/to/sympy:/sympy \
  -p 8000:80 \
  sympy_htmldoc live
```

and then navigate your browser to `localhost:8000`. You can use a different port by changing the `8000` in the command. Again, be sure to substitute the actual absolute filesystem path to sympy.

When finished, you can stop the server with `ctrl-c` in the terminal.

Alternatively, you may run the server in detached mode, using:

```
docker run --rm -d --name=sympy-livehtml \
  -v /absolute/path/to/sympy:/sympy \
  -p 8000:80 \
  sympy_htmldoc live
```

and then stop it with:

```
docker stop sympy-livehtml
```
Local Installation

If you installed the build dependencies locally, then simply use:

```bash
cd doc
make livehtml
```

to start the server. Your web browser should then automatically open a new tab, showing the index page of the SymPy docs.

When you are finished, you can use `ctrl-c` in the terminal to stop the server.

6.3.5 PDF Documentation

**Note:** It is not necessary for the majority of contributors to build the PDF documentation. The PDF documentation will be built automatically on GitHub Actions on pull requests. PDF documentation for each release is included on the [GitHub releases page](https://github.com/sympy/sympy/releases).

If the PDF documentation build fails on GitHub Actions, 99% of the time this is due to bad LaTeX math formatting. Double check that any math you have added is formatted correctly, and make sure you use ``double backticks`` for code (`single backticks` will render as math, not code). See the resources in the [style guide](https://github.com/sympy/sympy/blob/master/doc/styleguide.md) (page 3098) for tips on formatting LaTeX math.

Building the PDF documentation requires a few extra dependencies. First you will need to have a TeXLive installation that includes XeLaTeX and latexmk. You will also need to have Chrome or Chromium installed, as it is used to convert some SVG files for the PDF.

On Ubuntu, you can install these with:

```bash
apt-get install chromium-browser texlive texlive-xetex texlive-fonts-recommended texlive-latex-extra latexmk lmodern
```

On Mac, you can use:

```bash
brew install texlive
brew install --cask chromium
brew tap homebrew/cask-fonts
brew install font-dejavu
```

On Windows 10, you can use:

```bash
choco install chromium strawberryperl miktex dejavufonts
```

If DejaVu fonts are not installed in `C:\Windows\Fonts`, then open `\AppData\Local\Microsoft\Windows\Fonts`, select all DejaVu fonts, right-click and click `Install for all users`.

To build the pdf docs run:
cd doc
make pdf

The resulting PDF will be in:

_build/latex/sympy-<version>.pdf

where <version> is the SymPy version (e.g., sympy-1.10.dev.pdf).

## 6.4 Debugging

To start sympy in debug mode set the SYMPY_DEBUG variable. For instance in a unix-like system you would do

$ SYMPY_DEBUG=True bin/isympy

or in Windows

> set SYMPY_DEBUG=True > python bin/isympy

Now just use for example the `limit()` function. You will get a nice printed tree, which is very useful for debugging.

### 6.5 SymPy Docstrings Style Guide

#### 6.5.1 General Guidelines

To contribute to SymPy’s docstrings, please read these guidelines in full.

A documentation string (docstring) is a string literal that occurs as the first statement in a module, function, class, or method definition. Such a docstring becomes the `__doc__` special attribute of that object.

**Example**

Here is a basic docstring:

```python
def fdiff(self, argindex=1):
    """
    Returns the first derivative of a Heaviside Function.
    
    Examples
    ========

    >>> from sympy import Heaviside, diff
    >>> from sympy.abc import x

    >>> Heaviside(x).fdiff()
    DiracDelta(x)
    >>> Heaviside(x**2 - 1).fdiff()
    (continues on next page)```
Every public function, class, method, and module should have a docstring that describes what it does. Documentation that is specific to a function or class in the module should be in the docstring of that function or class. The module level docstring should discuss the purpose and scope of the module, and give a high-level example of how to use the functions or classes in the module. A module docstring is the docstring at the very top of the file, for example, the docstring for `solvers.ode`.

A public function is one that is intended to be used by the end-user, or the public. Documentation is important for public functions because they will be seen and used by many people.

A private function, on the other hand, is one that is only intended to be used in the code in SymPy itself. Although it is less important to document private functions, it also helps to have docstrings on private functions to help other SymPy developers understand how to use the function.

It may not always be clear what is a public function and what is a private function. If a function begins with an underscore, it is private, and if a function is included in `__init__.py` it is public, but the converse is not always true, so sometimes you have to decide based on context. In general, if you are unsure, having documentation on a function is better than not having documentation, regardless if it is public or private.

Docstrings should contain information aimed at users of the function. Comments specific to the code or other notes that would only distract users should go in comments in the code, not in docstrings.

Every docstring should have examples that show how the function works. Examples are the most important part of a docstring. A single example showing input and output to a function can be more helpful than a paragraph of descriptive text.

Remember that the primary consumers of docstrings are other human beings, not machines, so it is important to describe what the function does in plain English. Likewise, examples of how to use the function should be designed for human readers, not just for the doctest machinery.

Keep in mind that while Sphinx is the primary way users consume docstrings, and therefore the first platform to keep in mind while writing docstrings (especially for public functions), it is not the only way users consume docstrings. You can also view docstrings using `help()` or `?` in IPython. When using `help()`, for instance, it will show you all of the docstrings on private methods. Additionally, anyone reading the source code directly will see every docstring.

All public functions, classes, and methods and their corresponding docstrings should be imported into the Sphinx docs, instructions on which can be found at the end of this guide.
6.5.2 Formatting

Docstrings are written in reStructuredText format extended by Sphinx. Here is a concise guide to Quick reStructuredText. More in-depth information about using reStructuredText can be found in the Sphinx Documentation.

In order for Sphinx to render docstrings nicely in the HTML documentation, some formatting guidelines should be followed when writing docstrings:

- Always use """triple double quotes"""" around docstrings. Use r""""raw triple double quotes"""" if you use any backslashes in your docstrings.
- Include a blank line before the docstring’s closing quotes.
- Lines should not be longer than 80 characters.
- Always write class-level docstrings under the class definition line, as that is better to read in the source code.
- The various methods on the class can be mentioned in the docstring or examples if they are important, but details on them should go in the docstring for the method itself.
- Be aware that :: creates code blocks, which are rarely used in the docstrings. Any code example with example Python should be put in a doctest. Always check that the final version as rendered by Sphinx looks correct in the HTML.
- In order to make section underlining work nicely in docstrings, numpydoc Sphinx extension is used.
- Always double check that you have formatted your docstring correctly:
  1. Make sure that your docstring is imported into Sphinx.
  2. Build the Sphinx docs (cd doc; make html).
  3. Make sure that Sphinx doesn’t output any errors.
  4. Open the page in _build/html and make sure that it is formatted correctly.

6.5.3 Sections

In SymPy’s docstrings, it is preferred that function, class, and method docstrings consist of the following sections in this order:

1. Single-Sentence Summary
2. Explanation
3. Examples
4. Parameters
5. See Also
6. References

The Single-Sentence Summary and Examples sections are required for every docstring. Docstrings will not pass review if these sections are not included.

Do not change the names of these supported sections, for example, the heading “Examples” as a plural should be used even if there is only one example.

SymPy will continue to support all of the section headings listed in the NumPy Docstring Guide.
Headings should be underlined with the same length in equals signs.

If a section is not required and that information for the function in question is unnecessary, do not use it. Unnecessary sections and cluttered docstrings can make a function harder to understand. Aim for the minimal amount of information required to understand the function.

1. Single-Sentence Summary

This section is **required** for every docstring. A docstring will not pass review if it is not included. No heading is necessary for this section.

This section consists of a one-line sentence ending in a period that describes the function, class, or method’s effect.

Deprecation warnings should go directly after the Single-Sentence Summary, so as to notify users right away. Deprecation warnings should be written as a deprecated in the Sphinx directive:

```
.. deprecated:: 1.1

The `simplify_this` function is deprecated. Use :func:`simplify` instead. See its documentation for more information.
```

See *Documenting a deprecation* (page 3107) for more details.

2. Explanation Section

This section is encouraged. If you choose to include an Explanation section in your docstring, it should be labeled with the heading “Explanation” underlined with the same length in equals signs.

```
Explanation

This section consists of a more elaborate description of what the function, class, or method does when the concise Single-Sentence Summary will not suffice. This section should be used to clarify functionality in several sentences or paragraphs.
```

3. Examples Section

This section is **required** for every docstring. A docstring will not pass review if it is not included. It should be labeled with the heading “Examples” (even if there is only one example) underlined with the same length in equals signs.

```
Examples

This section consists of examples that show how the function works, called doctests. Doctests should be complicated enough that they fully demonstrate the API and functionality of the function, but simple enough that a user can understand them without too much thought. The perfect doctest tells the user exactly what they need to know about the function without reading any other part of the docstring.
```
There should always be a blank line before the doctest. When multiple examples are provided, they should be separated by blank lines. Comments explaining the examples should have blank lines both above and below them.

Do not think of doctests as tests. Think of them as examples that happen to be tested. They should demonstrate the API of the function to the user (i.e., what the input parameters look like, what the output looks like, and what it does). If you only want to test something, add a test to the relevant test_*.py file.

You can use the ./bin/coverage_doctest.py script to test the doctest coverage of a file or module. Run the doctests with ./bin/doctest.

You should only skip the testing of an example if it is impossible to test it. If necessary, testing of an example can be skipped by adding a special comment.

Example

```python
>>> import random
>>> random.random()
0.6868680200532414
```

If an example is longer than 80 characters, it should be line wrapped. Examples should be line wrapped so that they are still valid Python code, using ... continuation as in a Python prompt. For example, from the ODE module documentation:

Example

```python
>>> from sympy import Function, dsolve, cos, sin
>>> from sympy.abc import x
>>> f = Function('f')
>>> dsolve(cos(f(x)) - (x*sin(f(x)) - f(x)**2)*f(x).diff(x),
... f(x), hint='1st_exact')
Eq(x*cos(f(x)) + f(x)**3/3, C1)
```

Here `dsolve(cos(f(x)) - (x*sin(f(x)) - f(x)**2)*f(x).diff(x), f(x), hint='1st_exact')` is too long, so we line break it after a comma so that it is readable, and put ... on the continuation lines. If this is not done correctly, the doctests will fail.

The output of a command can also be line wrapped. No ... should be used in this case. The doctester automatically accepts output that is line wrapped.

Example

```python
>>> list(range(30))
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20,
21, 22, 23, 24, 25, 26, 27, 28, 29]
```

In a doctest, write imports like `sympy import ...` instead of `import sympy` or from `sympy import *`. To define symbols, use `from sympy.abc import x`, unless the name is not in `sympy.abc` (for instance, if it has assumptions), in which case use `symbols('x y')`.

In general, you should run ./bin/doctest to make sure your examples run correctly, and fix them if they do not.
4. Parameters Section

This section is encouraged. If you choose to include a Parameters section in your docstring, it should be labeled with the heading “Parameters” underlined with the same length in equals signs.

If you have parameters listed in parentheses after a function, class, or method name, you must include a parameters section.

This section consists of descriptions of the function arguments, keywords, and their respective types.

Enclose variables in double backticks. The colon must be preceded by a space, or omitted if the type is absent. For the parameter types, be as precise as possible. If it is not necessary to specify a keyword argument, use optional. Optional keyword parameters have default values, which are displayed as part of the function signature. They can also be detailed in the description.

When a parameter can only assume one of a fixed set of values, those values can be listed in braces, with the default appearing first. When two or more input parameters have exactly the same type, shape, and description, they can be combined.

If the Parameters section is not formatted correctly, the documentation build will render incorrectly.

If you wish to include a Returns section, write it as its own section with its own heading.

**Example**

Here is an example of a correctly formatted Parameters section:

```python
def opt_cse(exprs, order='canonical'):
    """
    Find optimization opportunities in Adds, Muls, Pows and negative
coefficient Muls.

    Parameters
    =========

    exprs : list of sympy expressions
        The expressions to optimize.
    order : string, 'none' or 'canonical'
        The order by which Mul and Add arguments are processed. For large
        expressions where speed is a concern, use the setting order='none'.
    """
```
5. See Also Section

This section is encouraged. If you choose to include a See Also section in your docstring, it should be labeled with the heading “See Also” underlined with the same length in equals signs.

See Also
========

This section consists of a listing of related functions, classes, and methods. The related items can be described with a concise fragment (not a full sentence) if desired, but this is not required. If the description spans more than one line, subsequent lines must be indented.

The See Also section should only be used to reference other SymPy objects. Anything that is a link should be embedded as a hyperlink in the text of the docstring instead; see the References section for details.

Do not reference classes with `class:Classname`, `class:`Classname`, or `:class:`Classname`, but rather only by their class name.

Examples

Here is a correctly formatted See Also section with concise descriptions:

```python
class erf(Function):
    
    """
    The Gauss error function.
    
    See Also
    ========
    
    erfc: Complementary error function.
    erfi: Imaginary error function.
    erf2: Two-argument error function.
    erfinv: Inverse error function.
    erfcinv: Inverse Complementary error function.
    erf2inv: Inverse two-argument error function.
    """
```

Here is a correctly formatted See Also section with just a list of names:

```python
class besselj(BesselBase):
    
    """
    Bessel function of the first kind.
    
    See Also
    ========
    
    bessely, besseli, besselk
    """
```
6. References Section

This section is encouraged. If you choose to include a References section in your docstring, it should be labeled with the heading “References” underlined with the same length in equals signs.

References

This section consists of a list of references cited anywhere in the previous sections. Any reference to other SymPy objects should go in the See Also section instead.

The References section should include online resources, paper citations, and/or any other printed resource giving general information about the function. References are meant to augment the docstring, but should not be required to understand it. References are numbered, starting from one, in the order in which they are cited.

For online resources, only link to freely accessible and stable online resources such as Wikipedia, Wolfram MathWorld, and the NIST Digital Library of Mathematical Functions (DLMF), which are unlikely to suffer from hyperlink rot. References for papers should include, in this order: reference citation, author name, title of work, journal or publication, year published, page number.

If there is a DOI (Digital Object Identifier), include it in the citation and make sure it is a clickable hyperlink.

Examples

Here is a References section that cites a printed resource:

References

Here is a References section that cites printed and online resources:

References

.. [1] Abramowitz, Milton; Stegun, Irene A., "Chapter 9," Handbook of Mathematical Functions with Formulas, Graphs, and Mathematical Tables, eds. (1965)
.. [4] https://functions.wolfram.com/Bessel-TypeFunctions/BesselJ/
6.5.4 Sample Docstring

Here is an example of a correctly formatted docstring:

```python
class gamma(Function):
    r""
    The gamma function
    .. math::
        \Gamma(x) := \int^\infty_0 t^{x-1} e^{-t} \, dt.
    Explanation
    ===========
    The \`gamma\` function implements the function which passes through the
    values of the factorial function (i.e., $\Gamma(n) = (n - 1)!$), when $n$
    is an integer. More generally, $\Gamma(z)$ is defined in the whole
    complex plane except at the negative integers where there are simple
    poles.
    Examples
    ========
    >>> from sympy import S, I, pi, oo, gamma
    >>> from sympy.abc import x
    Several special values are known:
    >>> gamma(1)
    1
    >>> gamma(4)
    6
    >>> gamma(S(3)/2)
    sqrt(pi)/2
    The \`gamma\` function obeys the mirror symmetry:
    >>> from sympy import conjugate
    >>> conjugate(gamma(x))
    gamma(conjugate(x))
    Differentiation with respect to $x$ is supported:
    >>> from sympy import diff
    >>> diff(gamma(x), x)
    gamma(x)*polygamma(0, x)
    Series expansion is also supported:
    >>> from sympy import series
    >>> series(gamma(x), x, 0, 3)
    1/x - EulerGamma + x*(EulerGamma**2/2 + pi**2/12) +
    x**2*(-EulerGamma*pi**2/12 - zeta(3)/3 - EulerGamma**3/6) + O(x**3)
```

(continues on next page)
We can numerically evaluate the \`\`gamma\`\` function to arbitrary precision on the whole complex plane:

```python
>>> gamma(pi).evalf(40)
2.288037795340032417959588909060233922890
>>> gamma(1+I).evalf(20)
0.49801566811835604271 - 0.15494982830181068512*I
```

See Also
=======

lowergamma: Lower incomplete gamma function.
uppergamma: Upper incomplete gamma function.
polygamma: Polygamma function.
loggamma: Log Gamma function.
digamma: Digamma function.
trigamma: Trigamma function.
beta: Euler Beta function.

References

6.5.5 Docstrings for Classes that are Mathematical Functions

SymPy is unusual in that it also has classes that are mathematical functions. The docstrings for classes that are mathematical functions should include details specific to this kind of class, as noted below:

- The Explanation section should include a mathematical definition of the function. This should use LaTeX math. Use $$ for inline math (page 3097) and .. math:: for display math, which should be used for the main definition. The variable names in the formulas should match the names of the parameters, and the LaTeX formatting should match the LaTeX pretty printing used by SymPy. As relevant, the mathematical definitions should mention their domain of definition, especially if the domain is different from the complex numbers.

- If there are multiple conventions in the literature for a function, make sure to clearly specify which convention SymPy uses.

- The Explanation section may also include some important mathematical facts about the function. These can alternately be demonstrated in the Examples section. Mathematical discussions should not be too long, as users can check the references for more details.

- The docstring does not need to discuss every implementation detail such as at which operations are defined on the function or at which points it evaluates in the “eval” method.
Important or illuminating instances of these can be shown in the Examples section.

- The docstring should go on the class level (right under the line that has “class”). The “eval” method should not have a docstring.
- Private methods on the class, that is, any method that starts with an underscore, do not need to be documented. They can still be documented if you like, but note that these docstrings are not pulled into the Sphinx documentation, so they will only be seen by developers who are reading the code, so if there is anything very important that you want to mention here, it should go in the class-level docstring as well.

### 6.5.6 Best Practices for Writing Docstrings

When writing docstrings, please follow all of the same formatting, style, and tone preferences as when writing narrative documentation. For guidelines, see Best Practices for Writing Documentation (page 3097), Formatting, Style, and Tone.

### 6.5.7 Importing Docstrings into the Sphinx Documentation

Here are excerpts from the doc/src/modules/geometry directory that imports the relevant docstrings from geometry module into documentation:

```plaintext
Utils
=====
.. module:: sympy.geometry.util

.. autofunction:: intersection

.. autofunction:: convex_hull

.. autofunction:: are_similar

Points
=====

.. module:: sympy.geometry.point

.. autoclass:: Point
   :members:

Lines
=====

.. module:: sympy.geometry.line

.. autoclass:: LinearEntity
   :members:

.. autoclass:: Line
   :members:
```

(continues on next page)
.. autoclass:: Ray
   :members:

.. autoclass:: Segment
   :members:

Curves
======

.. module:: sympy.geometry.curve

.. autoclass:: Curve
   :members:

Ellipses
=======

.. module:: sympy.geometry.ellipse

.. autoclass:: Ellipse
   :members:

.. autoclass:: Circle
   :members:

Polygons
========

.. module:: sympy.geometry.polygon

.. autoclass:: Polygon
   :members:

.. autoclass:: RegularPolygon
   :members:

.. autoclass:: Triangle
   :members:

First namespace is set to particular submodule (file) with .. module:: directive, then docstrings are imported with .. autoclass:: or .. autofunction:: relative to that submodule (file). Other methods are either cumbersome to use (using full paths for all objects) or break something (importing relative to main module using .. module:: sympy.geometry breaks viewcode Sphinx extension). All files in doc/src/modules/ should use this format.
Cross-Referencing

Any text that references another SymPy function should be formatted so that a cross-reference link to that function’s documentation is created automatically. This is done using the RST cross-reference syntax. There are two different kinds of objects that have conventions here:

1. Objects that are included in `from sympy import *`, for example, `sympy.acos()`.
   For these, use `:obj:`~.acos()`. The ~ makes it so that the text in the rendered HTML only shows `acos` instead of the fully qualified name `sympy.functions.elementary.trigonometric.acos`. (This will encourage importing names from the global sympy namespace instead of a specific submodule.) The . makes it so that the function name is found automatically. (If Sphinx gives a warning that there are multiple names found, replace the . with the full name. For example, `:obj:`~sympy.solvers.solvers.solve()`. Adding a trailing pair of parentheses is a convention for indicating the name is a function, method, or class.

   You may also use a more specific type indicator instead of `obj` (see [https://www.sphinx-doc.org/en/master/usage/restructuredtext/domains.html#cross-referencing-python-objects](https://www.sphinx-doc.org/en/master/usage/restructuredtext/domains.html#cross-referencing-python-objects)). However, `obj` will always work, and sometimes SymPy names are not the type you might expect them to be. For example, mathematical function objects such as `sin` are not actually a Python function, rather they are a Python class, therefore `:func:`~.sin` will not work.

2. Objects that are not included in `from sympy import *`, for example, `sympy.physics.vector.dynamicsymbols()`.
   This can be public API objects from submodules that are not included in the main `sympy/__init__.py`, such as the physics submodule, or private API objects that are not necessarily intended to be used by end-users (but should still be documented). In this case, you must show the fully qualified name, so do not use the ~. syntax. For example, `:obj:`~sympy.physics.vector.dynamicsymbols()`.

   You may also write custom text that links to the documentation for something using the following syntax `:obj:`custom text<object>``. For example, `:obj:`the sine function <. sin>` produces the text “the sine function” that links to the documentation for `sin`. Note that the ~ character should not be used here.

   Note that references in the See Also (page 3087) section of the docstrings do not require the :obj: syntax.

   If the resulting cross reference is written incorrectly, Sphinx will error when building the docs with an error like:

   WARNING: py:obj reference target not found: expand

Here are some troubleshooting tips to fix the errors:

- Make sure you have used the correct syntax, as described above.
- Make sure you spelled the function name correctly.
- Check if the function you are trying to cross-reference is actually included in the Sphinx documentation. If it is not, Sphinx will not be able to create a reference for it. In that case, you should add it to the appropriate RST file as described in the Docstring Guidelines (page 3081).
- If the function or object is not included in `from sympy import *`, you will need to use the fully qualified name, like `sympy.submodule.submodule.function` instead of just function.
• A fully qualified name must include the full submodule for a function all the way down to the file. For example, sympy.physics.vector.ReferenceFrame will not work (even though you can access it that way in code). It has to be sympy.physics.vector.frame.ReferenceFrame.

• If the thing you are referring to does not actually have somewhere to link to, do not use the :obj: syntax. Instead, mark it as code using double backticks. Examples of things that cannot be linked to are Python built in functions like int or NotImplementedError, functions from other modules outside of SymPy like matplotlib.plot, and variable or parameter names that are specific to the text at hand. In general, if the object cannot be accessed as sympy.something.something.object, it cannot be cross-referenced and you should not use the :obj: syntax.

• If you are using are using one of the type specific identifiers like :func:, be sure that the type for it is correct. :func: only refers to Python functions. For classes, you need to use :class:, and for methods on a class you need to use :method:. In general, it is recommended to use :obj:, as this will work for any type of object.

• If you cannot get the cross-referencing syntax to work, go ahead and submit the pull request as is and ask the reviewers for help.

You may also see errors like:

```
WARNING: more than one target found for cross-reference 'subs()':
sympy.core.basic.Basic.subs, sympy.matrices.common.MatrixCommon.subs,
sympy.physics.vector.vector.Vector.subs,
sympy.physics.vector.dyadic.Dyadic.subs
```

for instance, from using :obj:`~.subs`. This means that the . is not sufficient to find the function, because there are multiple names in SymPy named subs. In this case, you need to use the fully qualified name. You can still use ~ to make it shortened in the final text, like :obj:`~sympy.core.basic.Basic.subs`.

The line numbers for warnings in Python files are relative to the top of the docstring, not the file itself. The line numbers are often not completely correct, so you will generally have to search the docstring for the part that the warning is referring to. This is due to a bug in Sphinx.

### 6.6 Docstring Style Guide

#### 6.6.1 General Guidelines

Documentation is one of the most highly valued aspects of an open source project. Documentation teaches users and contributors how to use a project, how to contribute, and the standards of conduct within an open source community. But according to GitHub’s [Open Source Survey](https://github.com/open-source-survey), incomplete or confusing documentation is the most commonly encountered problem in open source. This style guide aims to change that.

The purpose of this style guide is to provide the SymPy community with a set of style and formatting guidelines that can be utilized and followed when writing SymPy documentation. Adhering to the guidelines offered in this style guide will bring greater consistency and clarity to SymPy’s documentation, supporting its mission to become a full-featured, open source computer algebra system (CAS).
The SymPy documentation found at docs.sympy.org is generated from docstrings in the source code and dedicated narrative documentation files in the doc/src directory. Both are written in reStructuredText format extended by Sphinx.

The documentation contained in the doc/src directory and the docstrings embedded in the Python source code are processed by Sphinx and various Sphinx extensions. This means that the documentation source format is specified by the documentation processing tools. The SymPy Documentation Style Guide provides both the essential elements for writing SymPy documentation as well as any deviations in style we specify relative to these documentation processing tools. The following lists the processing tools:

- reStructuredText: Narrative documentation files and documentation strings embedded in Python code follow the reStructuredText format. Advanced features not described in this document can be found at https://docutils.sourceforge.io/rst.html.

- Sphinx: Sphinx includes additional default features for the reStructuredText specification that are described at: https://www.sphinx-doc.org/en/master.

- Sphinx extensions included with Sphinx that we enable:
  - sphinx.ext.linkcode: Causes links to source code to direct to the related files on Github. More information is at: https://www.sphinx-doc.org/en/master/usage/extensions/linkcode.html. No bearing on documentation source format.

- Sphinx extensions that are not included with Sphinx that we enable:
  - numpydoc: Processes docstrings written in the “numpydoc” format, see https://numpydoc.readthedocs.io/en/stable/. We recommend the subset of numpydoc formatting features in this document. (Note that we currently use an older modified fork of numpydoc, which is included in the SymPy source code.)
  - sphinx_math_dollar: Allows math to be delimited with dollar signs instead of reStructuredText directives (e.g., $a^2$ instead of :math:`a^2`). See https://www.sympy.org/sphinx-math-dollar/ for more info.
  - matplotlib.sphinxext.plot_directive: Provides directives for included matplotlib generated figures in reStructuredText. See https://matplotlib.org/devel/plot_directive.html for more info.

Everything supported by the above processing tools is available for use in the SymPy documentation, but this style guide supersedes any recommendations made in the above documents. Note that we do not follow PEP 257 or the www.python.org documentation recommendations.

If you are contributing to SymPy for the first time, please read our Introduction to Contributing page as well as this guide.
6.6.2 Types of Documentation

There are four main locations where SymPy’s documentation can be found:

SymPy Website https://www.sympy.org/

The SymPy website’s primary function is to advertise the software to users and developers. It also serves as an initial location to point viewers to other relevant resources on the web. The SymPy website has basic information on SymPy and how to obtain it, as well as examples to advertise it to users, but it does not have technical documentation. The source files are located in the SymPy webpage directory. Appropriate items for the website are:

- General descriptions of what SymPy and the SymPy community are
- Explanations/demonstrations of major software features
- Listings of other major software that uses SymPy
- Getting started info for users (download and install instructions)
- Getting started info for developers
- Where users can get help and support on using SymPy
- News about SymPy

SymPy Documentation https://docs.sympy.org

This is the main place where users go to learn how to use SymPy. It contains a tutorial for SymPy as well as technical documentation for all of the modules. The source files are hosted in the main SymPy repository in the doc directory and are built using the Sphinx site generator and uploaded to the docs.sympy.org site automatically. There are two primary types of pages that are generated from different source files in the docs directory:

- Narrative Pages: reStructuredText files that correspond to manually written documentation pages not present in the Python source code. Examples are the tutorial RST files. In general, if your documentation is not API documentation it belongs in a narrative page.
- API Documentation Pages: reStructuredText files that contain directives that generate the Application Programming Interface documentation. These are automatically generated from the SymPy Python source code.

SymPy Source Code https://github.com/sympy/sympy

Most functions and classes have documentation written inside it in the form of a docstring, which explains the function and includes examples called doctests. The purpose of these docstrings is to explain the API of that class or function. The doctests examples are tested as part of the test suite, so that we know that they always produce the output that they say that they do. Here is an example docstring. Most docstrings are also automatically included in the Sphinx documentation above, so that they appear on the SymPy Documentation website. Here is that same docstring (page 443) on the SymPy website. The docstrings are formatted in a specific way so that Sphinx can render them correctly for the docs website. The SymPy sources all contain sparse technical documentation in the form of source code comments, although this does not generally constitute anything substantial and is not displayed on the documentation website.

SymPy Wiki https://github.com/sympy/sympy/wiki

The SymPy Wiki can be edited by anyone without review. It contains various types of documentation, including:

- High-level developer documentation (for example: https://github.com/sympy/sympy/wiki/Args-Invariant)
6.6.3 Narrative Documentation Guidelines

Extensive documentation, or documentation that is not centered around an API reference, should be written as a narrative document in the Sphinx docs (located in the doc/src directory). The narrative documents do not reside in the Python source files, but as standalone restructured files in the doc/src directory. SymPy’s narrative documentation is defined as the collective documents, tutorials, and guides that teach users how to use SymPy. Reference documentation should go in the docstrings and be pulled into the RST with autodoc. The RST itself should only have narrative style documentation that is not a reference for a single specific function.

6.6.4 Documentation using Markdown

Narrative documentation can be written using either Restructured Text (.rst) or Markdown (.md). Markdown documentation uses MyST. See this guide for more information on how to write documents in MArkdown. Markdown is only supported for narrative documentation. Docstrings should continue to use RST syntax. Any part of this style guide that is not specific to RST syntax should still apply to Markdown documents.

6.6.5 Best Practices for Writing Documentation

Please follow these formatting, style, and tone preferences when writing documentation.

Formatting Preferences

In order for math and code to render correctly on the SymPy website, please follow these formatting guidelines.

Math

Text that is surrounded by dollar signs $ _ $ will be rendered as LaTeX math. Any text that is meant to appear as LaTeX math should be written as $math$. In the HTML version of the docs, MathJax will render the math.

Example

The Bessel $J$ function of order $\nu$ is defined to be the function satisfying Bessel’s differential equation.
LaTeX Recommendations

• If a docstring has any LaTeX, be sure to make it “raw.” See the Docstring Formatting (page 3083) section for details.

• If you are not sure how to render something, you can use the SymPy latex() (page 2245) function. But be sure to strip out the unimportant parts (the bullet points below).

• Avoid unnecessary \left and \right (but be sure to use them when they are required).

• Avoid unnecessary {}. (For example, write x^2 instead of x^{2}).

• Use whitespace in a way that makes the equation easiest to read.

• Always check the final rendering to make sure it looks the way you expect it to.

• The HTML documentation build will not fail if there is invalid math, but rather it will show as an error on the page. However, the PDF build, which is run on GitHub Actions on pull requests, will fail. If the LaTeX PDF build fails on CI, there is likely an issue with LaTeX math somewhere.

Examples

Correct:

\[ \int \sin(x) \, dx \]

Incorrect:

\[ \int \sin{\left( x \right)} \, dx \]

For more in-depth resources on how to write math in LaTeX, see:

• https://math.meta.stackexchange.com/questions/5020/mathjax-basic-tutorial-and-quick-reference

• https://en.wikibooks.org/wiki/LaTeX/Mathematics

• https://www.overleaf.com/learn/latex/Mathematical_expressions

Code

Text that should be printed verbatim, such as code, should be surrounded by a set of double backticks like this.

Example

To use this class, define the ``_rewrite()`` and ``_expand()`` methods.

Sometimes a variable will be the same in both math and code, and can even appear in the same paragraph, making it difficult to know if it should be formatted as math or code. If the sentence in question is discussing mathematics, then LaTeX should be used, but if the sentence is discussing the SymPy implementation specifically, then code should be used.

In general, the rule of thumb is to consider if the variable in question were something that rendered differently in code and in math. For example, the Greek letter $\alpha$ would be written as alpha in code and $\alpha$ in LaTeX. The reason being that $\alpha$ cannot be used in contexts referring to Python code because it is not valid Python, and conversely alpha would be incorrect in a math context because it does not render as the Greek letter ($\alpha$).
class loggamma(Function):
    
    The ```loggamma``` function implements the logarithm of the gamma function (i.e., $\log\Gamma(x)$).
    
Variables listed in the parameters after the function name should, in written text, be italicized using Sphinx emphasis with asterisks like *this*.

Example

def stirling(n, k, d=None, kind=2, signed=False):
    
    The first kind of Stirling number counts the number of permutations of *n* distinct items that have *k* cycles; the second kind counts the ways in which *n* distinct items can be partitioned into *k* parts. If *d* is given, the "reduced Stirling number of the second kind" is returned: $S^d(n, k) = S(n - d + 1, k - d + 1)$ with $\ge k \ge d$. This counts the ways to partition $n$ consecutive integers into $k$ groups with no pairwise difference less than $d$.

Note that in the above example, the first instances of $n$ and $k$ are referring to the input parameters of the function `stirling`. Because they are Python variables but also parameters listed by themselves, they are formatted as parameters in italics. The last instances of $n$ and $k$ are talking about mathematical expressions, so they are formatted as math.

If a variable is code, but is also a parameter written by itself, the parameter formatting takes precedence and it should be rendered in italics. However, if a parameter appears in a larger code expression it should be within double backticks to be rendered as code. If a variable is only code and not a parameter as well, it should be in double backticks to be rendered as code.

Please note that references to other functions in SymPy are handled differently from parameters or code. If something is referencing another function in SymPy, the cross-reference reStructuredText syntax should be used. See the section on Cross-Referencing (page 3093) for more information.

Headings

Section headings in reStructuredText files are created by underlining (and optionally overlining) the section title with a punctuation character at least as long as the text.

Normally, there are no heading levels assigned to certain characters as the structure is determined from the succession of headings. However, for SymPy’s documentation, here is a suggested convention:

```
=== with overline: title (top level heading)
=== heading 1
--- heading 2
```
**Style Preferences**

**Spelling and Punctuation**

All narrative writing in SymPy follows American spelling and punctuation standards. For example, “color” is preferred over “colour” and commas should be placed inside of quotation marks.

**Examples**

If the `line_color` aesthetic is a function of arity 1, then the coloring is a function of the x value of a point.

The term "unrestricted necklace," or "bracelet," is used to imply an object that can be turned over or a sequence that can be reversed.

If there is any ambiguity about the spelling of a word, such as in the case of a function named after a person, refer to the spelling of the actual SymPy function.

For example, Chebyshev polynomials are named after Pafnuty Lvovich Tchebychev, whose name is sometimes transliterated from Russian to be spelled with a “T,” but in SymPy it should always be spelled “Chebyshev” to refer to the SymPy function.

**Example**

```python
class chebyshevt(OrthogonalPolynomial):
    r""
    Chebyshev polynomial of the first kind, $T_n(x)$
    ...""
```

**Capitalization**

Title case capitalization is preferred in all SymPy headings.

**Example**

What is Symbolic Computation?

.................................
**Tone Preferences**

Across SymPy documentation, please write in:

- The present tense (e.g., In the following section, we are going to learn...)
- The first-person inclusive plural (e.g., We did this the long way, but now we can try it the short way...)
- Use the generic pronoun “you” instead of “one.” Or use “the reader” or “the user.” (e.g., You can access this function by... The user can then access this function by...)
- Use the gender-neutral pronoun “they” instead of “he” or “she.” (e.g., A good docstring tells the user exactly what they need to know.)

Avoid extraneous or belittling words such as “obviously,” “easily,” “simply,” “just,” or “straightforward.”

Avoid unwelcoming or judgement-based phrases like “That is wrong.” Instead use friendly and inclusive language like “A common mistake is...”

Avoid extraneous phrases like, “we just have to do one more thing.”

### 6.7 Making a Contribution

For in-depth instructions on how to contribute to SymPy’s code base including coding conventions, creating your environment, picking an issue to fix, and opening a pull request, please read our full Development Workflow guide.

### 6.8 Deprecation Policy

This page outlines SymPy’s policy on doing deprecations, and describes the steps developers should take to properly deprecate code.

A list of all currently active deprecations in SymPy can be found at [List of active deprecations](#) (page 214).

#### 6.8.1 What is a deprecation?

A deprecation is a way to make backwards incompatible changes in a way that allows users to update their code. Deprecated code continues to work as it used to, but whenever someone uses it, it prints a warning to the screen indicating that it will be removed in a future version of SymPy, and indicating what the user should be using instead.

This allows users a chance to update their code without it completely breaking. It also gives SymPy an opportunity to give users an informative message on how to update their code, rather than making their code simply error or start giving wrong answers.
6.8.2 Try to avoid backwards incompatible changes in the first place

Backwards incompatible API changes should not be made lightly. Any backwards compatibility break means that users will need to fix their code. Whenever you want to make a breaking change, you should consider whether this is worth the pain for users. Users who have to update their code to match new APIs with every SymPy release will become frustrated with the library, and may go seek a more stable alternative. Consider whether the behavior you want can be done in a way that is compatible with existing APIs. New APIs do not necessarily need to completely supplant old ones. It is sometimes possible for old APIs to exist alongside newer, better designed ones without removing them. For example, the newer solveset (page 905) API was designed to be a superior replacement for the older solve (page 882) API. But the older solve() function remains intact and is still supported.

It is important to try to be cognizant of API design whenever adding new functionality. Try to consider what a function may do in the future, and design the API in a way that it can do so without having to make a breaking change. For example, if you add a property to an object A.attr, it is impossible to later convert that property into a method A.attr() so that it can take arguments, except by doing so in a backwards incompatible way. If you are unsure about your API design for a new functionality, one option is to mark the new functionality as explicitly private or as experimental.

With that being said, it may be decided that the API of SymPy must change in some incompatible way. Some reasons APIs are changed can include:

- The existing API is confusing.
- There is unnecessary redundancy in the API.
- The existing API limits what is possible.

Because one of the core use-cases of SymPy is to be usable as a library, we take API breakage very seriously. Whenever an API breakage is necessary, the following steps should be taken:

- Discuss the API change with the community. Be sure that the improved API is indeed better, and worth a breakage. It is important to get API right so that we will not need to break the API again to “fix” it a second time.
- If it is possible, deprecate the old API. The technical steps for doing this are described below (page 3105).
- Document the change so that users know how to update their code. The documentation that should added is described below (page 3107).

6.8.3 When does a change require deprecation?

When considering whether a change requires a deprecation, two things must be considered:

- Is the change backwards incompatible?
- Is the behavior changing public API?

A change is backwards incompatible if user code making use of it would stop working after the change.

What counts as “public API” needs to be considered on a case-by-case basis. The exact rules for what does and doesn’t constitute public API for SymPy are still not yet fully codified. Cleaning up the distinction between public and private APIs, as well as the categorization in the reference documentation is currently an open issue for SymPy.
Here are some things that constitute public API. Note: these are just general guidelines. This list is not exhaustive, and there are always exceptions to the rules.

**Public API**

- Function names.
- Keyword argument names.
- Keyword argument default values.
- Positional argument order.
- Submodule names.
- The mathematical conventions used to define a function.

And here are some things that generally aren’t public API, and therefore don’t require deprecations to change (again, this list is only a general set of guidelines).

**Not Public API**

- The precise form of an expression. In general, functions may be changed to return a different but mathematically equivalent form of the same expression. This includes a function returning a value which it was not able to compute previously.
- Functions and methods that are private, i.e., for internal use only. Such things should generally be prefixed with an underscore _, although this convention is not currently universally adhered to in the SymPy codebase.
- Anything explicitly marked as “experimental”.
- Changes to behavior that were mathematically incorrect previously (in general, bug fixes are not considered breaking changes, because despite the saying, bugs in SymPy are not features).
- Anything that was added before the most recent release. Code that has not yet made it into a release does not need to be deprecated. If you are going to change the API of new code, it is best to do it before a release is made so that no deprecations are necessary for future releases.

Note: both public and private API functions are included in the reference documentation (page 243), and many functions are not included there which should be, or are not documented at all which should be, so this should not be used to determine whether something public or not.

If you’re unsure, there is no harm in deprecating something even if it might not actually be “public API.”
The purpose of deprecation

Deprecation has several purposes:

- To allow existing code to continue to work for a while, giving people a chance to upgrade SymPy without fixing all deprecation issues immediately.

- To warn users that their code will break in a future version.

- To inform users how to fix their code so that it will continue work in future versions.

All deprecation warnings should be something that users can remove by updating their code. Deprecation warnings that fire unconditionally, even when using the “correct” newer APIs, should be avoided.

This also means all deprecated code must have a completely functioning replacement. If there is no way for users to update their code, then this means API in question is not yet ready to be deprecated. The deprecation warning should inform users of a way to change their code so that it works in the same version of SymPy, as well as all future versions, and, if possible, previous versions of SymPy as well. See below (page 3107).

Deprecations should always

1. Allow users to continue to use the existing APIs unchanged during the deprecation period (with a warning, which can be silenced (page 214) with warnings.filterwarnings).

2. Allow users to always fix their code so that it stops giving the warning.

3. After users fix their code, it should continue to work after the deprecated code is removed.

The third point is important. We do not want the “new” method to itself cause another API break when the deprecation period is over. Doing this would completely defeat the purpose of doing a deprecation.

When it is not technically possible to deprecate

In some cases, this is not technically possible to make a deprecation that follows the above three rules. API changes of this nature should be considered the most heavily, as they will break people’s code immediately without warning. Consideration into how easy it will be for users to support multiple versions of SymPy, one with the change and one without, should also be taken into account.

If you decide that the change is nonetheless worth making, there are two options:

- Make the non-deprecatable change immediately, with no warnings. This will break user code.

- Warn that the code will change in the future. There won’t be a way for users to fix their code until a version is released with the breaking change, but they will at least be aware that changes are coming.

Which of the two to make should decided on a case-by-case basis.
6.8.5 How long should deprecations last?

Deprecations should remain intact for at least 1 year after the first major release is made with the deprecation. This is only a minimum period: deprecations are allowed to remain intact for longer than this. If a change is especially hard for users to migrate, the deprecation period should be lengthened. The period may also be lengthened for deprecated features that do not impose a significant maintenance burden to keep around.

The deprecation period policy is time-based rather than release-based for a few reasons. Firstly, SymPy does not have a regular release schedule. Sometimes multiple releases will be made in a year, and some years only a single release will be made. Being time-based assures that users have sufficient opportunity to update their code regardless of how often releases happen to be made.

Secondly, SymPy does not make use of a rigorous versioning scheme like semantic versioning. The API surface of SymPy and number of contributions are both large enough that virtually every major release has some deprecations and backwards incompatible changes made in some submodule. Encoding this into the version number would be virtually impossible. The development team also does not backport changes to prior major releases, except in extreme cases. Thus a time-based deprecation scheme is more accurate to SymPy’s releasing model than a version-based one would be.

Finally, a time-based scheme removes any temptation to “fudge” a deprecation period down by releasing early. The best way for the developers to accelerate the removal of deprecated functionality is to make a release containing the deprecation as early as possible.

6.8.6 How to deprecate code

Checklist

Here is a checklist for doing a deprecation. See below for details on each step.

Discuss the backwards incompatible change with the community. Ensure the change is really worth making as per the discussion above.

Remove all instance of the deprecated code from everywhere in the codebase (including doctest examples).

Add `sympy_deprecation_warning()` (page 2138) to the code.

Write a descriptive message for the `sympy_deprecation_warning()` (page 2138). Make sure the message explains both what is deprecated and what to replace it with. The message may be a multiline string and contain examples.

Set `deprecated_since_version` to the version in `sympy/release.py` (without the .dev).

Set `active_deprecations_target` to the target used in the `active-deprecations.md` file.

Make sure `stacklevel` is set to the right value so that the deprecation warning shows the user line of code.

Visually confirm the deprecation warning looks good in the console.

Add a .. deprecated:: <version> note to the top of the relevant docstring(s).

Add a section to the `doc/src/explanation/active-deprecations.md` file.

Add a cross-reference target (deprecation-xyz)= before the section header (this is the same reference used by `active_deprecations_target` above).
Explain what is deprecated and what to replace it with.

Explain why the given thing is deprecated.

Add a test using `warns_deprecated_sympy()` (page 2100) that tests that the deprecation warning is issued properly. This test should be the only place in the code that actually uses the deprecated functionality.

Run the test suite to ensure the above test works and that no other code uses the deprecated code, which will cause the tests to fail.

In your PR, add a BREAKING CHANGE entry to the release notes for the deprecation.

Once the PR is merged, manually add the change to the “Backwards compatibility breaks and deprecations” section of the release notes on the wiki.

**Adding the deprecation to the code**

All deprecations should use `sympy.utilities.exceptions.sympy_deprecation_warning()` (page 2138). If an entire function or method is deprecated, you can use the `sympy.utilities.decorator.deprecated()` (page 2128) decorator. The `deprecated_since_version` and `active_deprecations_target` flags are required. Do not use the SymPyDeprecationWarning class directly to issue a deprecation warning. Please see the docstring of `sympy_deprecation_warning()` (page 2138) for more information. See below (page 3107) for an example.

Add a test for the deprecated behavior. Use the `sympy.testing.pytest.warns_deprecated_sympy()` (page 2100) context manager.

```python
from sympy.testing.pytest import warns_deprecated_sympy

with warns_deprecated_sympy():
    <deprecated behavior>
```

**Note:** `warns_deprecated_sympy` is only intended to be used internally by the SymPy test suite. Users of SymPy should use the `warnings` module directly to filter SymPy deprecation warnings. See *Silencing SymPy Deprecation Warnings* (page 214).

This has two purposes: to test that the warning is emitted correctly, and to test that the deprecated behavior still actually functions.

If you want to test multiple things and assert that each emits a warning then use separate with blocks for each:

```python
with warns_deprecated_sympy():
    <deprecated behavior1>

with warns_deprecated_sympy():
    <deprecated behavior2>
```

This should be the only part of the codebase and test suite that uses the deprecated behavior. Everything else should be changed to use the new, non-deprecated behavior. The SymPy test suite is configured to fail if a SymPyDeprecationWarning is issued anywhere except in a `warns_deprecated_sympy()` block. You should not use this function or a `warnings.filterwarnings(SymPyDeprecationWarning)` anywhere except in the test for the deprecation. This includes the documentation examples. The documentation for a deprecated func-
tion should just have a note pointing to the non-deprecated alternative. If you want to show a deprecated function in a doctest use `# doctest: +SKIP`. The only exception to this rule is that you may use `ignore_warnings(SymPyDeprecationWarning)` to prevent the exact same warning from triggering twice, i.e., if a deprecated function calls another function that issues the same or a similar warning.

If it is not possible to remove the deprecated behavior somewhere, that is a sign that it is not ready to be deprecated yet. Consider that users may not be able to replace the deprecated behavior for exact same reason.

**Documenting a deprecation**

All deprecations should be documented. Every deprecation needs to be documented in three primary places:

- The `sympy_deprecation_warning()` warning text. This text is allowed to be long enough to describe the deprecation, but it should not be more than one paragraph. The primary purpose of the warning text should be to inform users how to update their code. The warning text should not discuss why a feature was deprecated or unnecessary internal technical details. This discussion can go in the other sections mentioned below. Do not include information in the message that is already part of the metadata provided to the keyword arguments to `sympy_deprecation_warning()`, like the version number or a link to the active deprecations document. Remember that the warning text will be shown in plain-text, so do not use RST or Markdown markup in the text. Code blocks should be clearly delineated with newlines so that they are easy to read. All text in the warning message should be wrapped to 80 characters, except for code examples that cannot be wrapped.

  Always include full context of what is deprecated in the message. For example, write “the abc keyword to func() is deprecated” instead of just “the abc keyword is deprecated”. That way if a user has a larger line of code that is using the deprecated functionality, it will be easier for them to see exactly which part is causing the warning.

- A deprecation note in the relevant docstring(s). This should use the `deprecated` Sphinx directive. This uses the syntax `.. deprecated:: <version>`. If the entire function is deprecated, this should be placed at the top of the docstring, right below the first line. Otherwise, if only part of a function is deprecated (e.g., a single keyword argument), it should be placed near the part of the docstring that discusses that feature, e.g., in the parameters list.

  The text in the deprecation should be short (no more than a paragraph), explaining what is deprecated and what users should use instead. If you want, you may use the same text here as in the `sympy_deprecation_warning()` (page 2138). Be sure to use RST formatting, including cross-references to the new function if relevant, and a cross-reference to the longer description in the `active-deprecations.md` document (see below (page 3108)).

  If the documentation for the feature is otherwise the same as the replaced feature (i.e., the deprecation is just a renaming of a function or argument), you may replace the rest of the documentation with a note like “see the documentation for `<new feature>`”. Otherwise, the documentation for the deprecated functionality should be left intact.

  Here are some (imaginary) examples:

```{}
@deprecated
The simplify_this(expr) function is deprecated. Use simplify(expr)
```

(continues on next page)
instead."

```python
def simplify_this(expr):
    
    Simplify `expr`.
    .. deprecated:: 1.1
        The `simplify_this` function is deprecated. Use :func:`simplify`
        instead. See its documentation for more information. See
        :ref:`simplify-this-deprecation` for details.
    
    return simplify(expr)
```

```python
def is_this_zero(x, y=0):
    
    Determine if x = 0.
    
    Parameters
    =========
    x : Expr
        The expression to check.
    y : Expr, optional
        If provided, check if x = y.
    
    .. deprecated:: 1.1
        The `y` argument to `is_zero()` is deprecated. Use `is_zero(x - y)` instead. See
        :ref:`is-this-zero-y-deprecated` for more details.
    
    if y != 0:
        sympy_deprecation_warning("""
        The `y` argument to `is_zero()` is deprecated. Use `is_zero(x - y)` instead.""
        
        deprecated_since_version="1.1",
        active_deprecations_target='is-this-zero-y-deprecated')
    return simplify(x - y) == 0
```

• A longer description of the deprecation should be added to the page listing all currently active deprecations (page 214) in the documentation (in doc/src/explanation/active-deprecations.md).

This page is where you can go into more detail about the technical details of a deprecation. Here you should also list why a feature was deprecated. You may link to relevant issues, pull requests, and mailing list discussions about the deprecation, but these discussion should be summarized so that users can get the basic idea of why the deprecation without having to read through pages of old discussions. You may also give longer examples here that would not fit in the `sympy_deprecation_warning()` (page 2138) message.
or .. deprecated:: text.

Every deprecation should have a cross-reference target (using (target-name)= above
the section header) so that the .. deprecated:: note in the relevant docstring can
refer to it. This target should also be passed to the active_deprecations_target option
of sympy_deprecation_warning() (page 2138) or @deprecated (page 2128). This will
automatically put a link to the page in the documentation in the warning message. The
target name should include the word “deprecation” or “deprecated” (target names are
global in Sphinx, so the target name needs to be unique across the entire documentation).

The section header name should be the thing that is deprecated, and should be a level
3 header under the corresponding version (typically it should be added to the top of the
file).

If multiple deprecations are related to one another, they can all share a single section
on this page.

If the deprecated function is not included in the top-level sympy/__init__.py be sure
to clearly indicate which submodule the object is referring to. If you refer to anything
that is documented in the Sphinx module reference, cross-reference it, like {func}`~.
func_name`.

Note that examples here are helpful, but you generally should not use doctests to show
the deprecated functionality, as this will itself raise the deprecation warning and fail the
doctest. Instead you may use # doctest: +SKIP, or just show the example as a code
block instead of a doctest.

Here are examples corresponding to the (imaginary) examples above:

```py
(simplify-this-deprecation)=
### `simplify_this()`

The `sympy.simplify.simplify_this()` function is deprecated. It has been
replaced with the {func}`~.simplify` function. Code using `simplify_
this()`
can be fixed by replacing `simplify_this(expr)` with `simplify(expr)`.

The behavior of the two functions is otherwise identical.

This change was made because `simplify` is a much more Pythonic name than
`simplify_this`.
```

```py
(is-this-zero-y-deprecation)=
### `is_this_zero()` second argument

The second argument to {func}`~.is_this_zero()` is deprecated. Previously
`is_this_zero(x, y)` would check if x = y. However, this was removed
because
it is trivially equivalent to `is_this_zero(x - y)`. Furthermore,
allowing
to check $x=y$ in addition to just $x=0$ is is confusing given the
function
is named “is this zero”.

In particular, replace
```
In addition to the above examples, there are dozens of examples of existing deprecations which can be found by searching for sympy_deprecation_warning in the SymPy codebase.

**Release notes entry**

In the pull request, document the breaking change in the release notes section with BREAKING CHANGE.

Once the PR is merged, you should also add it to the “Backwards compatibility breaks and deprecations” section of the release notes for the upcoming release. This needs to be done manually, in addition to the change from the bot. See https://github.com/sympy/sympy/wiki/Writing-Release-Notes#backwards-compatibility-breaks-and-deprecations

Whenever a deprecated functionality is removed entirely after its deprecation period, this also needs to be marked as a BREAKING CHANGE and added to the “Backwards compatibility breaks and deprecations” section of the release notes.

[R93] https://en.wikipedia.org/wiki/Summation#Capital-sigma_notation

This implementation detail is that Python provides no reliable method to determine that a chained inequality is being built. Chained comparison operators are evaluated pairwise, using “and” logic (see https://docs.python.org/3/reference/expressions.html#not-in). This is done in an efficient way, so that each object being compared is only evaluated once and the comparison can short-circuit. For example, \( 1 > 2 > 3 \) is evaluated by Python as \((1 > 2) \text{ and } (2 > 3)\). The and operator coerces each side into a bool, returning the object itself when it short-circuits. The bool of the –Than operators will raise TypeError on purpose, because SymPy cannot determine the mathematical ordering of symbolic expressions. Thus, if we were to compute \( x > y > z \), with \( x \), \( y \), and \( z \) being Symbols, Python converts the statement (roughly) into these steps:

1. \( x > y > z \)
2. \((x > y) \text{ and } (y > z)\)
3. \((\text{GreaterThanObject}) \text{ and } (y > z)\)
4. \((\text{GreaterThanObject.__bool__})() \text{ and } (y > z)\)
5. TypeError

Because of the and added at step 2, the statement gets turned into a weak ternary statement, and the first object’s __bool__ method will raise TypeError. Thus, creating a chained inequality is not possible.

In Python, there is no way to override the and operator, or to control how it short circuits, so it is impossible to make something like \( x > y > z \) work. There was a PEP to change this, PEP 335, but it was officially closed in March, 2012.

This implementation detail is that Python provides no reliable method to determine that a chained inequality is being built. Chained comparison operators are evaluated pairwise, using “and” logic (see https://docs.python.org/3/reference/expressions.html#not-in). This is done in an efficient way, so that each object being compared is only evaluated once and the comparison can short-circuit. For example, \( 1 > 2 > 3 \) is evaluated by Python as \((1 > 2) \text{ and } (2 > 3)\). The and operator coerces each side into a bool, returning the object itself when it short-circuits. The bool of the –Than operators will raise TypeError on purpose, because SymPy cannot determine the mathematical ordering of symbolic expressions. Thus, if we were to compute \( x > y > z \), with \( x \), \( y \), and \( z \) being Symbols, Python converts the statement (roughly) into these steps:

1. \( x > y > z \)
Because of the and added at step 2, the statement gets turned into a weak ternary statement, and the first object’s __bool__ method will raise TypeError. Thus, creating a chained inequality is not possible.

In Python, there is no way to override the and operator, or to control how it short circuits, so it is impossible to make something like $x > y > z$ work. There was a PEP to change this, PEP 335, but it was officially closed in March, 2012.

This implementation detail is that Python provides no reliable method to determine that a chained inequality is being built. Chained comparison operators are evaluated pairwise, using “and” logic (see https://docs.python.org/3/reference/expressions.html#not-in). This is done in an efficient way, so that each object being compared is only evaluated once and the comparison can short-circuit. For example, $1 > 2 > 3$ is evaluated by Python as $(1 > 2)$ and $(2 > 3)$. The and operator coerces each side into a bool, returning the object itself when it short-circuits. The bool of the -Than operators will raise TypeError on purpose, because SymPy cannot determine the mathematical ordering of symbolic expressions. Thus, if we were to compute $x > y > z$, with $x$, $y$, and $z$ being Symbols, Python converts the statement (roughly) into these steps:

1. $x > y > z$
2. $(x > y)$ and $(y > z)$
3. (GreaterThanObject) and $(y > z)$
4. (GreaterThanObject.__bool__()) and $(y > z)$
5. TypeError

Because of the and added at step 2, the statement gets turned into a weak ternary statement, and the first object’s __bool__ method will raise TypeError. Thus, creating a chained inequality is not possible.

In Python, there is no way to override the and operator, or to control how it short circuits, so it is impossible to make something like $x > y > z$ work. There was a PEP to change this, PEP 335, but it was officially closed in March, 2012.
(2) `(x > y) and (y > z)`

(3) `(GreaterThanObject) and (y > z)`

(4) `(GreaterThanObject.__bool__()) and (y > z)`

(5) `TypeError`

Because of the `and` added at step 2, the statement gets turned into a weak ternary statement, and the first object’s `__bool__` method will raise `TypeError`. Thus, creating a chained inequality is not possible.

In Python, there is no way to override the `and` operator, or to control how it short circuits, so it is impossible to make something like `x > y > z` work. There was a PEP to change this, **PEP 335**, but it was officially closed in March, 2012.

SymPy Documentation, Release 1.12.1

sympy.solvers.ode.single, 840
alternating() (sympy.combinatorics.generators method), 342
AlternatingGroup() (in module sympy.combinatorics.named_groups), 410
altitudes (sympy.geometry.polygon.Triangle property), 2369
ambient_dimension (sympy.geometry.curve.Curve property), 2323
ambient_dimension (sympy.geometry.entity.GeometryEntity property), 2269
ambient_dimension (sympy.geometry.line.LinearEntity property), 2291
ambient_dimension (sympy.geometry.point.Point property), 2278
amplitude (sympy.physics.optics.waves.TWave property), 1960
an (sympy.functions.special.hyper.meijerg property), 581
analytic_func() (sympy.matrices.matrices.MatrixBase method), 1332
ancestors() (sympy.polys.numberfields.modules.Module method), 2804
And (class in sympy.logic.boolalg), 1210
andre (class in sympy.functions.combinatorial.numbertuples), 499
andre_poly() (in module sympy.polys.appellseqs), 2520
anf_coeffs() (in module sympy.logic.boolalg), 1227
ang_acc_in() (sympy.physics.vector.frame.ReferenceFrame method), 1677
ang_vel_in() (sympy.physics.mechanics.body.Body method), 1804
ang_vel_in() (sympy.physics.vector.frame.ReferenceFrame method), 1677
angle (sympy.physics.optics.gaussopt.GeometricRay property), 1932
angle() (sympy.algebras.Quaternion method), 934
angle_between() (sympy.geometry.line.LinearEntity method), 2291
angle_between() (sympy.geometry.plane.Plane method), 2379
angle_between() (sympy.physics.vector.vector.Vector method), 1690
angles (sympy.geometry.polygon.Polygon property), 2349
angles (sympy.geometry.polygon.RegularPolygon property), 2360
angular_deflection() (sympy.physics.continuum_mechanics.beam.Beam3D method), 2052
angular_momentum() (in module sympy.physics.mechanics.functions), 1799
angular_momentum() (sympy.physics.mechanics.particle.Particle method), 1790
angular_momentum() (sympy.physics.mechanics.rigidbody.RigidBody method), 1794
angular_velocity (sympy.physics.optics.waves.TWave property), 1960
Anhari (class in sympy.polys.polyclasses), 2650
AnnihilateBoson (in module sympy.physics.secondquant), 1587
AnnihilateFermion (in module sympy.physics.secondquant), 1588
annotated() (in module sympy.printing.pretty.pretty_symbology), 2261
antiderivative, 233
antidivisor_count() (in module sympy.ntheory.factor_.factor_count), 1545
antidivisors() (in module sympy.ntheory.factor_.factor_divisors), 1545
antihermitian, 977
AntiSymmetricTensor (class in sympy.physics.secondquant), 1590
Apothem (class in sympy.geometry.polygon), 2361
analytic_func() (sympy.matrices.matrices.MatrixBase method), 1332
antiderivative, 233
antidivisor_count() (in module sympy.ntheory.factor_.factor_count), 1545
antidivisors() (in module sympy.ntheory.factor_.factor_divisors), 1545
antihermitian, 977
AntiSymmetricTensor (class in sympy.physics.secondquant), 1590
Apothem (class in sympy.geometry.polygon), 2361
approximation(), applyfunc(), apply_torque(), apply_support(), apply_operators(), apply_operator(), apply_moment_load(), apply_load(), apply_grover(), apply_force(), apply_finite_diff()

(state (in module sympy.physics.quantum.state), 1903)

state() (sympy.physics.secondquant.FixedBosonicBasis method), 1596

state() (sympy.physics.secondquant.VarBosonicBasis method), 1606

state_to_operators() (in module sympy.physics.quantum.operatorset), 1882

StateBase (class in sympy.physics.quantum.state), 1903

states (sympy.physics.mechanics.system.SymbolicSystem property), 1903

stationary_distribution() (sympy.stats.DiscreteMarkovChain method), 3034

stationary_points() (in module sympy.calculus.util), 305

std() (in module sympy.stats), 3054

step_response_numerical_data() (sympy.physics.control.control_plots method), 2017

step_response_plot() (sympy.physics.control.control_plots method), 2016

stieltjes (class in sympy.functions.special.zeta_functions), 576

stirling() (in module sympy.functions.combinatorial.numbers), 501

stokes_vector() (in module sympy.physics.optics.polarization), 1949

stop (sympy.series.sequences.RecursiveSeq property), 698

stop (sympy.series.sequences.SeqBase property), 692

Stream (class in sympy.codegen.ast), 1180

strict (sympy.core.reational.Relational property), 1070

StrictGreaterThan (class in sympy.core.reational), 1079

StrictLessThan (class in sympy.core.reational), 1083

strides (sympy.tensor.indexed.IndexedBase property), 1453

String (class in sympy.codegen.ast), 1181

stringify_expr() (in module sympy.parsing.sympy_parser), 2197

stringPict (class in sympy.printing.pretty.stringpict), 2261

strip_zero() (sympy.polys.rings.PolyElement method), 2640

strip_lines() (in module sympy.utilities.misc), 2187

strong_gens (sympy.combinatorics.perm_groups.PermutationGroup method), 383

strong_presentation() (sympy.combinatorics.perm_groups.PermutationGroup method), 384

strongly_connected_components() (in module sympy.utilities.iterables), 2166

strongly_connected_components_decomposition() (sympy.matrices.matrices.MatrixBase method), 1355

StrPrinter (class in sympy.printing.str), 2253

struct (class in sympy.codegen.cnodes), 1193

Structural Equality, 240

StudentT() (in module sympy.stats), 3008

sturm() (in module sympy.polys.polytools), 2445

sturm() (sympy.polys.polyclasses.DMP method), 2648

sturm() (sympy.polys.polyclasses.DMF method), 2494

sub (in module sympy.printing.pretty.pretty_symbology), 2260

sub() (sympy.polys.domains.domain.Domain method), 2597

sub() (sympy.polys.matrices.dmm.DDM method), 2774

sub() (sympy.polys.matrices.domainmatrix.DomainMatrix method), 2769

sub() (sympy.polys.matrices.sdm.SDM method), 2781

sub() (sympy.polys.polyclasses.DMF method), 2650

sub() (sympy.polys.polytools.Poly method), 2495

sub_ground() (sympy.polys.polyclasses.DMF method), 2648

sub_ground() (sympy.polys.polytools.Poly method), 2495

subdiagram_from_objects() (sympy.categories.Diagram method), 2836

Subexpression, 240
SymPy Documentation, Release 1.12.1

subfactorial (class in sympy.functions.combinatorial.factorials), 491

subgroup() (sympy.combinatorics.perm_groups.PermutationGroup method), 384

subgroup_search() (sympy.combinatorics.perm_groups.PermutationGroup method), 384

SubModule (class in sympy.polys.agca.modules), 2536

Submodule (class in sympy.polys.numberfields.modules), 2810

submodule() (sympy.polys.agca.modules.Module method), 2533

submodule() (sympy.polys.agca.modules.QuotientModule method), 2540

submodule_from_gens() (sympy.polys.agca.modules.Module method), 2533

submodule_from_matrix() (sympy.polys.agca.modules.Module method), 2533

SubQuotientModule (class in sympy.polys.agca.modules), 2547

subresultants() (in module sympy.polys.polytools), 2440

subresultants() (sympy.polys.polyclasses.DMP method), 2648

subresultants() (sympy.polys.polytools.Poly method), 2495

Subs (class in sympy.core.function), 1098

SubsSet (class in sympy.series.gruntz), 683

subset() (sympy.combinatorics.subsets.Subset class method), 400

subset() (sympy.combinatorics.subsets.Subset class method), 400

subset() (method in sympy.utilities.iterables), 2168

subset() (in module sympy.series.gruntz), 683

subset() (method in module sympy.physics.secondquant), 1609

subset_from_bitlist() (sympy.combinatorics.subsets.Subsetclassmethod), 400

subset_indices() (sympy.combinatorics.subsets.Subsetclassmethod), 400

subsets() (in module sympy.concrete.summations), 952

sum_of_four_squares() (in module sympy.solvers.diophantine.diophantine), 790

sum_of_powers() (in module sympy.solvers.diophantine.diophantine), 790

sum_of_squares() (in module sympy.solvers.diophantine.diophantine), 791

sum_of_three_squares() (in module sympy.solvers.diophantine.diophantine), 789

SumApprox (class in sympy.codegen.approximations), 1167

summation() (in module sympy.concrete.summations), 967

superposition_basis() (in module sympy.printing.pretty.pretty_symbology), 2260

sup (sympy.sets.sets.Set property), 1237

superposition_basis() (in module sympy.physics.quantum.grover), 1918

superset (sympy.combinatorics.subsets.Subset property), 401

superset_size (sympy.combinatorics.subsets.Subset property), 401

supplement_a_subspace() (in module sympy.polys.numberfields.utilities), 2824

support() (sympy.combinatorics.permutations.Permutation method), 337

supports (sympy.physics.continuum_mechanics.truss.Truss property), 2098

SurfaceBaseSeries (class in sympy.plotting.plot), 2951

SurfaceOver2DRangeSeries (class in sympy.plotting.plot), 2951

SWAP (in module sympy.physics.quantum.gate), 1914

swap_point() (sympy.physics.quantum.circuitplot.CircuitPlot method), 1910
SwapGate  (class in sympy.physics.quantum.gate), 1914

swhinnerton_dyer_poly() (in module sympy.polys.specialpolys), 2514

sylow_subgroup() (sympy.combinatorics.permutation_group, method), 386

symarray() (in module sympy.matrices.dense), 1372

symb_2txt (in module sympy.printing.pretty.pretty_symbology), 2260

Symbol, 241

SymbolicSystem  (class in sympy.physics.mechanics.system), 1852

symbols() (in module sympy.core.symbol), 1030

symmetric() (sympy.combinatorics.generators, method), 342

symmetric_difference() (sympy.sets.sets.Set, method), 1237

symmetric_poly() (in module sympy.polys.specialpolys), 2514

symmetric_poly()(sympy.polys.rings.PolyRing, method), 2635

symmetric_residue() (in module sympy.ntheory.modular), 1554

SymmetricDifference  (class in sympy.sets.sets), 1244

SymmetricGroup() (in module sympy.combinatorics.named_groups), 408

SymmetricPredicate (class in sympy.assumptions.predicates.matrices), 261

symmetrize() (in module sympy.polys.polyfuncs), 2501

symmetrize() (sympy.polys.rings.PolyElement, method), 2640
