</table>

Deprecated since version 3.1: The fail* aliases listed in the second column have been deprecated.

Deprecated since version 3.2: The assert* aliases listed in the third column have been deprecated.

Deprecated since version 3.2: assertRegexpMatches and assertRaisesRegex have been renamed to assertRegex() and assertRaisesRegex().

Deprecated since version 3.5: The assertNotRegexpMatches name is deprecated in favor of assertNotRegexp().
Grouping tests

class unittest.TestSuite(tests=())

This class represents an aggregation of individual test cases and test suites. The class presents the interface needed by the test runner to allow it to be run as any other test case. Running a TestSuite instance is the same as iterating over the suite, running each test individually.

If tests is given, it must be an iterable of individual test cases or other test suites that will be used to build the suite initially. Additional methods are provided to add test cases and suites to the collection later on.

TestSuite objects behave much like TestCase objects, except they do not actually implement a test. Instead, they are used to aggregate tests into groups of tests that should be run together. Some additional methods are available to add tests to TestSuite instances:

addTest(test)
  Add a TestCase or TestSuite to the suite.

addTests(tests)
  Add all the tests from an iterable of TestCase and TestSuite instances to this test suite.

  This is equivalent to iterating over tests, calling addTest() for each element.

TestSuite shares the following methods with TestCase:

run(result)
  Run the tests associated with this suite, collecting the result into the test result object passed as result.

  Note that unlike TestCase.run(), TestSuite.run() requires the result object to be passed in.

debug()
  Run the tests associated with this suite without collecting the result. This allows exceptions raised by the test to be propagated to the caller and can be used to support running tests under a debugger.

countTestCases()
  Return the number of tests represented by this test object, including all individual tests and sub-suites.

__iter__()
  Tests grouped by a TestSuite are always accessed by iteration. Subclasses can lazily provide tests by overriding __iter__(). Note that this method may be called several times on a single suite (for example when counting tests or comparing for equality) so the tests returned by repeated iterations before TestSuite.run() must be the same for each call iteration. After TestSuite.run(), callers should not rely on the tests returned by this method unless the caller uses a subclass that overrides TestSuite._removeTestAtIndex() to preserve test references.

  Changed in version 3.2: In earlier versions the TestSuite accessed tests directly rather than through iteration, so overriding __iter__() wasn’t sufficient for providing tests.

  Changed in version 3.4: In earlier versions the TestSuite held references to each TestCase after TestSuite.run(). Subclasses can restore that behavior by overriding TestSuite._removeTestAtIndex().

In the typical usage of a TestSuite object, the run() method is invoked by a TestRunner rather than by the end-user test harness.
Loading and running tests

class unittest.TestLoader

The TestLoader class is used to create test suites from classes and modules. Normally, there is no need to create an instance of this class; the unittest module provides an instance that can be shared as unittest.defaultTestLoader. Using a subclass or instance, however, allows customization of some configurable properties.

TestLoader objects have the following attributes:

errors
A list of the non-fatal errors encountered while loading tests. Not reset by the loader at any point. Fatal errors are signalled by the relevant a method raising an exception to the caller. Non-fatal errors are also indicated by a synthetic test that will raise the original error when run.

New in version 3.5.

TestLoader objects have the following methods:

loadTestsFromTestCase(testCaseClass)
Return a suite of all test cases contained in the TestCase-derived testCaseClass.

A test case instance is created for each method named by getTestCaseNames(). By default these are the method names beginning with test. If getTestCaseNames() returns no methods, but the runTest() method is implemented, a single test case is created for that method instead.

loadTestsFromModule(module, pattern=None)
Return a suite of all test cases contained in the given module. This method searches module for classes derived from TestCase and creates an instance of the class for each test method defined for the class.

loadTestsFromName(name, module=None)
Return a suite of all test cases given a string specifier.

The specifier name is a “dotted name” that may resolve either to a module, a test case class, a test method within a test case class, a TestSuite instance, or a callable object which returns a TestCase or TestSuite instance. These checks are applied in the order listed here; that is, a method on a possible test case class will be picked up as “a test method within a test case class”, rather than “a callable object”.

If a module provides a load_tests function it will be called to load the tests. This allows modules to customize test loading. This is the load_tests protocol. The pattern argument is passed as the third argument to load_tests.

Changed in version 3.2: Support for load_tests added.

Changed in version 3.5: The undocumented and unofficial use_load_tests default argument is deprecated and ignored, although it is still accepted for backward compatibility. The method also now accepts a keyword-only argument pattern which is passed to load_tests as the third argument.

loadTestsFromName (name, module=None)

Return a suite of all test cases given a string specifier.

The specifier name is a “dotted name” that may resolve either to a module, a test case class, a test method within a test case class, a TestSuite instance, or a callable object which returns a TestCase or TestSuite instance. These checks are applied in the order listed here; that is, a method on a possible test case class will be picked up as “a test method within a test case class”, rather than “a callable object”.

For example, if you have a module SampleTests containing a TestCase-derived class SampleTestCase with three test methods (test_one(), test_two(), and test_three()), the specifier 'SampleTests.SampleTestCase' would cause this method to return a suite which will run all three test methods. Using the specifier 'SampleTests.SampleTestCase.test_two' would cause it to return a test suite which will run only the test_two() test method. The specifier can refer to modules and packages which have not been imported; they will be imported as a side-effect.

The method optionally resolves name relative to the given module.
Changed in version 3.5: If an `ImportError` or `AttributeError` occurs while traversing `name` then a synthetic test that raises that error when run will be returned. These errors are included in the errors accumulated by self.errors.

`loadTestsFromNames(names, module=None)`  
Similar to `loadTestsFromName()`, but takes a sequence of names rather than a single name. The return value is a test suite which supports all the tests defined for each name.

`getTestCaseNames(testCaseClass)`  
Return a sorted sequence of method names found within testCaseClass; this should be a subclass of `TestCase`.

`discover(start_dir, pattern='test*.py', top_level_dir=None)`  
Find all the test modules by recursing into subdirectories from the specified start directory, and return a TestSuite object containing them. Only test files that match `pattern` will be loaded. (Using shell style pattern matching.) Only module names that are importable (i.e. are valid Python identifiers) will be loaded.

All test modules must be importable from the top level of the project. If the start directory is not the top level directory then the top level directory must be specified separately.

If importing a module fails, for example due to a syntax error, then this will be recorded as a single error and discovery will continue. If the import failure is due to `SkipTest` being raised, it will be recorded as a skip instead of an error.

If a package (a directory containing a file named `__init__.py`) is found, the package will be checked for a `load_tests` function. If this exists then it will be called `package.load_tests(loader, tests, pattern)`. Test discovery takes care to ensure that a package is only checked for tests once during an invocation, even if the `load_tests` function itself calls `loader.discover`.

If `load_tests` exists then discovery does not recurse into the package, `load_tests` is responsible for loading all tests in the package.

The pattern is deliberately not stored as a loader attribute so that packages can continue discovery themselves. `top_level_dir` is stored so `load_tests` does not need to pass this argument in to `loader.discover()`.

`start_dir` can be a dotted module name as well as a directory.

New in version 3.2.

Changed in version 3.4: Modules that raise `SkipTest` on import are recorded as skips, not errors.

Changed in version 3.4: `start_dir` can be a `namespace` packages.

Changed in version 3.4: Paths are sorted before being imported so that execution order is the same even if the underlying file system’s ordering is not dependent on file name.

Changed in version 3.5: Found packages are now checked for `load_tests` regardless of whether their path matches `pattern`, because it is impossible for a package name to match the default pattern.

The following attributes of a `TestLoader` can be configured either by subclassing or assignment on an instance:

`testMethodPrefix`  
String giving the prefix of method names which will be interpreted as test methods. The default value is 'test'.

This affects `getTestCaseNames()` and all the `loadTestsFrom*()` methods.

`sortTestMethodsUsing`  
Function to be used to compare method names when sorting them in `getTestCaseNames()` and all the `loadTestsFrom*()` methods.

`suiteClass`  
Callable object that constructs a test suite from a list of tests. No methods on the resulting object are needed. The default value is the `TestSuite` class.
This affects all the loadTestsFrom*() methods.

**testNamePatterns**
List of Unix shell-style wildcard test name patterns that test methods have to match to be included in test suites (see -v option).

If this attribute is not None (the default), all test methods to be included in test suites must match one of the patterns in this list. Note that matches are always performed using `fnmatch.fnmatchcase()`, so unlike patterns passed to the -v option, simple substring patterns will have to be converted using * wildcards.

This affects all the loadTestsFrom*() methods.

New in version 3.7.

```python
class unittest.TestResult
```
This class is used to compile information about which tests have succeeded and which have failed.

A TestResult object stores the results of a set of tests. The `TestCase` and `TestSuite` classes ensure that results are properly recorded; test authors do not need to worry about recording the outcome of tests.

Testing frameworks built on top of `unittest` may want access to the TestResult object generated by running a set of tests for reporting purposes; a TestResult instance is returned by the TestRunner.run() method for this purpose.

TestResult instances have the following attributes that will be of interest when inspecting the results of running a set of tests:

**errors**
A list containing 2-tuples of `TestCase` instances and strings holding formatted tracebacks. Each tuple represents a test which raised an unexpected exception.

**failures**
A list containing 2-tuples of `TestCase` instances and strings holding formatted tracebacks. Each tuple represents a test where a failure was explicitly signalled using the `TestCase.assert*()` methods.

**skipped**
A list containing 2-tuples of `TestCase` instances and strings holding the reason for skipping the test.

New in version 3.1.

**expectedFailures**
A list containing 2-tuples of `TestCase` instances and strings holding formatted tracebacks. Each tuple represents an expected failure or error of the test case.

**unexpectedSuccesses**
A list containing `TestCase` instances that were marked as expected failures, but succeeded.

**shouldStop**
Set to True when the execution of tests should stop by `stop()`.

**testsRun**
The total number of tests run so far.

**buffer**
If set to true, sys.stdout and sys.stderr will be buffered in between `startTest()` and `stopTest()` being called. Collected output will only be echoed onto the real sys.stdout and sys.stderr if the test fails or errors. Any output is also attached to the failure / error message.

New in version 3.2.

**failfast**
If set to true `stop()` will be called on the first failure or error, halting the test run.

New in version 3.2.

**tb_locals**
If set to true then local variables will be shown in tracebacks.
wasSuccessful ()
Return True if all tests run so far have passed, otherwise returns False.
Changed in version 3.4: Returns False if there were any unexpectedSuccesses from tests marked with the expectedFailure() decorator.

stop ()
This method can be called to signal that the set of tests being run should be aborted by setting the shouldStop attribute to True. TestRunner objects should respect this flag and return without running any additional tests.
For example, this feature is used by the TextTestRunner class to stop the test framework when the user signals an interrupt from the keyboard. Interactive tools which provide TestRunner implementations can use this in a similar manner.

The following methods of the TestResult class are used to maintain the internal data structures, and may be extended in subclasses to support additional reporting requirements. This is particularly useful in building tools which support interactive reporting while tests are being run.

startTest (test)
Called when the test case test is about to be run.

stopTest (test)
Called after the test case test has been executed, regardless of the outcome.

startTestRun ()
Called once before any tests are executed.
New in version 3.1.

stopTestRun ()
Called once after all tests are executed.
New in version 3.1.

addError (test, err)
Called when the test case test raises an unexpected exception. err is a tuple of the form returned by sys.exc_info(): (type, value, traceback).
The default implementation appends a tuple (test, formatted_err) to the instance’s errors attribute, where formatted_err is a formatted traceback derived from err.

addFailure (test, err)
Called when the test case test signals a failure. err is a tuple of the form returned by sys.exc_info(): (type, value, traceback).
The default implementation appends a tuple (test, formatted_err) to the instance’s failures attribute, where formatted_err is a formatted traceback derived from err.

addSuccess (test)
Called when the test case test succeeds.
The default implementation does nothing.

addSkip (test, reason)
Called when the test case test is skipped. reason is the reason the test gave for skipping.
The default implementation appends a tuple (test, reason) to the instance’s skipped attribute.

addExpectedFailure (test, err)
Called when the test case test fails or errors, but was marked with the expectedFailure() decorator.
The default implementation appends a tuple (test, formatted_err) to the instance’s expectedFailures attribute, where formatted_err is a formatted traceback derived from err.

addUnexpectedSuccess (test)
Called when the test case test was marked with the expectedFailure() decorator, but succeeded.
The default implementation appends the test to the instance’s `unexpectedSuccesses` attribute.

```python
addSubTest(test, subtest, outcome)
```
Called when a subtest finishes. `test` is the test case corresponding to the test method. `subtest` is a custom `TestCase` instance describing the subtest.

If `outcome` is `None`, the subtest succeeded. Otherwise, it failed with an exception where `outcome` is a tuple of the form returned by `sys.exc_info()`:

```python
(type, value, traceback)
```

The default implementation does nothing when the outcome is a success, and records subtest failures as normal failures.

New in version 3.4.

```python
class unittest.TextTestResult(stream, descriptions, verbosity)
```
A concrete implementation of `TestResult` used by the `TextTestRunner`.

New in version 3.2: This class was previously named `_TextTestResult`. The old name still exists as an alias but is deprecated.

```python
unittest.defaultTestLoader
```
Instance of the `TestLoader` class intended to be shared. If no customization of the `TestLoader` is needed, this class can be used instead of repeatedly creating new instances.

```python
class unittest.TextTestRunner(stream=None, descriptions=True, verbosity=1, failfast=False, buffer=False, resultclass=None, warnings=None, **kwargs)
```
A basic test runner implementation that outputs results to a stream. If `stream` is `None`, the default, `sys.stderr` is used as the output stream. This class has a few configurable parameters, but is essentially very simple. Graphical applications which run test suites should provide alternate implementations. Such implementations should accept `**kwargs` as the interface to construct runners changes when features are added to unittest.

By default this runner shows `DeprecationWarning`, `PendingDeprecationWarning`, `ResourceWarning` and `ImportWarning` even if they are ignored by `default`. Deprecation warnings caused by `deprecated unittest methods` are also special-cased and, when the warning filters are `'default'` or `'always'`, they will appear only once per-module, in order to avoid too many warning messages. This behavior can be overridden using Python’s `-Wd` or `-Wa` options (see Warning control) and leaving `warnings` to `None`.

Changed in version 3.2: Added the `warnings` argument.

Changed in version 3.2: The default stream is set to `sys.stderr` at instantiation time rather than import time.

Changed in version 3.5: Added the `tb_locals` parameter.

```python
_makeResult()
```
This method returns the instance of `TestResult` used by `run()`. It is not intended to be called directly, but can be overridden in subclasses to provide a custom `TestResult`.

```python
_makeResult()` instantiates the class or callable passed in the `TextTestRunner` constructor as the `resultclass` argument. It defaults to `TextTestResult` if no `resultclass` is provided. The result class is instantiated with the following arguments:

```python
stream, descriptions, verbosity
```

```python
run(test)
```
This method is the main public interface to the `TextTestRunner`. This method takes a `TestSuite` or `TestCase` instance. A `TestResult` is created by calling `_makeResult()` and the test(s) are run and the results printed to stdout.

```python
unittest.main(module='__main__', defaultTest=None, argv=None, testRunner=None, testLoader=unittest.defaultTestLoader, exit=True, verbosity=1, failfast=None, catchbreak=None, buffer=None, warnings=None)
```
A command-line program that loads a set of tests from `module` and runs them; this is primarily for making test
modules conveniently executable. The simplest use for this function is to include the following line at the end of a test script:

```python
if __name__ == '__main__':
    unittest.main()
```

You can run tests with more detailed information by passing in the verbosity argument:

```python
if __name__ == '__main__':
    unittest.main(verbosity=2)
```

The `defaultTest` argument is either the name of a single test or an iterable of test names to run if no test names are specified via `argv`. If not specified or `None` and no test names are provided via `argv`, all tests found in `module` are run.

The `argv` argument can be a list of options passed to the program, with the first element being the program name. If not specified or `None`, the values of `sys.argv` are used.

The `testRunner` argument can either be a test runner class or an already created instance of it. By default `main` calls `sys.exit()` with an exit code indicating success or failure of the tests run.

The `testLoader` argument has to be a `TestLoader` instance, and defaults to `defaultTestLoader`. `main` supports being used from the interactive interpreter by passing in the argument `exit=False`. This displays the result on standard output without calling `sys.exit()`:

```python
>>> from unittest import main
>>> main(module='test_module', exit=False)
```

The `failfast`, `catchbreak` and `buffer` parameters have the same effect as the same-name command-line options.

The `warnings` argument specifies the warning filter that should be used while running the tests. If it’s not specified, it will remain `None` if a `-W` option is passed to `python` (see Warning control), otherwise it will be set to 'default'.

Calling `main` actually returns an instance of the `TestProgram` class. This stores the result of the tests run as the `result` attribute.

Changed in version 3.1: The `exit` parameter was added.

Changed in version 3.2: The `verbosity`, `failfast`, `catchbreak`, `buffer` and `warnings` parameters were added.

Changed in version 3.4: The `defaultTest` parameter was changed to also accept an iterable of test names.

**load_tests Protocol**

New in version 3.2.

Modules or packages can customize how tests are loaded from them during normal test runs or test discovery by implementing a function called `load_tests`.

If a test module defines `load_tests` it will be called by `TestLoader.loadTestsFromModule()` with the following arguments:

```python
load_tests(loader, standard_tests, pattern)
```

where `pattern` is passed straight through from `loadTestsFromModule`. It defaults to `None`.

It should return a `TestSuite`.

`loader` is the instance of `TestLoader` doing the loading. `standard_tests` are the tests that would be loaded by default from the module. It is common for test modules to only want to add or remove tests from the standard set of tests. The third argument is used when loading packages as part of test discovery.

A typical `load_tests` function that loads tests from a specific set of `TestCase` classes may look like:
test_cases = (TestCase1, TestCase2, TestCase3)

def load_tests(loader, tests, pattern):
    suite = TestSuite()
    for test_class in test_cases:
        tests = loader.loadTestsFromTestCase(test_class)
        suite.addTests(tests)
    return suite

If discovery is started in a directory containing a package, either from the command line or by calling TestLoader.discover(), then the package __init__.py will be checked for load_tests. If that function does not exist, discovery will recurse into the package as though it were just another directory. Otherwise, discovery of the package's tests will be left up to load_tests which is called with the following arguments:

load_tests(loader, standard_tests, pattern)

This should return a TestSuite representing all the tests from the package. (standard_tests will only contain tests collected from __init__.py.)

Because the pattern is passed into load_tests the package is free to continue (and potentially modify) test discovery. A 'do nothing' load_tests function for a test package would look like:

def load_tests(loader, standard_tests, pattern):
    # top level directory cached on loader instance
    this_dir = os.path.dirname(__file__)
    package_tests = loader.discover(start_dir=this_dir, pattern=pattern)
    standard_tests.addTests(package_tests)
    return standard_tests

Changed in version 3.5: Discovery no longer checks package names for matching pattern due to the impossibility of package names matching the default pattern.

26.8.9 Class and Module Fixtures

Class and module level fixtures are implemented in TestSuite. When the test suite encounters a test from a new class then tearDownClass() from the previous class (if there is one) is called, followed by setUpClass() from the new class.

Similarly if a test is from a different module from the previous test then tearDownModule from the previous module is run, followed by setUpModule from the new module.

After all the tests have run the final tearDownClass and tearDownModule are run.

Note that shared fixtures do not play well with [potential] features like test parallelization and they break test isolation. They should be used with care.

The default ordering of tests created by the unittest test loaders is to group all tests from the same modules and classes together. This will lead to setUpClass / setUpModule (etc) being called exactly once per class and module. If you randomize the order, so that tests from different modules and classes are adjacent to each other, then these shared fixture functions may be called multiple times in a single test run.

Shared fixtures are not intended to work with suites with non-standard ordering. A BaseTestSuite still exists for frameworks that don’t want to support shared fixtures.

If there are any exceptions raised during one of the shared fixture functions the test is reported as an error. Because there is no corresponding test instance an _ErrorHolder object (that has the same interface as a TestCase) is created to represent the error. If you are just using the standard unittest test runner then this detail doesn’t matter, but if you are a framework author it may be relevant.
setUpClass and tearDownClass

These must be implemented as class methods:

```python
import unittest

class Test(unittest.TestCase):
    @classmethod
def setUpClass(cls):
        cls._connection = createExpensiveConnectionObject()

    @classmethod
def tearDownClass(cls):
        cls._connection.destroy()
```

If you want the setUpClass and tearDownClass on base classes called then you must call up to them yourself. The implementations in TestCase are empty.

If an exception is raised during a setUpClass then the tests in the class are not run and the tearDownClass is not run. Skipped classes will not have setUpClass or tearDownClass run. If the exception is a SkipTest exception then the class will be reported as having been skipped instead of as an error.

setUpModule and tearDownModule

These should be implemented as functions:

```python
def setUpModule():
    createConnection()

def tearDownModule():
    closeConnection()
```

If an exception is raised in a setUpModule then none of the tests in the module will be run and the tearDownModule will not be run. If the exception is a SkipTest exception then the module will be reported as having been skipped instead of as an error.

To add cleanup code that must be run even in the case of an exception, use addModuleCleanup:

```python
unittest.addModuleCleanup (function, I, *args, **kwargs)
```

Add a function to be called after tearDownModule() to cleanup resources used during the test class. Functions will be called in reverse order to the order they are added (LIFO). They are called with any arguments and keyword arguments passed into addModuleCleanup() when they are added.

If setUpModule() fails, meaning that tearDownModule() is not called, then any cleanup functions added will still be called.

New in version 3.8.

```python
unittest.doModuleCleanups()
```

This function is called unconditionally after tearDownModule(), or after setUpModule() if setUpModule() raises an exception.

It is responsible for calling all the cleanup functions added by addCleanupModule(). If you need cleanup functions to be called prior to tearDownModule() then you can call doModuleCleanups() yourself.

doModuleCleanups() pops methods off the stack of cleanup functions one at a time, so it can be called at any time.

New in version 3.8.
26.8.10 Signal Handling

New in version 3.2.

The -c/--catch command-line option to unittest, along with the catchbreak parameter to unittest.main(), provide more friendly handling of control-C during a test run. With catch break behavior enabled control-C will allow the currently running test to complete, and the test run will then end and report all the results so far. A second control-c will raise a KeyboardInterrupt in the usual way.

The control-c handling signal handler attempts to remain compatible with code or tests that install their own signal.SIGINT handler. If the unittest handler is called but isn’t the installed signal.SIGINT handler, i.e. it has been replaced by the system under test and delegated to, then it calls the default handler. This will normally be the expected behavior by code that replaces an installed handler and delegates to it. For individual tests that need unittest control-c handling disabled the removeHandler() decorator can be used.

There are a few utility functions for framework authors to enable control-c handling functionality within test frameworks.

```python
unittest.installHandler()
```

Install the control-c handler. When a signal.SIGINT is received (usually in response to the user pressing control-c) all registered results have stop() called.

```python
unittest.registerResult(result)
```

Register a TestResult object for control-c handling. Registering a result stores a weak reference to it, so it doesn’t prevent the result from being garbage collected.

Registering a TestResult object has no side-effects if control-c handling is not enabled, so test frameworks can unconditionally register all results they create independently of whether or not handling is enabled.

```python
unittest.removeResult(result)
```

Remove a registered result. Once a result has been removed then stop() will no longer be called on that result object in response to a control-c.

```python
unittest.removeHandler(function=None)
```

When called without arguments this function removes the control-c handler if it has been installed. This function can also be used as a test decorator to temporarily remove the handler while the test is being executed:

```python
@unittest.removeHandler
def test_signal_handling(self):
    ...
```

26.9 unittest.mock — mock object library

New in version 3.3.

Source code: Lib/unittest/mock.py

unittest.mock is a library for testing in Python. It allows you to replace parts of your system under test with mock objects and make assertions about how they have been used.

unittest.mock provides a core Mock class removing the need to create a host of stubs throughout your test suite. After performing an action, you can make assertions about which methods / attributes were used and arguments they were called with. You can also specify return values and set needed attributes in the normal way.

Additionally, mock provides a patch() decorator that handles patching module and class level attributes within the scope of a test, along with sentinel for creating unique objects. See the quick guide for some examples of how to use Mock, MagicMock and patch().

Mock is designed for use with unittest and is based on the ‘action -> assertion’ pattern instead of ‘record -> replay’ used by many mocking frameworks.

There is a backport of unittest.mock for earlier versions of Python, available as mock on PyPI.
26.9.1 Quick Guide

Mock and MagicMock objects create all attributes and methods as you access them and store details of how they have been used. You can configure them, to specify return values or limit what attributes are available, and then make assertions about how they have been used:

```python
>>> from unittest.mock import MagicMock
>>> thing = ProductionClass()
>>> thing.method = MagicMock(return_value=3)
>>> thing.method(3, 4, 5, key='value')
3
>>> thing.method.assert_called_with(3, 4, 5, key='value')
```

side_effect allows you to perform side effects, including raising an exception when a mock is called:

```python
>>> mock = Mock(side_effect=KeyError('foo'))
>>> mock()
Traceback (most recent call last):
... 
KeyError: 'foo'
```

```python
>>> values = {'a': 1, 'b': 2, 'c': 3}
>>> def side_effect(arg):
...     return values[arg]
... 
>>> mock.side_effect = side_effect
>>> mock('a'), mock('b'), mock('c')
(1, 2, 3)
>>> mock.side_effect = [5, 4, 3, 2, 1]
>>> mock(), mock(), mock()
(5, 4, 3)
```

Mock has many other ways you can configure it and control its behaviour. For example the spec argument configures the mock to take its specification from another object. Attempting to access attributes or methods on the mock that don’t exist on the spec will fail with an AttributeError.

The patch() decorator / context manager makes it easy to mock classes or objects in a module under test. The object you specify will be replaced with a mock (or other object) during the test and restored when the test ends:

```python
>>> from unittest.mock import patch
>>> @patch('module.ClassName2')
... @patch('module.ClassName1')
... def test(MockClass1, MockClass2):
...     module.ClassName1()
...     module.ClassName2()
...     assert MockClass1 is module.ClassName1
...     assert MockClass2 is module.ClassName2
...     assert MockClass1.called
...     assert MockClass2.called
... 
>>> test()
```

**Note**: When you nest patch decorators the mocks are passed in to the decorated function in the same order they applied (the normal Python order that decorators are applied). This means from the bottom up, so in the example above the mock for module.ClassName1 is passed in first.

With patch() it matters that you patch objects in the namespace where they are looked up. This is normally straightforward, but for a quick guide read where to patch.

As well as a decorator patch() can be used as a context manager in a with statement:
>>> with patch.object(ProductionClass, 'method', return_value=None) as mock_method:
...     thing = ProductionClass()
...     thing.method(1, 2, 3)
... >>> mock_method.assert_called_once_with(1, 2, 3)

There is also `patch.dict()` for setting values in a dictionary just during a scope and restoring the dictionary to its original state when the test ends:

```python
>>> foo = {'key': 'value'}
>>> original = foo.copy()
>>> with patch.dict(foo, {'newkey': 'newvalue'}, clear=True):
...     assert foo == {'newkey': 'newvalue'}
... >>> assert foo == original
```

Mock supports the mocking of Python `magic methods`. The easiest way of using magic methods is with the `MagicMock` class. It allows you to do things like:

```python
>>> mock = MagicMock()
>>> mock.__str__.return_value = 'foobarbaz'
>>> str(mock)
'foobarbaz'
>>> mock.__str__.assert_called_with()
```

Mock allows you to assign functions (or other Mock instances) to magic methods and they will be called appropriately. The `MagicMock` class is just a Mock variant that has all of the magic methods pre-created for you (well, all the useful ones anyway).

The following is an example of using magic methods with the ordinary Mock class:

```python
>>> mock = Mock()
>>> mock.__str__ = Mock(return_value='wheeeeee')
>>> str(mock)
'wheeeeee'
```

For ensuring that the mock objects in your tests have the same api as the objects they are replacing, you can use `auto-specing`. Auto-specing can be done through the `autospec` argument to `patch`, or the `create_autospec()` function. Auto-specing creates mock objects that have the same attributes and methods as the objects they are replacing, and any functions and methods (including constructors) have the same call signature as the real object.

This ensures that your mocks will fail in the same way as your production code if they are used incorrectly:

```python
>>> from unittest.mock import create_autospec
>>> def function(a, b, c):
...     pass
... >>> mock_function = create_autospec(function, return_value='fishy')
>>> mock_function(1, 2, 3)
'fishy'
>>> mock_function.assert_called_once_with(1, 2, 3)
>>> mock_function('wrong arguments')
Traceback (most recent call last):
  ... TypeError: <lambda>() takes exactly 3 arguments (1 given)
```

`create_autospec()` can also be used on classes, where it copies the signature of the `__init__` method, and on callable objects where it copies the signature of the `__call__` method.
26.9.2 The Mock Class

Mock is a flexible mock object intended to replace the use of stubs and test doubles throughout your code. Mocks are callable and create attributes as new mocks when you access them. Accessing the same attribute will always return the same mock. Mocks record how you use them, allowing you to make assertions about what your code has done to them.

MagicMock is a subclass of Mock with all the magic methods pre-created and ready to use. There are also non-callable variants, useful when you are mocking out objects that aren’t callable: NonCallableMock and NonCallable MagicMock

The patch() decorator makes it easy to temporarily replace classes in a particular module with a Mock object. By default patch() will create a MagicMock for you. You can specify an alternative class of Mock using the new_callable argument to patch().

class unittest.mock.Mock(spec=None, side_effect=None, return_value=DEFAULT, wraps=None, name=None, spec_set=None, unsafe=False, **kwargs)

Create a new Mock object. Mock takes several optional arguments that specify the behavior of the Mock object:

• spec: This can be either a list of strings or an existing object (a class or instance) that acts as the specification for the mock object. If you pass in an object then a list of strings is formed by calling dir on the object (excluding unsupported magic attributes and methods). Accessing any attribute not in this list will raise an AttributeError.

If spec is an object (rather than a list of strings) then __class__ returns the class of the spec object. This allows mocks to pass isinstance() tests.

• spec_set: A stricter variant of spec. If used, attempting to set or get an attribute on the mock that isn’t on the object passed as spec_set will raise an AttributeError.

• side_effect: A function to be called whenever the Mock is called. See the side_effect attribute. Useful for raising exceptions or dynamically changing return values. The function is called with the same arguments as the mock, and unless it returns DEFAULT, the return value of this function is used as the return value.

Alternatively side_effect can be an exception class or instance. In this case the exception will be raised when the mock is called.

If side_effect is an iterable then each call to the mock will return the next value from the iterable.

A side_effect can be cleared by setting it to None.

• return_value: The value returned when the mock is called. By default this is a new Mock (created on first access). See the return_value attribute.

• unsafe: By default, accessing any attribute with name starting with assert, asserter, asserter, aseert or asert will raise an AttributeError. Passing unsafe=True will allow access to these attributes.

New in version 3.5.

• wraps: Item for the mock object to wrap. If wraps is not None then calling the Mock will pass the call through to the wrapped object (returning the real result). Attribute access on the mock will return a Mock object that wraps the corresponding attribute of the wrapped object (so attempting to access an attribute that doesn’t exist will raise an AttributeError).

If the mock has an explicit return_value set then calls are not passed to the wrapped object and the return_value is returned instead.

• name: If the mock has a name then it will be used in the repr of the mock. This can be useful for debugging. The name is propagated to child mocks.

Mocks can also be called with arbitrary keyword arguments. These will be used to set attributes on the mock after it is created. See the configure_mock() method for details.

1 The only exceptions are magic methods and attributes (those that have leading and trailing double underscores). Mock doesn’t create these but instead raises an AttributeError. This is because the interpreter will often implicitly request these methods, and gets very confused to get a new Mock object when it expects a magic method. If you need magic method support see magic methods.
assert_called()
Assert that the mock was called at least once.

```python
>>> mock = Mock()
>>> mock.method()
<Mock name='mock.method()' id='...'>
>>> mock.method.assert_called()
```

New in version 3.6.

assert_called_once()
Assert that the mock was called exactly once.

```python
>>> mock = Mock()
>>> mock.method()
<Mock name='mock.method()' id='...'>
>>> mock.method.assert_called_once()
```

```python
>>> mock.method()
<Mock name='mock.method()' id='...'>
>>> mock.method.assert_called_once()
Traceback (most recent call last):
  ...
AssertionError: Expected 'method' to have been called once. Called 2 times.
```

New in version 3.6.

assert_called_with(*args, **kwargs)
This method is a convenient way of asserting that the last call has been made in a particular way:

```python
>>> mock = Mock()
>>> mock.method(1, 2, 3, test='wow')
<Mock name='mock.method()' id='...'>
>>> mock.method.assert_called_with(1, 2, 3, test='wow')
```

assert_called_once_with(*args, **kwargs)
Assert that the mock was called exactly once and that call was with the specified arguments.

```python
>>> mock = Mock(return_value=None)
>>> mock('foo', bar='baz')
>>> mock.assert_called_once_with('foo', bar='baz')
>>> mock('other', bar='values')
>>> mock.assert_called_once_with('other', bar='values')
Traceback (most recent call last):
  ...
AssertionError: Expected 'mock' to be called once. Called 2 times.
```

assert_any_call(*args, **kwargs)
assert the mock has been called with the specified arguments.

The assert passes if the mock has ever been called, unlike `assert_called_with()` and `assert_called_once_with()` that only pass if the call is the most recent one, and in the case of `assert_called_once_with()` it must also be the only call.

```python
>>> mock = Mock(return_value=None)
>>> mock(1, 2, arg='thing')
>>> mock('some', 'thing', 'else')
>>> mock.assert_any_call(1, 2, arg='thing')
```

assert_has_calls(calls, any_order=False)
assert the mock has been called with the specified calls. The `mock_calls` list is checked for the calls.

If `any_order` is false then the calls must be sequential. There can be extra calls before or after the specified calls.
If \texttt{any\_order} is true then the calls can be in any order, but they must all appear in \texttt{mock\_calls}.

```python
>>> mock = Mock(return_value=None)
>>> mock(1)
>>> mock(2)
>>> mock(3)
>>> mock(4)
>>> calls = [call(2), call(3)]
>>> mock.assert_has_calls(calls)
>>> calls = [call(4), call(2), call(3)]
>>> mock.assert_has_calls(calls, any_order=True)
```

\textbf{assert\_not\_called()}

Assert the mock was never called.

```python
>>> m = Mock()
>>> m.hello.assert_not_called()
>>> obj = m.hello()
>>> m.hello.assert_not_called()
AssertionError: Expected 'hello' to not have been called. Called 1 times.
```

New in version 3.5.

\textbf{reset\_mock(*, return\_value=False, side\_effect=False)}

The \texttt{reset\_mock} method resets all the call attributes on a mock object:

```python
>>> mock = Mock(return_value=None)
>>> mock('hello')
>>> mock.called
True
>>> mock.reset_mock()
>>> mock.called
False
```

Changed in version 3.6: Added two keyword only argument to the \texttt{reset\_mock} function.

This can be useful where you want to make a series of assertions that reuse the same object. Note that \texttt{reset\_mock()} doesn't clear the return value, \texttt{side\_effect} or any child attributes you have set using normal assignment by default. In case you want to reset \texttt{return\_value} or \texttt{side\_effect}, then pass the corresponding parameter as \texttt{True}. Child mocks and the return value mock (if any) are reset as well.

\textbf{Note:} \texttt{return\_value}, and \texttt{side\_effect} are keyword only argument.

\textbf{mock\_add\_spec(spec, spec\_set=False)}

Add a spec to a mock. \texttt{spec} can either be an object or a list of strings. Only attributes on the \texttt{spec} can be fetched as attributes from the mock.

If \texttt{spec\_set} is true then only attributes on the spec can be set.

\textbf{attach\_mock(mock, attribute)}

Attach a mock as an attribute of this one, replacing its name and parent. Calls to the attached mock will be recorded in the \texttt{method\_calls} and \texttt{mock\_calls} attributes of this one.

\textbf{configure\_mock(**kwargs)}

Set attributes on the mock through keyword arguments.

Attributes plus return values and side effects can be set on child mocks using standard dot notation and unpacking a dictionary in the method call:
The same thing can be achieved in the constructor call to mocks:

```python
>>> attrs = {'method.return_value': 3, 'other.side_effect': KeyError}
>>> mock = Mock(some_attribute='eggs', **attrs)
>>> mock.some_attribute
'eggs'
>>> mock.method()
3
>>> mock.other()
Traceback (most recent call last):
  ... KeyError
```

configure_mock() exists to make it easier to do configuration after the mock has been created.

```python
attrs = {'method.return_value': 3, 'other.side_effect': KeyError}
mock = Mock(some_attribute='eggs', **attrs)
mock.some_attribute
'eggs'
mock.method()
3
mock.other()
Traceback (most recent call last):
  ... KeyError
```

__dir__() Mock objects limit the results of dir(some_mock) to useful results. For mocks with a spec this includes all the permitted attributes for the mock.

See FILTER_DIR for what this filtering does, and how to switch it off.

_get_child_mock(**kw)
Create the child mocks for attributes and return value. By default child mocks will be the same type as the parent. Subclasses of Mock may want to override this to customize the way child mocks are made.

For non-callable mocks the callable variant will be used (rather than any custom subclass).

called
A boolean representing whether or not the mock object has been called:

```python
>>> mock = Mock(return_value=None)
>>> mock.called
False
>>> mock()
>>> mock.called
True
```

call_count
An integer telling you how many times the mock object has been called:

```python
>>> mock = Mock(return_value=None)
>>> mock.call_count
0
>>> mock()
>>> mock()
>>> mock.call_count
2
```

return_value
Set this to configure the value returned by calling the mock:

```python
>>> mock = Mock()
>>> mock.return_value = 'fish'
```
The default return value is a mock object and you can configure it in the normal way:

```python
>>> mock = Mock()
>>> mock.return_value = sentinel.Attribute
>>> mock.return_value()
<Mock name='mock()' id='...'>
```

`return_value` can also be set in the constructor:

```python
>>> mock = Mock(return_value=3)
>>> mock.return_value
3
>>> mock()
3
```

### side_effect

This can either be a function to be called when the mock is called, an iterable or an exception (class or instance) to be raised.

If you pass in a function it will be called with same arguments as the mock and unless the function returns the `DEFAULT` singleton the call to the mock will then return whatever the function returns. If the function returns `DEFAULT` then the mock will return its normal value (from the `return_value`).

If you pass in an iterable, it is used to retrieve an iterator which must yield a value on every call. This value can either be an exception instance to be raised, or a value to be returned from the call to the mock (`DEFAULT` handling is identical to the function case).

An example of a mock that raises an exception (to test exception handling of an API):

```python
>>> mock = Mock()
>>> mock.side_effect = Exception('Boom!')
>>> mock()
Traceback (most recent call last):
  ...  
Exception: Boom!
```

Using `side_effect` to return a sequence of values:

```python
>>> mock = Mock()
>>> mock.side_effect = [3, 2, 1]
>>> mock(), mock(), mock()
(3, 2, 1)
```

Using a callable:

```python
>>> mock = Mock(return_value=3)
>>> def side_effect(*args, **kwargs):
...    return DEFAULT
...    ...
>>> mock.side_effect = side_effect
>>> mock()
3
```

`side_effect` can be set in the constructor. Here’s an example that adds one to the value the mock is called with and returns it:
>>> side_effect = lambda value: value + 1
>>> mock = Mock(side_effect=side_effect)
>>> mock(3)
4
>>> mock(-8)
-7

Setting `side_effect` to `None` clears it:

```python
>>> m = Mock(side_effect=KeyError, return_value=3)
>>> m()
Traceback (most recent call last):
...
KeyError
>>> m.side_effect = None
>>> m()
3
```

### call_args

This is either `None` (if the mock hasn’t been called), or the arguments that the mock was last called with. This will be in the form of a tuple: the first member, which can also be accessed through the `args` property, is any ordered arguments the mock was called with (or an empty tuple) and the second member, which can also be accessed through the `kwargs` property, is any keyword arguments (or an empty dictionary).

```python
>>> mock = Mock(return_value=None)
>>> print(mock.call_args)
None
>>> mock()
>>> mock.call_args
()  # empty args
>>> mock.call_args == ()
True
>>> mock(3, 4)
>>> mock.call_args
((3, 4),)  # (3, 4) as a tuple
>>> mock.call_args == ((3, 4),)
True
>>> mock.call_args.args
(3, 4)
>>> mock.call_args.kwargs
()  # empty kwargs
>>> mock(3, 4, 5, key='fish', next='w00t!')
>>> mock.call_args
((3, 4, 5, key='fish', next='w00t!'),)  # (3, 4, 5) and dictionary
>>> mock.call_args == ((3, 4, 5, key='fish', next='w00t!'),)
True
>>> mock.call_args.args
(3, 4, 5)
>>> mock.call_args.kwargs
{'key': 'fish', 'next': 'w00t!'}
```

`call_args`, along with members of the lists `call_args_list`, `method_calls` and `mock_calls` are `call` objects. These are tuples, so they can be unpacked to get at the individual arguments and make more complex assertions. See `calls as tuples`.

Changed in version 3.8: Added `args` and `kwargs` properties.

### call_args_list

This is a list of all the calls made to the mock object in sequence (so the length of the list is the number of times it has been called). Before any calls have been made it is an empty list. The `call` object can be used for conveniently constructing lists of calls to compare with `call_args_list`.

26.9. unittest.mock — mock object library
>>> mock = Mock(return_value=None)
>>> mock()
>>> mock(3, 4)
>>> mock(key='fish', next='w00t!')
>>> mock.call_args_list
[(call(), call(3, 4), call(key='fish', next='w00t!'))]
>>> expected = [((), ((3, 4),), {'key': 'fish', 'next': 'w00t!'}),]
>>> mock.call_args_list == expected
True

Members of `call_args_list` are call objects. These can be unpacked as tuples to get at the individual arguments. See `calls as tuples`.

**method_calls**

As well as tracking calls to themselves, mocks also track calls to methods and attributes, and their methods and attributes:

>>> mock = Mock()
>>> mock.method()
<Mock name='mock.method()' id='...'>
>>> mock.property.method.attribute()
<Mock name='mock.property.method.attribute()' id='...'>
>>> mock.method_calls
[call.method(), call.property.method.attribute()]

Members of `method_calls` are call objects. These can be unpacked as tuples to get at the individual arguments. See `calls as tuples`.

**mock_calls**

`mock_calls` records all calls to the mock object, its methods, magic methods and return value mocks.

>>> mock = MagicMock()
>>> result = mock(1, 2, 3)
>>> mock.first(a=3)
<Mock name='mock.first()' id='...'>
>>> mock.second()
<Mock name='mock.second()' id='...'>
>>> int(mock)
1
>>> result(1)
<Mock name='mock()' id='...'>
>>> expected = [call(1, 2, 3), call.first(a=3), call.second(), ...
... call.__int__(), call(){1}]
>>> mock.mock_calls == expected
True

Members of `mock_calls` are call objects. These can be unpacked as tuples to get at the individual arguments. See `calls as tuples`.

**Note:** The way `mock_calls` are recorded means that where nested calls are made, the parameters of ancestor calls are not recorded and so will always compare equal:

>>> mock = MagicMock()
>>> mock.top(a=3).bottom()
<Mock name='mock.top().bottom()' id='...'>
>>> mock.mock_calls
[call.top(a=3), call.top().bottom()]
>>> mock.mock_calls[-1] == call.top(a=-1).bottom()
True

__class__
Normally the __class__ attribute of an object will return its type. For a mock object with a spec, __class__ returns the spec class instead. This allows mock objects to pass `isinstance()` tests for the object they are replacing/masquerading as:

```python
>>> mock = Mock(spec=3)
>>> isinstance(mock, int)
True
```

__class__ is assignable to, this allows a mock to pass an `isinstance()` check without forcing you to use a spec:

```python
>>> mock = Mock()
>>> mock.__class__ = dict
>>> isinstance(mock, dict)
True
```

class unittest.mock.NonCallableMock (spec=None,  
  wraps=None,  
  name=None,  
  spec_set=None,  
  **kwargs)

A non-callable version of Mock. The constructor parameters have the same meaning of Mock, with the exception of return_value and side_effect which have no meaning on a non-callable mock.

Mock objects that use a class or an instance as a spec or spec_set are able to pass `isinstance()` tests:

```python
>>> mock = Mock(spec=SomeClass)
>>> isinstance(mock, SomeClass)
True
>>> mock = Mock(spec_set=SomeClass())
>>> isinstance(mock, SomeClass)
True
```

The Mock classes have support for mocking magic methods. See magic methods for the full details.

The mock classes and the patch() decorators all take arbitrary keyword arguments for configuration. For the patch() decorators the keywords are passed to the constructor of the mock being created. The keyword arguments are for configuring attributes of the mock:

```python
>>> m = MagicMock(attribute=3, other='fish')
>>> m.attribute
3
>>> m.other
'fish'
```

The return value and side effect of child mocks can be set in the same way, using dotted notation. As you can't use dotted names directly in a call you have to create a dictionary and unpack it using **:

```python
>>> attrs = {'method.return_value': 3, 'other.side_effect': KeyError}
>>> mock = Mock(some_attribute='eggs', **attrs)
>>> mock.some_attribute
'eggs'
>>> mock.method()
3
>>> mock.other()
Traceback (most recent call last):
  ...
KeyError
```

A callable mock which was created with a spec (or a spec_set) will introspect the specification object’s signature when matching calls to the mock. Therefore, it can match the actual call's arguments regardless of whether they were passed positionally or by name:

```python
>>> def f(a, b, c): pass
...```
>>> mock = Mock(spec=f)
>>> mock(1, 2, c=3)
<Mock name='mock()' id='140161580456576'>
>>> mock.assert_called_with(1, 2, 3)
>>> mock.assert_called_with(a=1, b=2, c=3)

This applies to `assert_called_with()`, `assert_called_once_with()`, `assert_has_calls()` and `assert_any_call()`. When Autospeccing, it will also apply to method calls on the mock object.

Changed in version 3.4: Added signature introspection on specced and autospecced mock objects.

class unittest.mock.PropertyMock(*args, **kwargs)
A mock intended to be used as a property, or other descriptor, on a class. `PropertyMock` provides `__get__()` and `__set__()` methods so you can specify a return value when it is fetched.

Fetching a `PropertyMock` instance from an object calls the mock, with no args. Setting it calls the mock with the value being set.

```python
>>> class Foo:
    ...     @property
    ...     def foo(self):
    ...         return 'something'
    ...     @foo.setter
    ...     def foo(self, value):
    ...         pass
    ...
    >>> with patch('__main__.Foo.foo', new_callable=PropertyMock) as mock_foo:
    ...         mock_foo.return_value = 'mockity-mock'
    ...         this_foo = Foo()
    ...         print(this_foo.foo)
    ...         this_foo.foo = 6
    ...         mockity-mock
    >>> mock_foo.mock_calls
    [call(), call(6)]
```

Because of the way mock attributes are stored you can’t directly attach a `PropertyMock` to a mock object. Instead you can attach it to the mock type object:

```python
>>> m = MagicMock()
>>> p = PropertyMock(return_value=3)
>>> type(m).foo = p
>>> m.foo
3
>>> p.assert_called_once_with()
```

class unittest.mock.AsyncMock(*args, **kwargs)
An asynchronous version of `MagicMock`. The `AsyncMock` object will behave so the object is recognized as an async function, and the result of a call is an awaitable.

```python
>>> mock = AsyncMock()
>>> asyncio.iscoroutinefunction(mock)
True
>>> inspect.isawaitable(mock())
True
```

The result of `mock()` is an async function which will have the outcome of `side_effect` or `return_value` after it has been awaited:

- if `side_effect` is a function, the async function will return the result of that function,
• if `side_effect` is an exception, the async function will raise the exception,

• if `side_effect` is an iterable, the async function will return the next value of the iterable, however, if the sequence of result is exhausted, `StopAsyncIteration` is raised immediately,

• if `side_effect` is not defined, the async function will return the value defined by `return_value`, hence, by default, the async function returns a new `AsyncMock` object.

Setting the `spec` of a `Mock` or `MagicMock` to an async function will result in a coroutine object being returned after calling.

```python
global asyncio

>>> async def async_func(): pass
... >>> mock = MagicMock(async_func)
... >>> mock
<coroutine object AsyncMockMixin._mock_call at ...>
```

Setting the `spec` of a `Mock`, `MagicMock`, or `AsyncMock` to a class with asynchronous and synchronous functions will automatically detect the synchronous functions and set them as `MagicMock` (if the parent mock is `AsyncMock` or `MagicMock`) or `Mock` (if the parent mock is `Mock`). All asynchronous functions will be `AsyncMock`.

```python
global asyncio

class ExampleClass:
...     def sync_foo():
...         pass
...     async def async_foo():
...         pass
... >>> a_mock = AsyncMock(ExampleClass)
... >>> a_mock.sync_foo
<MagicMock name='mock.sync_foo' id='...'>
... >>> a_mock.async_foo
<AsyncMock name='mock.async_foo' id='...'>
... >>> mock = Mock(ExampleClass)
... >>> mock.sync_foo
<Mock name='mock.sync_foo' id='...'>
... >>> mock.async_foo
<AsyncMock name='mock.async_foo' id='...'>
```

New in version 3.8.

`assert_awaited()`

Assert that the mock was awaited at least once. Note that this is separate from the object having been called, the `await` keyword must be used:

```python
global asyncio

>>> mock = AsyncMock()
... >>> async def main(coroutine_mock):
...     await coroutine_mock
...     await coroutine_mock
...     await coroutine_mock
... >>> coroutine_mock = mock()
... >>> mock.called
True
... >>> mock.assert_awaited()
Traceback (most recent call last):
... AssertionError: Expected mock to have been awaited.
... >>> asyncio.run(main(coroutine_mock))
... >>> mock.assert_awaited()
```

`assert_awaited_once()`

Assert that the mock was awaited exactly once.
>>> mock = AsyncMock()
>>> async def main():
...    await mock()
...    asyncio.run(main())
>>> mock.assert.awaited_once()
>>> asyncio.run(main())
>>> mock.assert.awaited_once()
Traceback (most recent call last):
...  AssertionError: Expected mock to have been awaited once. Awaited 2 times.

**assert.awaited_with** (*args, **kwargs)

Assert that the last await was with the specified arguments.

>>> mock = AsyncMock()
>>> async def main(*args, **kwargs):
...    await mock(*args, **kwargs)
...    asyncio.run(main('foo', bar='bar'))
>>> mock.assert.awaited.with('foo', bar='bar')
>>> mock.assert.awaited.with('other')
Traceback (most recent call last):
...  AssertionError: expected call not found.
Expected: mock('other')
Actual: mock('foo', bar='bar')

**assert.awaited.once_with** (*args, **kwargs)

Assert that the mock was awaited exactly once and with the specified arguments.

>>> mock = AsyncMock()
>>> async def main(*args, **kwargs):
...    await mock(*args, **kwargs)
...    asyncio.run(main('foo', bar='bar'))
>>> mock.assert.awaited.once.with('foo', bar='bar')
>>> mock.assert.awaited.once.with('other')
>>> asyncio.run(main('foo', bar='bar'))
>>> mock.assert.awaited.once.with('foo', bar='bar')
>>> asyncio.run(main('hello'))
>>> mock.assert.any.await('foo', bar='bar')
>>> mock.assert.any.await('other')
Traceback (most recent call last):
...  AssertionError: Expected mock to have been awaited once. Awaited 2 times.

**assert.any.await** (*args, **kwargs)

Assert the mock has ever been awaited with the specified arguments.

>>> mock = AsyncMock()
>>> async def main(*args, **kwargs):
...    await mock(*args, **kwargs)
...    asyncio.run(main('foo', bar='bar'))
>>> asyncio.run(main('hello'))
>>> mock.assert.any.await('foo', bar='bar')
>>> mock.assert.any.await('other')
Traceback (most recent call last):
...  AssertionError: mock('other') await not found

**assert.has.await** (calls, any_order=False)

Assert the mock has been awaited with the specified calls. The *await_args_list* list is checked for the awaits.
If `any_order` is false then the awaits must be sequential. There can be extra calls before or after the specified awaits.

If `any_order` is true then the awaits can be in any order, but they must all appear in `await_args_list`.

```python
>>> mock = AsyncMock()
>>> async def main(*args, **kwargs):
...     await mock(*args, **kwargs)
...
>>> calls = [call("foo"), call("bar")]
>>> mock.assert_has_awaits(calls)
Traceback (most recent call last):
  ...  
AssertionError: Awaits not found.
Expected: [call('foo'), call('bar')]
Actual: []
>>> asyncio.run(main('foo'))
>>> asyncio.run(main('bar'))
>>> mock.assert_has_awaits(calls)
```

**assert_not_awaits()**

Assert that the mock was never awaited.

```python
>>> mock = AsyncMock()
>>> mock.assert_not_awaits()
```

**reset_mock(**args, **kwargs)**

See `Mock.reset_mock()` Also sets `await_count` to 0, `await_args` to None, and clears the `await_args_list`.

**await_count**

An integer keeping track of how many times the mock object has been awaited.

```python
>>> mock = AsyncMock()
>>> async def main():
...     await mock()
...
>>> asyncio.run(main())
>>> mock.await_count
1
>>> asyncio.run(main())
>>> mock.await_count
2
```

**await_args**

This is either `None` (if the mock hasn’t been awaited), or the arguments that the mock was last awaited with. Functions the same as `Mock.call_args`.

```python
>>> mock = AsyncMock()
>>> async def main(*args):
...     await mock(*args)
...
>>> mock.await_args
>>> asyncio.run(main('foo'))
>>> mock.await_args
    call('foo')
>>> asyncio.run(main('bar'))
>>> mock.await_args
    call('bar')
```

**await_args_list**

This is a list of all the awaits made to the mock object in sequence (so the length of the list is the number of times it has been awaited). Before any awaits have been made it is an empty list.
Calling

Mock objects are callable. The call will return the value set as the `return_value` attribute. The default return value is a new Mock object; it is created the first time the return value is accessed (either explicitly or by calling the Mock) - but it is stored and the same one returned each time.

Calls made to the object will be recorded in the attributes like `call_args` and `call_args_list`.

If `side_effect` is set then it will be called after the call has been recorded, so if `side_effect` raises an exception the call is still recorded.

The simplest way to make a mock raise an exception when called is to make `side_effect` an exception class or instance:

```python
>>> m = MagicMock(side_effect=IndexError)
>>> m(1, 2, 3)
Traceback (most recent call last):
...
IndexError
>>> m.mock_calls
[call(i, 2, 3)]
>>> m.side_effect = KeyError('Bang!')
>>> m('two', 'three', 'four')
Traceback (most recent call last):
...
KeyError: 'Bang!'
>>> m.mock_calls
[call(i, 2, 3), call('two', 'three', 'four')]
```

If `side_effect` is a function then whatever that function returns is what calls to the mock return. The `side_effect` function is called with the same arguments as the mock. This allows you to vary the return value of the call dynamically, based on the input:

```python
>>> def side_effect(value):
...     return value + 1
...
>>> m = MagicMock(side_effect=side_effect)
>>> m(1)
2
>>> m(2)
3
>>> m.mock_calls
[call(1), call(2)]
```

If you want the mock to still return the default return value (a new mock), or any set return value, then there are two ways of doing this. Either return `mock.return_value` from inside `side_effect`, or return `DEFAULT`: 

```python
>>> def side_effect(value):
...     return mock.return_value
...
>>> m = MagicMock(side_effect=side_effect)
>>> m(1)
mock
>>> m(2)
mock
>>> m.mock_calls
[call(1), call(2)]
```
>>> m = MagicMock()
>>> def side_effect(*args, **kwargs):
...    return m.return_value
...
>>> m.side_effect = side_effect
>>> m.return_value = 3
>>> m()
3
>>> def side_effect(*args, **kwargs):
...    return DEFAULT
...
>>> m.side_effect = side_effect
>>> m()
3

To remove a side_effect, and return to the default behaviour, set the side_effect to None:

>>> m = MagicMock(return_value=6)
>>> def side_effect(*args, **kwargs):
...    return 3
...
>>> m.side_effect = side_effect
>>> m()
3
>>> m.side_effect = None
>>> m()
6

The side_effect can also be any iterable object. Repeated calls to the mock will return values from the iterable (until the iterable is exhausted and a StopIteration is raised):

>>> m = MagicMock(side_effect=[1, 2, 3])
>>> m()
1
>>> m()
2
>>> m()
3
>>> m()
Traceback (most recent call last):
 ... StopIteration

If any members of the iterable are exceptions they will be raised instead of returned:

>>> iterable = (33, ValueError, 66)
>>> m = MagicMock(side_effect=iterable)
>>> m()
33
>>> m()
Traceback (most recent call last):
 ... ValueError
>>> m()
66
Deleting Attributes

Mock objects create attributes on demand. This allows them to pretend to be objects of any type.

You may want a mock object to return `False` to a `hasattr()` call, or raise an `AttributeError` when an attribute is fetched. You can do this by providing an object as a `spec` for a mock, but that isn’t always convenient.

You “block” attributes by deleting them. Once deleted, accessing an attribute will raise an `AttributeError`.

```python
>>> mock = MagicMock()
>>> hasattr(mock, 'm')
True
>>> del mock.m
>>> hasattr(mock, 'm')
False
>>> del mock.f
>>> mock.f
Traceback (most recent call last):
  ... 
AttributeError: f
```

Mock names and the name attribute

Since “name” is an argument to the `Mock` constructor, if you want your mock object to have a “name” attribute you can’t just pass it in at creation time. There are two alternatives. One option is to use `configure_mock()`:

```python
>>> mock = MagicMock()
>>> mock.configure_mock(name='my_name')
>>> mock.name
'my_name'
```

A simpler option is to simply set the “name” attribute after mock creation:

```python
>>> mock = MagicMock()
>>> mock.name = 'foo'
```

Attaching Mocks as Attributes

When you attach a mock as an attribute of another mock (or as the return value) it becomes a “child” of that mock. Calls to the child are recorded in the `method_calls` and `mock_calls` attributes of the parent. This is useful for configuring child mocks and then attaching them to the parent, or for attaching mocks to a parent that records all calls to the children and allows you to make assertions about the order of calls between mocks:

```python
>>> parent = MagicMock()
>>> child1 = MagicMock(return_value=None)
>>> child2 = MagicMock(return_value=None)
>>> parent.child1 = child1
>>> parent.child2 = child2
>>> child1(1)
>>> child2(2)
>>> parent.mock_calls
[call.child1(1), call.child2(2)]
```

The exception to this is if the mock has a name. This allows you to prevent the “parenting” if for some reason you don’t want it to happen.

```python
>>> mock = MagicMock()
>>> not_a_child = MagicMock(name='not-a-child')
>>> mock.attribute = not_a_child
```
Mocks created for you by `patch()` are automatically given names. To attach mocks that have names to a parent you use the `attach_mock()` method:

```python
>>> thing1 = object()
>>> thing2 = object()
>>> parent = MagicMock()
>>> with patch('__main__.thing1', return_value=None) as child1:
...     with patch('__main__.thing2', return_value=None) as child2:
...         parent.attach_mock(child1, 'child1')
...         parent.attach_mock(child2, 'child2')
...         child1('one')
...         child2('two')
... >>> parent.mock_calls
[call.child1('one'), call.child2('two')]
```

### 26.9.3 The patchers

The patch decorators are used for patching objects only within the scope of the function they decorate. They automatically handle the unpching for you, even if exceptions are raised. All of these functions can also be used in with statements or as class decorators.

**patch**

**Note:** The key is to do the patching in the right namespace. See the section `where to patch`.

```python
unittest.mock.patch(target, new=DEFAULT, spec=None, create=False, spec_set=None, autospec=None, new_callable=None, **kwargs)
```

`patch()` acts as a function decorator, class decorator or a context manager. Inside the body of the function or with statement, the `target` is patched with a `new` object. When the function/with statement exits the patch is undone.

If `new` is omitted, then the target is replaced with an `AsyncMock` if the patched object is an async function or a `MagicMock` otherwise. If `patch()` is used as a decorator and `new` is omitted, the created mock is passed in as an extra argument to the decorated function. If `patch()` is used as a context manager the created mock is returned by the context manager.

`target` should be a string in the form `'package.module.ClassName'`. The `target` is imported and the specified object replaced with the `new` object, so the `target` must be importable from the environment you are calling `patch()` from. The target is imported when the decorated function is executed, not at decoration time.

The `spec` and `spec_set` keyword arguments are passed to the `MagicMock` if patch is creating one for you.

In addition you can pass `spec=True` or `spec_set=True`, which causes patch to pass in the object being mocked as the spec/spec_set object.

`new_callable` allows you to specify a different class, or callable object, that will be called to create the `new` object. By default `AsyncMock` is used for async functions and `MagicMock` for the rest.

A more powerful form of `spec` is `autospec`. If you set `autospec=True` then the mock will be created with a spec from the object being replaced. All attributes of the mock will also have the spec of the corresponding attribute of the object being replaced. Methods and functions being mocked will have their arguments checked.
and will raise a `TypeError` if they are called with the wrong signature. For mocks replacing a class, their return value (the ‘instance’) will have the same spec as the class. See the `create_autospec()` function and `Autospecing`.

Instead of `autospec=True` you can pass `autospec=some_object` to use an arbitrary object as the spec instead of the one being replaced.

By default `patch()` will fail to replace attributes that don’t exist. If you pass in `create=True`, and the attribute doesn’t exist, patch will create the attribute for you when the patched function is called, and delete it again after the patched function has exited. This is useful for writing tests against attributes that your production code creates at runtime. It is off by default because it can be dangerous. With it switched on you can write passing tests against APIs that don’t actually exist!

**Note:** Changed in version 3.5: If you are patching builtins in a module then you don’t need to pass `create=True`, it will be added by default.

Patch can be used as a `TestCase` class decorator. It works by decorating each test method in the class. This reduces the boilerplate code when your test methods share a common patchings set. `patch()` finds tests by looking for method names that start with `patch.TEST_PREFIX`. By default this is 'test', which matches the way `unittest` finds tests. You can specify an alternative prefix by setting `patch.TEST_PREFIX`.

Patch can be used as a context manager, with the with statement. Here the patching applies to the indented block after the with statement. If you use “as” then the patched object will be bound to the name after the “as”; very useful if `patch()` is creating a mock object for you.

`patch()` takes arbitrary keyword arguments. These will be passed to `AsyncMock` if the patched object is asynchronous, to `MagicMock` otherwise or to `new_callable` if specified.

`patch.dict(...)`, `patch.multiple(...)`, and `patch.object(...)` are available for alternate use-cases.

`patch()` as function decorator, creating the mock for you and passing it into the decorated function:

```python
>>> @patch('__main__.SomeClass')
... def function(normal_argument, mock_class):
...     print(mock_class is SomeClass)
...     return True
... >>> function(None)
True
```

Patching a class replaces the class with a `MagicMock` instance. If the class is instantiated in the code under test then it will be the `return_value` of the mock that will be used.

If the class is instantiated multiple times you could use `side_effect` to return a new mock each time. Alternatively you can set the `return_value` to be anything you want.

To configure return values on methods of `instances` on the patched class you must do this on the `return_value`. For example:

```python
>>> class Class:
...     def method(self):
...         pass
... >>> with patch('__main__.Class') as MockClass:
...     instance = MockClass.return_value
...     instance.method.return_value = 'foo'
...     assert Class() is instance
...     assert Class().method() == 'foo'
```

If you use `spec` or `spec_set` and `patch()` is replacing a class, then the return value of the created mock will have the same spec.
The new_callable argument is useful where you want to use an alternative class to the default MagicMock for the created mock. For example, if you wanted a NonCallableMock to be used:

```
>>> thing = object()
>>> with patch('__main__.thing', new_callable=NonCallableMock) as mock_thing:
...    assert thing is mock_thing
...    thing()
...
TypeError: 'NonCallableMock' object is not callable
```

Another use case might be to replace an object with an io.StringIO instance:

```
>>> from io import StringIO
>>> def foo():
...    print('Something')
...
>>> @patch('sys.stdout', new_callable=StringIO)
... def test(mock_stdout):
...    foo()
...    assert mock_stdout.getvalue() == 'Something
'
...
>>> test()
```

When patch() is creating a mock for you, it is common that the first thing you need to do is to configure the mock. Some of that configuration can be done in the call to patch. Any arbitrary keywords you pass into the call will be used to set attributes on the created mock:

```
>>> config = {'method.return_value': 3, 'other.side_effect': KeyError}
>>> patcher = patch('__main__.thing', **config)
>>> mock_thing = patcher.start()
>>> mock_thing.method()
3
>>> mock_thing.other()
Traceback (most recent call last):
...    KeyError
```

By default, attempting to patch a function in a module (or a method or an attribute in a class) that does not exist will fail with AttributeError:
>>> @patch('sys.non_existing_attribute', 42)
... def test():
...   assert sys.non_existing_attribute == 42
... >>> test()
Traceback (most recent call last):
  ... AttributeError: <module 'sys' (built-in)> does not have the attribute 'nonexisting_attribute'
but adding create=True in the call to patch() will make the previous example work as expected:

```python
>>> @patch('sys.non_existing_attribute', 42, create=True)
... def test(mock_stdout):
...   assert sys.non_existing_attribute == 42
... >>> test()
```

Changed in version 3.8: patch() now returns an AsyncMock if the target is an async function.

### patch.object

```python
patch.object(target, attribute, new=DEFAULT, spec=None, create=False, spec_set=None, autospec=None, new_callable=None, **kwargs)
```
patch the named member (attribute) on an object (target) with a mock object.

patch.object() can be used as a decorator, class decorator or a context manager. Arguments new, spec, create, spec_set, autospec and new_callable have the same meaning as for patch(). Like patch(), patch.object() takes arbitrary keyword arguments for configuring the mock object it creates.

When used as a class decorator patch.object() honours patch.TEST_PREFIX for choosing which methods to wrap.

You can either call `patch.object()` with three arguments or two arguments. The three argument form takes the object to be patched, the attribute name and the object to replace the attribute with.

When calling with the two argument form you omit the replacement object, and a mock is created for you and passed in as an extra argument to the decorated function:

```python
>>> @patch.object(SomeClass, 'class_method')
... def test(mock_method):
...   SomeClass.class_method(3)
...   mock_method.assert_called_with(3)
... >>> test()
```

`spec`, `create` and the other arguments to `patch.object()` have the same meaning as they do for `patch()`.

### patch.dict

```python
patch.dict(in_dict, values=(), clear=False, **kwargs)
```
Patch a dictionary, or dictionary like object, and restore the dictionary to its original state after the test.

`in_dict` can be a dictionary or a mapping like container. If it is a mapping then it must at least support getting, setting and deleting items plus iterating over keys.

`in_dict` can also be a string specifying the name of the dictionary, which will then be fetched by importing it.

`values` can be a dictionary of values to set in the dictionary. `values` can also be an iterable of (key, value) pairs.

If `clear` is true then the dictionary will be cleared before the new values are set.
patch.dict() can also be called with arbitrary keyword arguments to set values in the dictionary.

Changed in version 3.8: patch.dict() now returns the patched dictionary when used as a context manager.

patch.dict() can be used as a context manager, decorator or class decorator:

```python
>>> foo = {}
>>> @patch.dict(foo, {'newkey': 'newvalue'})
... def test():
...     assert foo == {'newkey': 'newvalue'}
>>> test()
>>> assert foo == {}
```

When used as a class decorator patch.dict() honours patch.TEST_PREFIX (default to 'test') for choosing which methods to wrap:

```python
>>> import os
>>> import unittest
>>> from unittest.mock import patch
>>> @patch('os.environ', {'newkey': 'newvalue'})
... class TestSample(unittest.TestCase):
...     def test_sample(self):
...         self.assertEqual(os.environ['newkey'], 'newvalue')
```

If you want to use a different prefix for your test, you can inform the patchers of the different prefix by setting patch.TEST_PREFIX. For more details about how to change the value of see TEST_PREFIX.

patch.dict() can be used to add members to a dictionary, or simply let a test change a dictionary, and ensure the dictionary is restored when the test ends.

```python
>>> foo = {}
>>> with patch.dict(foo, {'newkey': 'newvalue'}) as patched_foo:
...     assert foo == {'newkey': 'newvalue'}
...     patched_foo['spam'] = 'eggs'
...     assert patched_foo == {}
>>> assert foo == {}
>>> assert patched_foo == {}
```

```python
>>> import os
>>> with patch.dict('os.environ', {'newkey': 'newvalue'}):
...     print(os.environ['newkey'])
... newvalue
>>> assert 'newkey' not in os.environ
```

Keywords can be used in the patch.dict() call to set values in the dictionary:

```python
>>> mymodule = MagicMock()
>>> mymodule.function.return_value = 'fish'
>>> with patch.dict('sys.modules', mymodule=mymodule):
...     import mymodule
...     mymodule.function('some', 'args')
... 'fish'
```

patch.dict() can be used with dictionary like objects that aren’t actually dictionaries. At the very minimum they must support item getting, setting, deleting and either iteration or membership test. This corresponds to the magic methods __getitem__(), __setitem__(), __delitem__() and either __iter__() or __contains__().
```python
>> class Container:
...    def __init__(self):
...        self.values = {}
...    def __getitem__(self, name):
...        return self.values[name]
...    def __setitem__(self, name, value):
...        self.values[name] = value
...    def __delitem__(self, name):
...        del self.values[name]
...    def __iter__(self):
...        return iter(self.values)

>>> thing = Container()
>>> thing['one'] = 1
>>> with patch.dict(thing, one=2, two=3):
...    assert thing['one'] == 2
...    assert thing['two'] == 3

>>> assert thing['one'] == 1
>>> assert list(thing) == ['one']

patch.multiple

patch.multiple(target, spec=None, create=False, spec_set=None, autospec=None, new_callable=None, **kwargs)

Perform multiple patches in a single call. It takes the object to be patched (either as an object or a string to fetch the object by importing) and keyword arguments for the patches:

```python
with patch.multiple(settings, FIRST_PATCH='one', SECOND_PATCH='two'):
...
```

Use DEFAULT as the value if you want patch.multiple() to create mocks for you. In this case the created mocks are passed into a decorated function by keyword, and a dictionary is returned when patch.multiple() is used as a context manager.

patch.multiple() can be used as a decorator, class decorator or a context manager. The arguments spec, spec_set, create, autospec and new_callable have the same meaning as for patch(). These arguments will be applied to all patches done by patch.multiple().

When used as a class decorator patch.multiple() honours patch.TEST_PREFIX for choosing which methods to wrap.

If you want patch.multiple() to create mocks for you, then you can use DEFAULT as the value. If you use patch.multiple() as a decorator then the created mocks are passed into the decorated function by keyword.

```python
>>> thing = object()
>>> other = object()

>>> @patch.multiple('__main__', thing=DEFAULT, other=DEFAULT)
...    def test_function(thing, other):
...        assert isinstance(thing, MagicMock)
...        assert isinstance(other, MagicMock)

>>> test_function()
```

patch.multiple() can be nested with other patch decorators, but put arguments passed by keyword after any of the standard arguments created by patch():

```python
>>> @patch('sys.exit')
...    @patch.multiple('__main__', thing=DEFAULT, other=DEFAULT)
...    def test_function(mock_exit, other, thing):
...        ...
```

(continues on next page)
If `patch.multiple()` is used as a context manager, the value returned by the context manager is a dictionary where created mocks are keyed by name:

```python
with patch.multiple('__main__', thing=DEFAULT, other=DEFAULT) as values:
    assert 'other' in repr(values['other'])
    assert 'thing' in repr(values['thing'])
    assert values['thing'] is thing
    assert values['other'] is other
```

### patch methods: start and stop

All the patchers have `start()` and `stop()` methods. These make it simpler to do patching in `setUp` methods or where you want to do multiple patches without nesting decorators or with statements.

To use them call `patch()`, `patch.object()` or `patch.dict()` as normal and keep a reference to the returned `patcher` object. You can then call `start()` to put the patch in place and `stop()` to undo it.

If you are using `patch()` to create a mock for you then it will be returned by the call to `patcher.start`.

```python
patcher = patch('package.module.ClassName')
from package import module
original = module.ClassName
new_mock = patcher.start()
assert module.ClassName is not original
assert module.ClassName is new_mock
patcher.stop()
assert module.ClassName is original
assert module.ClassName is not new_mock
```

A typical use case for this might be for doing multiple patches in the `setUp` method of a `TestCase`:

```python
class MyTest(unittest.TestCase):
    def setUp(self):
        self.patcher1 = patch('package.module.Class1')
        self.patcher2 = patch('package.module.Class2')
        self.MockClass1 = self.patcher1.start()
        self.MockClass2 = self.patcher2.start()

    def tearDown(self):
        self.patcher1.stop()
        self.patcher2.stop()

    def test_something(self):
        assert package.module.Class1 is self.MockClass1
        assert package.module.Class2 is self.MockClass2

MyTest('test_something').run()
```

**Caution:** If you use this technique you must ensure that the patching is “undone” by calling `stop`. This can be fiddlier than you might think, because if an exception is raised in the `setUp` then `tearDown` is not called. `unittest.TestCase.addCleanup()` makes this easier:
```python
>>> class MyTest(unittest.TestCase):
...     def setUp(self):
...         patcher = patch('package.module.Class')
...         self.MockClass = patcher.start()
...         self.addCleanup(patcher.stop)
...     def test_something(self):
...         assert package.module.Class is self.MockClass
```

As an added bonus you no longer need to keep a reference to the `patcher` object.

It is also possible to stop all patches which have been started by using `patch.stopall()`.

```
patch.stopall()
```

Stop all active patches. Only stops patches started with `start`.

**patch builtins**

You can patch any builtins within a module. The following example patches builtin `ord()`:

```
>>> @patch('__main__.ord')
...     def test(mock_ord):
...         mock_ord.return_value = 101
...         print(ord('c'))
...>
>>> test()
101
```

**TEST_PREFIX**

All of the patchers can be used as class decorators. When used in this way they wrap every test method on the class. The patchers recognise methods that start with 'test' as being test methods. This is the same way that the `unittest.TestLoader` finds test methods by default.

It is possible that you want to use a different prefix for your tests. You can inform the patchers of the different prefix by setting `patch.TEST_PREFIX`:

```
>>> patch.TEST_PREFIX = 'foo'
>>> value = 3
>>> >>> @patch('__main__.value', 'not three')
...     class Thing:
...         def foo_one(self):
...             print(value)
...         def foo_two(self):
...             print(value)
...>
>>> Thing().foo_one()
not three
>>> Thing().foo_two()
not three
>>> value
3
```
Nesting Patch Decorators

If you want to perform multiple patches then you can simply stack up the decorators.

You can stack up multiple patch decorators using this pattern:

```python
>>> @patch.object(SomeClass, 'class_method')
... @patch.object(SomeClass, 'static_method')
... def test(mock1, mock2):
...     assert SomeClass.static_method is mock1
...     assert SomeClass.class_method is mock2
...     SomeClass.class_method('bar')
...     return mock1, mock2
... >>> mock1, mock2 = test()
>>> mock1.assert_called_once_with('foo')
>>> mock2.assert_called_once_with('bar')
```

Note that the decorators are applied from the bottom upwards. This is the standard way that Python applies decorators. The order of the created mocks passed into your test function matches this order.

Where to patch

`patch()` works by (temporarily) changing the object that a name points to with another one. There can be many names pointing to any individual object, so for patching to work you must ensure that you patch the name used by the system under test.

The basic principle is that you patch where an object is looked up, which is not necessarily the same place as where it is defined. A couple of examples will help to clarify this.

Imagine we have a project that we want to test with the following structure:

```
a.py
  -> Defines SomeClass

b.py
  -> from a import SomeClass
  -> some_function instantiates SomeClass
```

Now we want to test `some_function` but we want to mock out `SomeClass` using `patch()`. The problem is that when we import module b, which we will have to do then it imports `SomeClass` from module a. If we use `patch()` to mock out a.SomeClass then it will have no effect on our test; module b already has a reference to the real `SomeClass` and it looks like our patching had no effect.

The key is to patch out `SomeClass` where it is used (or where it is looked up). In this case `some_function` will actually look up `SomeClass` in module b, where we have imported it. The patching should look like:

```
@patch('b.SomeClass')
```

However, consider the alternative scenario where instead of `from a import SomeClass` module b does import a and `some_function` uses a.SomeClass. Both of these import forms are common. In this case the class we want to patch is being looked up in the module and so we have to patch a.SomeClass instead:

```
@patch('a.SomeClass')
```
Patching Descriptors and Proxy Objects

Both `patch` and `patch.object` correctly patch and restore descriptors: class methods, static methods and properties. You should patch these on the `class` rather than an instance. They also work with some objects that proxy attribute access, like the `django settings` object.

26.9.4 MagicMock and magic method support

Mocking Magic Methods

`Mock` supports mocking the Python protocol methods, also known as “magic methods”. This allows mock objects to replace containers or other objects that implement Python protocols.

Because magic methods are looked up differently from normal methods, this support has been specially implemented. This means that only specific magic methods are supported. The supported list includes almost all of them. If there are any missing that you need please let us know.

You mock magic methods by setting the method you are interested in to a function or a mock instance. If you are using a function then it must take `self` as the first argument.

```python
>>> def __str__(self):
...     return 'fooble'
... >>> mock = Mock()
>>> mock.__str__ = __str__
>>> str(mock)
'fooble'
```

```python
>>> mock = Mock()
>>> mock.__str__ = Mock()
>>> mock.__str__.return_value = 'fooble'
>>> str(mock)
'fooble'
```

```python
>>> mock = Mock()
>>> mock.__iter__ = Mock(return_value=iter([]))
>>> list(mock)
[]
```

One use case for this is for mocking objects used as context managers in a `with` statement:

```python
>>> mock = Mock()
>>> mock.__enter__ = Mock(return_value='foo')
>>> mock.__exit__ = Mock(return_value=False)
>>> with mock as m:
...     assert m == 'foo'
... >>> mock.__enter__.assert_called_with()
>>> mock.__exit__.assert_called_with(Non, None, None)
```

Calls to magic methods do not appear in `method_calls`, but they are recorded in `mock_calls`.

**Note:** If you use the `spec` keyword argument to create a mock then attempting to set a magic method that isn’t in the spec will raise an `AttributeError`.

The full list of supported magic methods is:

2 Magic methods should be looked up on the class rather than the instance. Different versions of Python are inconsistent about applying this rule. The supported protocol methods should work with all supported versions of Python.

3 The function is basically hooked up to the class, but each `Mock` instance is kept isolated from the others.
• __hash__, __sizeof__, __repr__ and __str__
• __dir__, __format__ and __subclasses__
• __round__, __floor__, __trunc__ and __ceil__

Comparisons: __lt__, __gt__, __le__, __ge__, __eq__ and __ne__

• Container methods: __getitem__, __setitem__, __delitem__, __contains__, __len__, __iter__, __reversed__ and __missing__

• Context manager: __enter__, __exit__, __aenter__ and __aexit__

• Unary numeric methods: __neg__, __pos__ and __invert__

• The numeric methods (including right hand and in-place variants): __add__, __sub__, __mul__, __matmul__, __div__, __truediv__, __floordiv__, __mod__, __divmod__, __lshift__, __rshift__, __and__, __xor__, __or__, and __pow__

• Numeric conversion methods: __complex__, __int__, __float__ and __index__

• Descriptor methods: __get__, __set__ and __delete__

• Pickling: __reduce__, __reduce_ex__, __getinitargs__, __getnewargs__, __getstate__ and __setstate__

• File system path representation: __fspath__

• Asynchronous iteration methods: __aiter__ and __anext__

Changed in version 3.8: Added support for `os.PathLike.__fspath__()`. Changed in version 3.8: Added support for __aenter__, __aexit__, __aiter__ and __anext__.

The following methods exist but are not supported as they are either in use by mock, can’t be set dynamically, or can cause problems:

• __getattr__, __setattr__, __init__ and __new__
• __prepare__, __instancecheck__, __subclasscheck__, __del__

**Magic Mock**

There are two MagicMock variants: **MagicMock** and **NonCallableMagicMock**.

class unittest.mock.MagicMock(*args, **kw)

MagicMock is a subclass of Mock with default implementations of most of the magic methods. You can use MagicMock without having to configure the magic methods yourself.

The constructor parameters have the same meaning as for Mock.

If you use the spec or spec_set arguments then only magic methods that exist in the spec will be created.

class unittest.mock.NonCallableMagicMock(*args, **kw)

A non-callable version of MagicMock.

The constructor parameters have the same meaning as for MagicMock, with the exception of return_value and side_effect which have no meaning on a non-callable mock.

The magic methods are setup with MagicMock objects, so you can configure them and use them in the usual way:

```python
>>> mock = MagicMock()
>>> mock[3] = 'fish'
>>> mock[3].assert_called_with(3, 'fish')
>>> mock[3].return_value = 'result'
>>> mock[2]
'result'
```
By default many of the protocol methods are required to return objects of a specific type. These methods are pre-configured with a default return value, so that they can be used without you having to do anything if you aren’t interested in the return value. You can still set the return value manually if you want to change the default.

Methods and their defaults:

- `__lt__`: `NotImplemented`
- `__gt__`: `NotImplemented`
- `__le__`: `NotImplemented`
- `__ge__`: `NotImplemented`
- `__int__`: 1
- `__contains__`: False
- `__len__`: 0
- `__iter__`: `iter([])`
- `__exit__`: False
- `__aexit__`: False
- `__complex__`: 1j
- `__float__`: 1.0
- `__bool__`: True
- `__index__`: 1
- `__hash__`: default hash for the mock
- `__str__`: default str for the mock
- `__sizeof__`: default sizeof for the mock

For example:

```python
>>> mock = MagicMock()
>>> int(mock)
1
>>> len(mock)
0
>>> list(mock)
[]
>>> object() in mock
False
```

The two equality methods, `__eq__()` and `__ne__()`, are special. They do the default equality comparison on identity, using the `side_effect` attribute, unless you change their return value to return something else:

```python
>>> MagicMock() == 3
False
>>> MagicMock() != 3
True
>>> mock = MagicMock()
>>> mock.__eq__.return_value = True
>>> mock == 3
True
```

The return value of `MagicMock.__iter__()` can be any iterable object and isn’t required to be an iterator:

```python
>>> mock = MagicMock()
>>> mock.__iter__.return_value = ['a', 'b', 'c']
>>> list(mock)
```

(continues on next page)
If the return value is an iterator, then iterating over it once will consume it and subsequent iterations will result in an empty list:

```python
>>> mock.__iter__.return_value = iter(['a', 'b', 'c'])
>>> list(mock)
['a', 'b', 'c']
>>> list(mock)
[]
```

MagicMock has all of the supported magic methods configured except for some of the obscure and obsolete ones. You can still set these up if you want.

Magic methods that are supported but not setup by default in MagicMock are:

- `__subclasses__`
- `__dir__`
- `__format__`
- `__get__, __set__ and __delete__`
- `__reversed__ and __missing__`
- `__reduce__, __reduce_ex__, __getinitargs__, __getnewargs__, __getstate__ and __setstate__`
- `__getformat__ and __setformat__`

### 26.9.5 Helpers

#### sentinel

`unittest.mock.sentinel`

The `sentinel` object provides a convenient way of providing unique objects for your tests.

Attributes are created on demand when you access them by name. Accessing the same attribute will always return the same object. The objects returned have a sensible repr so that test failure messages are readable.

Changed in version 3.7: The `sentinel` attributes now preserve their identity when they are copied or pickled.

Sometimes when testing you need to test that a specific object is passed as an argument to another method, or returned. It can be common to create named sentinel objects to test this. `sentinel` provides a convenient way of creating and testing the identity of objects like this.

In this example we monkey patch `method` to return `sentinel.some_object`:

```python
>>> real = ProductionClass()
>>> real.method = Mock(name="method")
>>> real.method.return_value = sentinel.some_object
>>> result = real.method()
>>> assert result is sentinel.some_object
>>> result
sentinel.some_object
```
DEFAULT

unittest.mock.DEFAULT

The `DEFAULT` object is a pre-created sentinel (actually `sentinel.DEFAULT`). It can be used by `side_effect` functions to indicate that the normal return value should be used.

call

unittest.mock.call(*args, **kwargs)

call()` is a helper object for making simpler assertions, for comparing with `call_args`, `call_args_list`, `mock_calls` and `method_calls`. `call()` can also be used with `assert_has_calls()`.

```python
>>> m = MagicMock(return_value=None)
>>> m(1, 2, a='foo', b='bar')
>>> m()
>>> m.call_args_list == [call(1, 2, a='foo', b='bar'), call()]
True
```

call.call_list()

For a call object that represents multiple calls, `call_list()` returns a list of all the intermediate calls as well as the final call.

call_list is particularly useful for making assertions on “chained calls”. A chained call is multiple calls on a single line of code. This results in multiple entries in `mock_calls` on a mock. Manually constructing the sequence of calls can be tedious.

call_list() can construct the sequence of calls from the same chained call:

```python
>>> m = MagicMock()
>>> m(1).method(arg='foo').other('bar')(2.0)
<MagicMock name='mock().method().other()' id='...'>
>>> kall = call(1).method(arg='foo').other('bar')(2.0)
>>> kall.call_list()
[call(1),
 call().method(arg='foo'),
 call().method().other('bar'),
 call().method().other()(2.0)]
>>> m.mock_calls == kall.call_list()
True
```

A call object is either a tuple of (positional args, keyword args) or (name, positional args, keyword args) depending on how it was constructed. When you construct them yourself this isn’t particularly interesting, but the call objects that are in the `Mock.call_args`, `Mock.call_args_list` and `Mock.mock_calls` attributes can be introspected to get at the individual arguments they contain.

The call objects in `Mock.call_args` and `Mock.call_args_list` are two-tuples of (positional args, keyword args) whereas the call objects in `Mock.mock_calls`, along with ones you construct yourself, are three-tuples of (name, positional args, keyword args).

You can use their “tupleness” to pull out the individual arguments for more complex introspection and assertions. The positional arguments are a tuple (an empty tuple if there are no positional arguments) and the keyword arguments are a dictionary:

```python
>>> m = MagicMock(return_value=None)
>>> m(1, 2, 3, arg='one', arg2='two')
>>> kall = m.call_args
>>> kall.args
(1, 2, 3)
>>> kall.kwargs
{'arg': 'one', 'arg2': 'two'}
```
>>> kall.args is kall[0]
True
>>> kall.kwargs is kall[1]
True

>>> m = MagicMock()
>>> m.foo(4, 5, 6, arg='two', arg2='three')
<Mock name='mock.foo()' id='...'>
>>> kall = m.mock_calls[0]
>>> name, args, kwargs = kall
>>> name
'foo'
>>> args
(4, 5, 6)
>>> kwargs
{'arg': 'two', 'arg2': 'three'}
>>> name is m.mock_calls[0][0]
True

create_autospec

unittest.mock.create_autospec (spec, spec_set=False, instance=False, **kwargs)

Create a mock object using another object as a spec. Attributes on the mock will use the corresponding attribute on the spec object as their spec.

Functions or methods being mocked will have their arguments checked to ensure that they are called with the correct signature.

If spec_set is True then attempting to set attributes that don’t exist on the spec object will raise an AttributeError.

If a class is used as a spec then the return value of the mock (the instance of the class) will have the same spec. You can use a class as the spec for an instance object by passing instance=True. The returned mock will only be callable if instances of the mock are callable.

create_autospec() also takes arbitrary keyword arguments that are passed to the constructor of the created mock.

See Autospeccing for examples of how to use auto-speccing with create_autospec() and the autospec argument to patch().

Changed in version 3.8: create_autospec() now returns an AsyncMock if the target is an async function.

ANY

unittest.mock.ANY

Sometimes you may need to make assertions about some of the arguments in a call to mock, but either not care about some of the arguments or want to pull them individually out of call_args and make more complex assertions on them.

To ignore certain arguments you can pass in objects that compare equal to everything. Calls to assert_called_with() and assert_called_once_with() will then succeed no matter what was passed in.

>>> mock = Mock(return_value=None)
>>> mock('foo', bar=object())
>>> mock.assert_called_once_with('foo', bar=ANY)

ANY can also be used in comparisons with call lists like mock_calls:
>>> m = MagicMock(return_value=None)
>>> m(1)
>>> m(1, 2)
>>> m(object())
>>> m.mock_calls == [call(1), call(1, 2), ANY]
True

FILTER_DIR

unittest.mock.FILTER_DIR

FILTER_DIR is a module level variable that controls the way mock objects respond to dir() (only for Python 2.6 or more recent). The default is True, which uses the filtering described below, to only show useful members. If you dislike this filtering, or need to switch it off for diagnostic purposes, then set mock.FILTER_DIR = False.

With filtering on, dir(some_mock) shows only useful attributes and will include any dynamically created attributes that wouldn’t normally be shown. If the mock was created with a spec (or autospec of course) then all the attributes from the original are shown, even if they haven’t been accessed yet:

```python
>>> dir(Mock())
['assert_any_call',
 'assert_called',
 'assert_called_once',
 'assert_called_once_with',
 'assert_called_with',
 'assert_has_calls',
 'assert_not_called',
 'attach_mock',
 ...]
```

```python
>>> from urllib import request
>>> dir(Mock(spec=request))
['AbstractBasicAuthHandler',
 'AbstractDigestAuthHandler',
 'AbstractHTTPHandler',
 'BaseHandler',
 ...]
```

Many of the not-very-useful (private to Mock rather than the thing being mocked) underscore and double underscore prefixed attributes have been filtered from the result of calling dir() on a Mock. If you dislike this behaviour you can switch it off by setting the module level switch FILTER_DIR:

```python
>>> from unittest import mock
>>> mock.FILTER_DIR = False
>>> dir(mock.Mock())
['_NonCallableMock__get_return_value',
 '_NonCallableMock__get_side_effect',
 '_NonCallableMock__return_value_doc',
 '_NonCallableMock__set_return_value',
 '_NonCallableMock__set_side_effect',
 '__call__',
 '__class__',
 ...]
```

Alternatively you can just use vars(my_mock) (instance members) and dir(type(my_mock)) (type members) to bypass the filtering irrespective of mock.FILTER_DIR.
**mock_open**

`unittest.mock.mock_open (mock=None, read_data=None)`

A helper function to create a mock to replace the use of `open()`. It works for `open()` called directly or used as a context manager.

The `mock` argument is the mock object to configure. If `None` (the default) then a `MagicMock` will be created for you, with the API limited to methods or attributes available on standard file handles.

`read_data` is a string for the `read()`, `readline()`, and `readlines()` methods of the file handle to return. Calls to those methods will take data from `read_data` until it is depleted. The mock of these methods is pretty simplistic: every time the `mock` is called, the `read_data` is rewound to the start. If you need more control over the data that you are feeding to the tested code you will need to customize this mock for yourself. When that is insufficient, one of the in-memory filesystem packages on PyPI can offer a realistic filesystem for testing.

Changed in version 3.4: Added `readline()` and `readlines()` support. The mock of `read()` changed to consume `read_data` rather than returning it on each call.

Changed in version 3.5: `read_data` is now reset on each call to the `mock`.

Changed in version 3.8: Added `__iter__()` to implementation so that iteration (such as in for loops) correctly consumes `read_data`.

Using `open()` as a context manager is a great way to ensure your file handles are closed properly and is becoming common:

```python
with open('/some/path', 'w') as f:
    f.write('something')
```

The issue is that even if you mock out the call to `open()` it is the returned object that is used as a context manager (and has `__enter__()` and `__exit__()` called).

Mocking context managers with a `MagicMock` is common enough and fiddly enough that a helper function is useful.

```python
>>> m = mock_open()
>>> with patch('__main__.open', m):
...     with open('foo', 'w') as h:
...         h.write('some stuff')
...

>>> m.mock_calls
[call('foo', 'w'),
 call().__enter__(),
 call().write('some stuff'),
 call().__exit__(None, None, None)]
>>> m.assert_called_once_with('foo', 'w')
>>> handle = m()
>>> handle.write.assert_called_once_with('some stuff')
```

And for reading files:

```python
>>> with patch('__main__.open', mock_open(read_data='bibble')) as m:
...     with open('foo') as h:
...         result = h.read()
...

>>> m.assert_called_once_with('foo')
>>> assert result == 'bibble'
```
Autospeccing

Autospeccing is based on the existing spec feature of mock. It limits the api of mocks to the api of an original object (the spec), but it is recursive (implemented lazily) so that attributes of mocks only have the same api as the attributes of the spec. In addition mocked functions / methods have the same call signature as the original so they raise a TypeError if they are called incorrectly.

Before I explain how auto-speccing works, here’s why it is needed.

Mock is a very powerful and flexible object, but it suffers from two flaws when used to mock out objects from a system under test. One of these flaws is specific to the Mock api and the other is a more general problem with using mock objects.

First the problem specific to Mock. Mock has two assert methods that are extremely handy: assert_called_with() and assert_called_once_with().

```python
>>> mock = Mock(name='Thing', return_value=None)
>>> mock(1, 2, 3)
>>> mock.assert_called_once_with(1, 2, 3)
>>> mock.assert_called_once_with(1, 2, 3)
Traceback (most recent call last):
...  
AssertionError: Expected 'mock' to be called once. Called 2 times.
```

Because mocks auto-create attributes on demand, and allow you to call them with arbitrary arguments, if you misspell one of these assert methods then your assertion is gone:

```python
>>> mock = Mock(name='Thing', return_value=None)
>>> mock(1, 2, 3)
>>> mock.assert_called_once_with(4, 5, 6)
```

Your tests can pass silently and incorrectly because of the typo.

The second issue is more general to mocking. If you refactor some of your code, rename members and so on, any tests for code that is still using the old api but uses mocks instead of the real objects will still pass. This means your tests can all pass even though your code is broken.

Note that this is another reason why you need integration tests as well as unit tests. Testing everything in isolation is all fine and dandy, but if you don’t test how your units are “wired together” there is still lots of room for bugs that tests might have caught.

Mock already provides a feature to help with this, called speccing. If you use a class or instance as the spec for a mock then you can only access attributes on the mock that exist on the real class:

```python
>>> from urllib import request
>>> mock = Mock(spec=request.Request)
>>> mock.assert_called_with
Traceback (most recent call last):
...  
AttributeError: Mock object has no attribute 'assret_called_with'
```

The spec only applies to the mock itself, so we still have the same issue with any methods on the mock:

```python
>>> mock.has_data()
<MockMock object at 0x...>
>>> mock.has_data.assert_called_with()
```

Auto-speccing solves this problem. You can either pass autospec=True to patch() / patch.object() or use the create_autospec() function to create a mock with a spec. If you use the autospec=True argument to patch() then the object that is being replaced will be used as the spec object. Because the speccing is done “lazily” (the spec is created as attributes on the mock are accessed) you can use it with very complex or deeply nested objects (like modules that import modules that import modules) without a big performance hit.
Here’s an example of it in use:

```python
>>> from urllib import request
>>> patcher = patch('__main__.request', autospec=True)
>>> mock_request = patcher.start()
>>> request is mock_request
True
>>> mock_request.Request
MagicMock name='request.Request' spec='Request' id='...
```

You can see that `request.Request` has a spec. `request.Request` takes two arguments in the constructor (one of which is `self`). Here’s what happens if we try to call it incorrectly:

```python
>>> req = request.Request()
Traceback (most recent call last):
...  TypeError: <lambda>() takes at least 2 arguments (1 given)
```

The spec also applies to instantiated classes (i.e. the return value of specced mocks):

```python
>>> req = request.Request('foo')
>>> req
NonCallableMock name='request.Request()' spec='Request' id='...
```

Request objects are not callable, so the return value of instantiating our mocked out `request.Request` is a non-callable mock. With the spec in place any typos in our asserts will raise the correct error:

```python
>>> req.add_header('spam', 'eggs')
<MagicMock name='request.Request().add_header()' id='...
```

```python
>>> req.add_header.assert_called_with('spam', 'eggs')
Traceback (most recent call last):
...  AttributeError: Mock object has no attribute 'assert_called_with'
```

In many cases you will just be able to add `autospec=True` to your existing `patch()` calls and then be protected against bugs due to typos and api changes.

As well as using `autospec` through `patch()` there is a `create_autospec()` for creating autospeced mocks directly:

```python
>>> from urllib import request
>>> mock_request = create_autospec(request)
>>> mock_request.Request('foo', 'bar')
NonCallableMock name='mock.Request()' spec='Request' id='...
```

This isn’t without caveats and limitations however, which is why it is not the default behaviour. In order to know what attributes are available on the spec object, autospec has to introspect (access attributes) the spec. As you traverse attributes on the mock a corresponding traversal of the original object is happening under the hood. If any of your specced objects have properties or descriptors that can trigger code execution then you may not be able to use autospec. On the other hand it is much better to design your objects so that introspection is safe.

A more serious problem is that it is common for instance attributes to be created in the `__init__()` method and not to exist on the class at all. `autospec` can’t know about any dynamically created attributes and restricts the api to visible attributes.

```python
>>> class Something:
...     def __init__(self):
...         self.a = 33

(continues on next page)
```

---

4 This only applies to classes or already instantiated objects. Calling a mocked class to create a mock instance does not create a real instance. It is only attribute lookups - along with calls to `dir()` - that are done.
There are a few different ways of resolving this problem. The easiest, but not necessarily the least annoying, way is to simply set the required attributes on the mock after creation. Just because autospec doesn’t allow you to fetch attributes that don’t exist on the spec it doesn’t prevent you setting them:

```python
>>> with patch('__main__.Something', autospec=True):
...     thing = Something()
...     thing.a
...
Traceback (most recent call last):
... AttributeError: Mock object has no attribute 'a'
```

There is a more aggressive version of both spec and autospec that does prevent you setting non-existent attributes. This is useful if you want to ensure your code only sets valid attributes too, but obviously it prevents this particular scenario:

```python
>>> with patch('__main__.Something', autospec=True, spec_set=True):
...     thing = Something()
...     thing.a = 33
...
Traceback (most recent call last):
... AttributeError: Mock object has no attribute 'a'
```

Probably the best way of solving the problem is to add class attributes as default values for instance members initialised in __init__(). Note that if you are only setting default attributes in __init__() then providing them via class attributes (shared between instances of course) is faster too. e.g.

```python
class Something:
    a = 33
```

This brings up another issue. It is relatively common to provide a default value of None for members that will later be an object of a different type. None would be useless as a spec because it wouldn’t let you access any attributes or methods on it. As None is never going to be useful as a spec, and probably indicates a member that will normally of some other type, autospec doesn’t use a spec for members that are set to None. These will just be ordinary mocks (well - MagicMocks):

```python
>>> class Something:
...     member = None
...
>>> mock = create_autospec(Something)
>>> mock.member.foo.bar.baz()
<Mock name='mock.member.foo.bar.baz()' id='...'>
```

If modifying your production classes to add defaults isn’t to your liking then there are more options. One of these is simply to use an instance as the spec rather than the class. The other is to create a subclass of the production class and add the defaults to the subclass without affecting the production class. Both of these require you to use an alternative object as the spec. Thankfully patch() supports this - you can simply pass the alternative object as the autospec argument:

```python
>>> class Something:
...     def __init__(self):
...         self.a = 33
...
>>> class SomethingForTest(Something):

(continues on next page)```
Sealing mocks

unittest.mock.seal(mock)

Seal will disable the automatic creation of mocks when accessing an attribute of the mock being sealed or any of its attributes that are already mocks recursively.

If a mock instance with a name or a spec is assigned to an attribute it won’t be considered in the sealing chain. This allows one to prevent seal from fixing part of the mock object.

```
>>> mock = Mock()
>>> mock.submock.attribute1 = 2
>>> mock.not_submock = mock.Mock(name="sample_name")
>>> seal(mock)
>>> mock.new_attribute  # This will raise AttributeError.
>>> mock.submock.attribute2  # This will raise AttributeError.
>>> mock.not_submock.attribute2  # This won't raise.
```

New in version 3.7.

26.10 unittest.mock — getting started

New in version 3.3.

26.10.1 Using Mock

Mock Patching Methods

Common uses for Mock objects include:

- Patching methods
- Recording method calls on objects

You might want to replace a method on an object to check that it is called with the correct arguments by another part of the system:

```
>>> real = SomeClass()
>>> real.method = MagicMock(name='method')
>>> real.method(3, 4, 5, key='value')
<MagicMock name='method()' id='...'>
```

Once our mock has been used (real.method in this example) it has methods and attributes that allow you to make assertions about how it has been used.

**Note:** In most of these examples the Mock and MagicMock classes are interchangeable. As the MagicMock is the more capable class it makes a sensible one to use by default.
Once the mock has been called its `called` attribute is set to `True`. More importantly we can use the `assert_called_with()` or `assert_called_once_with()` method to check that it was called with the correct arguments.

This example tests that calling `ProductionClass().method` results in a call to the `something` method:

```python
>>> class ProductionClass:
...     def method(self):
...         self.something(1, 2, 3)
...     def something(self, a, b, c):
...         pass
... >>> real = ProductionClass()
>>> real.something = MagicMock()
>>> real.method()
>>> real.something.assert_called_once_with(1, 2, 3)
```

### Mock for Method Calls on an Object

In the last example we patched a method directly on an object to check that it was called correctly. Another common use case is to pass an object into a method (or some part of the system under test) and then check that it is used in the correct way.

The simple `ProductionClass` below has a `closer` method. If it is called with an object then it calls `close` on it.

```python
>>> class ProductionClass:
...     def closer(self, something):
...         something.close()
... >>> real = ProductionClass()
>>> mock = Mock()
>>> real.closer(mock)
>>> mock.close.assert_called_with()
```

We don’t have to do any work to provide the ‘close’ method on our mock. Accessing close creates it. So, if ‘close’ hasn’t already been called then accessing it in the test will create it, but `assert_called_with()` will raise a failure exception.

### Mocking Classes

A common use case is to mock out classes instantiated by your code under test. When you patch a class, then that class is replaced with a mock. Instances are created by calling the class. This means you access the “mock instance” by looking at the return value of the mocked class.

In the example below we have a function `some_function` that instantiates `Foo` and calls a method on it. The call to `patch()` replaces the class `Foo` with a mock. The `Foo` instance is the result of calling the mock, so it is configured by modifying the mock `return_value`.

```python
>>> def some_function():
...     instance = module.Foo()
...     return instance.method()
... >>> with patch('module.Foo') as mock:
...     instance = mock.return_value
...     instance.method.return_value = 'the result'
(continues on next page)```
Naming your mocks

It can be useful to give your mocks a name. The name is shown in the repr of the mock and can be helpful when the mock appears in test failure messages. The name is also propagated to attributes or methods of the mock:

```python
>>> mock = MagicMock(name='foo')
>>> mock
<MagicMock name='foo' id='...'>
>>> mock.method
<MagicMock name='foo.method' id='...'>
```

Tracking all Calls

Often you want to track more than a single call to a method. The `mock_calls` attribute records all calls to child attributes of the mock - and also to their children.

```python
>>> mock = MagicMock()
>>> mock.method()
<MagicMock name='mock.method()' id='...'>
>>> mock.attribute.method(10, x=53)
<MagicMock name='mock.attribute.method()' id='...'>
>>> mock.mock_calls
[call.method(), call.attribute.method(10, x=53)]
```

If you make an assertion about `mock_calls` and any unexpected methods have been called, then the assertion will fail. This is useful because as well as asserting that the calls you expected have been made, you are also checking that they were made in the right order and with no additional calls:

You use the `call` object to construct lists for comparing with `mock_calls`:

```python
>>> expected = [call.method(), call.attribute.method(10, x=53)]
>>> mock.mock_calls == expected
True
```

However, parameters to calls that return mocks are not recorded, which means it is not possible to track nested calls where the parameters used to create ancestors are important:

```python
>>> m = Mock()
>>> m.factory(important=True).deliver()
<Mock name='mock.factory().deliver()' id='...'>
>>> m.mock_calls[-1] == call.factory(important=False).deliver()
True
```
Setting Return Values and Attributes

Setting the return values on a mock object is trivially easy:

```python
>>> mock = Mock()
>>> mock.return_value = 3
>>> mock()
3
```

Of course you can do the same for methods on the mock:

```python
>>> mock = Mock()
>>> mock.method.return_value = 3
>>> mock.method()
3
```

The return value can also be set in the constructor:

```python
>>> mock = Mock(return_value=3)
>>> mock()
3
```

If you need an attribute setting on your mock, just do it:

```python
>>> mock = Mock()
>>> mock.x = 3
>>> mock.x
3
```

Sometimes you want to mock up a more complex situation, like for example `mock.connection.cursor().execute("SELECT 1")`. If we wanted this call to return a list, then we have to configure the result of the nested call.

We can use `call` to construct the set of calls in a “chained call” like this for easy assertion afterwards:

```python
>>> mock = Mock()
>>> cursor = mock.connection.cursor.return_value
>>> cursor.execute.return_value = ['foo']
>>> mock.connection.cursor().execute("SELECT 1")
['foo']
>>> expected = call.connection.cursor().execute("SELECT 1").call_list()
>>> mock.mock_calls
[call.connection.cursor(), call.connection.cursor().execute('SELECT 1')]  
>>> mock.mock_calls == expected
True
```

It is the call to `.call_list()` that turns our call object into a list of calls representing the chained calls.

Raising exceptions with mocks

A useful attribute is `side_effect`. If you set this to an exception class or instance then the exception will be raised when the mock is called.

```python
>>> mock = Mock(side_effect=Exception('Boom!'))
>>> mock()
Traceback (most recent call last):
  ...
Exception: Boom!
```
Side effect functions and iterables

side_effect can also be set to a function or an iterable. The use case for side_effect as an iterable is where your mock is going to be called several times, and you want each call to return a different value. When you set side_effect to an iterable every call to the mock returns the next value from the iterable:

```python
>>> mock = MagicMock(side_effect=[4, 5, 6])
>>> mock()  
4
>>> mock()  
5
>>> mock()  
6
```

For more advanced use cases, like dynamically varying the return values depending on what the mock is called with, side_effect can be a function. The function will be called with the same arguments as the mock. Whatever the function returns is what the call returns:

```python
>>> vals = {(1, 2): 1, (2, 3): 2}
>>> def side_effect(*args):
...     return vals[args]
...     mock = MagicMock(side_effect=side_effect)
>>> mock(1, 2)  
1
>>> mock(2, 3)  
2
```

Mocking asynchronous iterators

Since Python 3.8, AsyncMock and MagicMock have support to mock async-iterators through __aiter__. The return_value attribute of __aiter__ can be used to set the return values to be used for iteration:

```python
>>> mock = MagicMock()  # AsyncMock also works here
>>> mock.__aiter__.return_value = [1, 2, 3]
>>> async def main():
...     return [i async for i in mock]
...     asyncio.run(main())
[1, 2, 3]
```

Mocking asynchronous context manager

Since Python 3.8, AsyncMock and MagicMock have support to mock async-context-managers through __aenter__ and __aexit__. By default, __aenter__ and __aexit__ are AsyncMock instances that return an async function.

```python
>>> class AsyncContextManager:
...     async def __aenter__(self):
...         return self
...     async def __aexit__(self, exc_type, exc, tb):
...         pass
...     mock_instance = MagicMock(AsyncContextManager())  # AsyncMock also works here
>>> async def main():
...     async with mock_instance as result:
...         pass
...     ...
```

(continues on next page)
Creating a Mock from an Existing Object

One problem with overuse of mocking is that it couples your tests to the implementation of your mocks rather than your real code. Suppose you have a class that implements `some_method`. In a test for another class, you provide a mock of this object that also provides `some_method`. If later you refactor the first class, so that it no longer has `some_method` - then your tests will continue to pass even though your code is now broken!

`Mock` allows you to provide an object as a specification for the mock, using the `spec` keyword argument. Accessing methods/attributes on the mock that don’t exist on your specification object will immediately raise an attribute error. If you change the implementation of your specification, then tests that use that class will start failing immediately without you having to instantiate the class in those tests.

```python
>>> mock = Mock(spec=SomeClass)
>>> mock.old_method()
Traceback (most recent call last):
  ... AttributeError: object has no attribute 'old_method'
```

Using a specification also enables a smarter matching of calls made to the mock, regardless of whether some parameters were passed as positional or named arguments:

```python
>>> def f(a, b, c): pass
... >>> mock = Mock(spec=f)
... >>> mock(1, 2, 3)
<Mock name='mock()' id='140161580456576'>
... >>> mock.assert_called_with(a=1, b=2, c=3)
```

If you want this smarter matching to also work with method calls on the mock, you can use `auto-specing`.

If you want a stronger form of specification that prevents the setting of arbitrary attributes as well as the getting of them then you can use `spec_set` instead of `spec`.

### 26.10.2 Patch Decorators

**Note:** With `patch()` it matters that you patch objects in the namespace where they are looked up. This is normally straightforward, but for a quick guide read `where to patch`.

A common need in tests is to patch a class attribute or a module attribute, for example patching a built-in or patching a class in a module to test that it is instantiated. Modules and classes are effectively global, so patching on them has to be undone after the test or the patch will persist into other tests and cause hard to diagnose problems.

`mock` provides three convenient decorators for this: `patch()`, `patch.object()` and `patch.dict()`. `patch` takes a single string, of the form `package/module.Class.attribute` to specify the attribute you are patching. It also optionally takes a value that you want the attribute (or class or whatever) to be replaced with. `patch.object` takes an object and the name of the attribute you would like patched, plus optionally the value to patch it with.

```python
>>> original = SomeClass.attribute
... >>> @patch.object(SomeClass, 'attribute', sentinel.attribute)
```

(continues on next page)
... def test():
    ...
    assert SomeClass.attribute == sentinel.attribute
    ...
>>> test()
>>> assert SomeClass.attribute == original

>>> @patch('package.module.attribute', sentinel.attribute)
... def test():
    ...
    from package.module import attribute
    ...
    assert attribute is sentinel.attribute
    ...
>>> test()

If you are patching a module (including `builtins`) then use `patch()` instead of `patch.object()`:

>>> mock = MagicMock(return_value=sentinel.file_handle)
>>> with patch('builtins.open', mock):
    ... handle = open('filename', 'r')
    ...
>>> mock.assert_called_with('filename', 'r')
>>> assert handle == sentinel.file_handle, "incorrect file handle returned"

The module name can be 'dotted', in the form `package.module` if needed:

>>> @patch('package.module.ClassName.attribute', sentinel.attribute)
... def test():
    ...
    from package.module import ClassName
    ...
    assert ClassName.attribute == sentinel.attribute
    ...
>>> test()

A nice pattern is to actually decorate test methods themselves:

>>> class MyTest(unittest.TestCase):
...     @patch.object(SomeClass, 'attribute', sentinel.attribute)
...     @patch('package.module.ClassName', sentinel.attribute)
...     def test_something(self):
...         self.assertEqual(SomeClass.attribute, sentinel.attribute)
...     ...
... original = SomeClass.attribute
>>> MyTest('test_something').test_something()
>>> assert SomeClass.attribute == original

If you want to patch with a Mock, you can use `patch()` with only one argument (or `patch.object()` with two arguments). The mock will be created for you and passed into the test function / method:

>>> class MyTest(unittest.TestCase):
...     @patch.object(SomeClass, 'static_method')
...     def test_something(self, mock_method):
...         SomeClass.static_method()
...         mock_method.assert_called_with()
...     ...
>>> MyTest('test_something').test_something()

You can stack up multiple patch decorators using this pattern:

>>> class MyTest(unittest.TestCase):
...     @patch('package.module.ClassName1')
...     @patch('package.module.ClassName2')
...     def test_something(self, MockClass2, MockClass1):
...         self.assertIs(package.module.ClassName1, MockClass1)
...         self.assertIs(package.module.ClassName2, MockClass2)

(continues on next page)
>>> MyTest('test_something').test_something()

When you nest patch decorators the mocks are passed in to the decorated function in the same order they applied (the normal Python order that decorators are applied). This means from the bottom up, so in the example above the mock for test_module.ClassName2 is passed in first.

There is also patch.dict() for setting values in a dictionary just during a scope and restoring the dictionary to its original state when the test ends:

```python
>>> foo = {'key': 'value'}
>>> original = foo.copy()
>>> with patch.dict(foo, {'newkey': 'newvalue'}, clear=True):
...    assert foo == {'newkey': 'newvalue'}
...    assert foo == original
```

patch, patch.object and patch.dict can all be used as context managers.

Where you use patch() to create a mock for you, you can get a reference to the mock using the “as” form of the with statement:

```python
>>> class ProductionClass:
...    def method(self):
...        pass
...
>>> with patch.object(ProductionClass, 'method') as mock_method:
...    mock_method.return_value = None
...    real = ProductionClass()
...    real.method(1, 2, 3)
...
>>> mock_method.assert_called_with(1, 2, 3)
```

As an alternative patch, patch.object and patch.dict can be used as class decorators. When used in this way it is the same as applying the decorator individually to every method whose name starts with “test”.

### 26.10.3 Further Examples

Here are some more examples for some slightly more advanced scenarios.

#### Mocking chained calls

Mocking chained calls is actually straightforward with mock once you understand the return_value attribute. When a mock is called for the first time, or you fetch its return_value before it has been called, a new Mock is created.

This means that you can see how the object returned from a call to a mocked object has been used by interrogating the return_value mock:

```python
>>> mock = Mock()
>>> mock().foo(a=2, b=3)
<Mock name='mock().foo()' id='...'>
>>> mock.return_value.foo.assert_called_with(a=2, b=3)
```

From here it is a simple step to configure and then make assertions about chained calls. Of course another alternative is writing your code in a more testable way in the first place…

So, suppose we have some code that looks a little bit like this:
>>> class Something:
...     def __init__(self):
...         self.backend = BackendProvider()
...     def method(self):
...         response = self.backend.get_endpoint('foobar').create_call('spam', 'eggs').start_call()
...         # more code

Assuming that BackendProvider is already well tested, how do we test method()? Specifically, we want to test that the code section # more code uses the response object in the correct way.

As this chain of calls is made from an instance attribute we can monkey patch the backend attribute on a Something instance. In this particular case we are only interested in the return value from the final call to start_call so we don’t have much configuration to do. Let’s assume the object it returns is ’file-like’, so we’ll ensure that our response object uses the builtin open() as its spec.

To do this we create a mock instance as our mock backend and create a mock response object for it. To set the response as the return value for that final start_call we could do this:

```python
mock_backend.get_endpoint.return_value.create_call.return_value.start_call.return_value = mock_response
```

We can do that in a slightly nicer way using the configure_mock() method to directly set the return value for us:

```python
>>> something = Something()
>>> mock_response = Mock(spec=open)
>>> mock_backend = Mock()
>>> config = {'get_endpoint.return_value.create_call.return_value.start_call.return_value': mock_response}
>>> mock_backend.configure_mock(**config)
```

With these we monkey patch the “mock backend” in place and can make the real call:

```python
>>> something.backend = mock_backend
>>> something.method()
```

Using mock_calls we can check the chained call with a single assert. A chained call is several calls in one line of code, so there will be several entries in mock_calls. We can use call.call_list() to create this list of calls for us:

```python
>>> chained = call.get_endpoint('foobar').create_call('spam', 'eggs').start_call()
>>> call_list = chained.call_list()
>>> assert mock_backend.mock_calls == call_list
```

Partial mocking

In some tests I wanted to mock out a call to datetime.date.today() to return a known date, but I didn’t want to prevent the code under test from creating new date objects. Unfortunately datetime.date is written in C, and so I couldn’t just monkey-patch out the static date.today() method.

I found a simple way of doing this that involved effectively wrapping the date class with a mock, but passing through calls to the constructor to the real class (and returning real instances).

The patch decorator is used here to mock out the date class in the module under test. The side_effect attribute on the mock date class is then set to a lambda function that returns a real date. When the mock date class is called a real date will be constructed and returned by side_effect.

```python
>>> from datetime import date
>>> with patch('mymodule.date') as mock_date:
...     mock_date.today.return_value = date(2001, 12, 31)
...     something = Something()
```

(continues on next page)
Note that we don’t patch `datetime.date` globally, we patch `date` in the module that uses it. See where to patch.

When `date.today()` is called a known date is returned, but calls to the `date(...)` constructor still return normal dates. Without this you can find yourself having to calculate an expected result using exactly the same algorithm as the code under test, which is a classic testing anti-pattern.

Calls to the date constructor are recorded in the `mock_date` attributes (call_count and friends) which may also be useful for your tests.

An alternative way of dealing with mocking dates, or other built-in classes, is discussed in this blog entry.

### Mocking a Generator Method

A Python generator is a function or method that uses the `yield` statement to return a series of values when iterated over.

A generator method / function is called to return the generator object. It is the generator object that is then iterated over. The protocol method for iteration is `__iter__`, so we can mock this using a `Mock`. Here’s an example class with an “iter” method implemented as a generator:

```python
>>> class Foo:
...     def iter(self):
...         for i in [1, 2, 3]:
...             yield i
... >>> foo = Foo()
>>> list(foo.iter())
[1, 2, 3]
```

How would we mock this class, and in particular its “iter” method?

To configure the values returned from the iteration (implicit in the call to `list`), we need to configure the object returned by the call to `foo.iter()`.

```python
>>> mock_foo = MagicMock()
>>> mock_foo.iter.return_value = iter([1, 2, 3])
>>> list(mock_foo.iter())
[1, 2, 3]
```

### Applying the same patch to every test method

If you want several patches in place for multiple test methods the obvious way is to apply the patch decorators to every method. This can feel like unnecessary repetition. For Python 2.6 or more recent you can use `patch()` (in all its various forms) as a class decorator. This applies the patches to all test methods on the class. A test method is identified by methods whose names start with `test`:

```python
>>> @patch('mymodule.SomeClass')
... class MyTest(unittest.TestCase):
...     ...
...     test_one(self, MockSomeClass):
```

---

1 There are also generator expressions and more advanced uses of generators, but we aren’t concerned about them here. A very good introduction to generators and how powerful they are is: Generator Tricks for Systems Programmers.
An alternative way of managing patches is to use the `patch methods: start and stop`. These allow you to move the patching into your `setUp` and `tearDown` methods.

```python
>>> class MyTest(unittest.TestCase):
...     def setUp(self):
...         patcher = patch('mymodule.foo')
...         self.mock_foo = patcher.start()
...     def test_foo(self):
...         self.assertIs(mymodule.foo, self.mock_foo)
...     def tearDown(self):
...         self.patcher.stop()

>>> MyTest('test_foo').run()
```

If you use this technique you must ensure that the patching is “undone” by calling `stop`. This can be fiddlier than you might think, because if an exception is raised in the `setUp` then `tearDown` is not called. `unittest.TestCase.addCleanup()` makes this easier:

```python
>>> class MyTest(unittest.TestCase):
...     def setUp(self):
...         patcher = patch('mymodule.foo')
...         self.addCleanup(patcher.stop)
...         self.mock_foo = patcher.start()
...     def test_foo(self):
...         self.assertIs(mymodule.foo, self.mock_foo)
...     def tearDown(self):
...         self.patcher.stop()

>>> MyTest('test_foo').run()
```

### Mocking Unbound Methods

Whilst writing tests today I needed to patch an unbound method (patching the method on the class rather than on the instance). I needed `self` to be passed in as the first argument because I want to make asserts about which objects were calling this particular method. The issue is that you can’t patch with a mock for this, because if you replace an unbound method with a mock it doesn’t become a bound method when fetched from the instance, and so it doesn’t get `self` passed in. The workaround is to patch the unbound method with a real function instead. The `patch()` decorator makes it so simple to patch out methods with a mock that having to create a real function becomes a nuisance.

If you pass `autospec=True` to patch then it does the patching with a real function object. This function object has the same signature as the one it is replacing, but delegates to a mock under the hood. You still get your mock auto-created in exactly the same way as before. What it means though, is that if you use it to patch out an unbound method on a class the mocked function will be turned into a bound method if it is fetched from an instance. It will have `self` passed in as the first argument, which is exactly what I wanted:
class Foo:
    def foo(self):
        pass

>>> with patch.object(Foo, 'foo', autospec=True) as mock_foo:
    foo = Foo()
    foo.foo()

'foo'

>>> mock_foo.assert_called_once_with(foo)

If we don’t use autospec=True then the unbound method is patched out with a Mock instance instead, and isn’t called with self.

Checking multiple calls with mock

mock has a nice API for making assertions about how your mock objects are used.

>>> mock = Mock()
>>> mock.foo_bar.return_value = None
>>> mock.foo_bar('baz', spam='eggs')
>>> mock.foo_bar.assert_called_with('baz', spam='eggs')

If your mock is only being called once you can use the assert_called_once_with() method that also asserts that the call_count is one.

>>> mock.foo_bar.assert_called_once_with('baz', spam='eggs')
>>> mock.foo_bar()  # will raise an AssertionError
Traceback (most recent call last):
  ...  
AssertionError: Expected to be called once. Called 2 times.

Both assert_called_with and assert_called_once_with make assertions about the most recent call. If your mock is going to be called several times, and you want to make assertions about all those calls you can use call_args_list:

>>> mock = Mock(return_value=None)
>>> mock(1, 2, 3)
>>> mock(4, 5, 6)
>>> mock()
>>> mock.call_args_list
[call(1, 2, 3), call(4, 5, 6), call()]

The call helper makes it easy to make assertions about these calls. You can build up a list of expected calls and compare it to call_args_list. This looks remarkably similar to the repr of the call_args_list:

>>> expected = [call(1, 2, 3), call(4, 5, 6), call()]
>>> mock.call_args_list == expected
True
Coping with mutable arguments

Another situation is rare, but can bite you, is when your mock is called with mutable arguments. call_args and call_args_list store references to the arguments. If the arguments are mutated by the code under test then you can no longer make assertions about what the values were when the mock was called.

Here’s some example code that shows the problem. Imagine the following functions defined in ‘mymodule’:

```python
def frob(val):
    pass

def grob(val):
    "First frob and then clear val"
    frob(val)
    val.clear()
```

When we try to test that grob calls frob with the correct argument look what happens:

```python
>>> with patch('mymodule.frob') as mock_frob:
...    val = {6}
...    mymodule.grob(val)
...
>>> val
set()
>>> mock_frob.assert_called_with({6})
Traceback (most recent call last):
...  AssertionError: Expected: (({6},), {}) 
Called with: ((set(),), ())
```

One possibility would be for mock to copy the arguments you pass in. This could then cause problems if you do assertions that rely on object identity for equality.

Here’s one solution that uses the side_effect functionality. If you provide a side_effect function for a mock then side_effect will be called with the same args as the mock. This gives us an opportunity to copy the arguments and store them for later assertions. In this example I’m using another mock to store the arguments so that I can use the mock methods for doing the assertion. Again a helper function sets this up for me.

```python
>>> from copy import deepcopy
>>> from unittest.mock import Mock, patch, DEFAULT
>>> def copy_call_args(mock):
...    new_mock = Mock()
...    def side_effect(*args, **kwargs):
...        args = deepcopy(args)
...        kwargs = deepcopy(kwargs)
...        new_mock(*args, **kwargs)
...        return DEFAULT
...    mock.side_effect = side_effect
...    return new_mock
...
>>> with patch('mymodule.frob') as mock_frob:
...    new_mock = copy_call_args(mock_frob)
...    val = {6}
...    mymodule.grob(val)
...    new_mock.assert_called_with({6})
...    new_mock.call_args(call({6}))
```

copy_call_args is called with the mock that will be called. It returns a new mock that we do the assertion on. The side_effect function makes a copy of the args and calls our new_mock with the copy.
Note: If your mock is only going to be used once there is an easier way of checking arguments at the point they are called. You can simply do the checking inside a `side_effect` function.

```python
>>> def side_effect(arg):
...     assert arg == {6}
...
>>> mock = Mock(side_effect=side_effect)
>>> mock({6})
Traceback (most recent call last):
  ...    AssertionError
```

An alternative approach is to create a subclass of `Mock` or `MagicMock` that copies (using `copy.deepcopy()`) the arguments. Here’s an example implementation:

```python
>>> from copy import deepcopy
>>> class CopyingMock(MagicMock):
...     def __call__(self, *, args, **kwargs):
...         args = deepcopy(args)
...         kwargs = deepcopy(kwargs)
...         return super().__call__(*args, **kwargs)
...
>>> c = CopyingMock(return_value=None)
>>> arg = set()
>>> c(arg)
>>> c.assert_called_with(set())
Traceback (most recent call last):
  ...    AssertionError: Expected call: mock({1})
Actual call: mock(set())
>>> c.foo
<CopyingMock name='mock.foo' id='...'>
```

When you subclass `Mock` or `MagicMock` all dynamically created attributes, and the `return_value` will use your subclass automatically. That means all children of a `CopyingMock` will also have the type `CopyingMock`.

### Nesting Patches

Using patch as a context manager is nice, but if you do multiple patches you can end up with nested with statements indenting further and further to the right:

```python
>>> class MyTest(unittest.TestCase):
...     ...
...     def test_foo(self):
...         with patch('mymodule.Foo') as mock_foo:
...             with patch('mymodule.Bar') as mock_bar:
...                 with patch('mymodule.Spam') as mock_spam:
...                     assert mymodule.Foo is mock_foo
...                     assert mymodule.Bar is mock_bar
...                     assert mymodule.Spam is mock_spam
...
>>> original = mymodule.Foo
>>> MyTest('test_foo').test_foo()
>>> assert mymodule.Foo is original
```

With unittest cleanup functions and the `patch methods: start and stop` we can achieve the same effect without the
nested indentation. A simple helper method, `create_patch`, puts the patch in place and returns the created mock for us:

```python
>>> class MyTest(unittest.TestCase):
...     ...
...     def create_patch(self, name):
...         patcher = patch(name)
...         thing = patcher.start()
...         self.addCleanup(patcher.stop)
...         return thing
...     ...
...     def test_foo(self):
...         mock_foo = self.create_patch('mymodule.Foo')
...         mock_bar = self.create_patch('mymodule.Bar')
...         mock_spam = self.create_patch('mymodule.Spam')
...         ...
...         assert mymodule.Foo is mock_foo
...         assert mymodule.Bar is mock_bar
...         assert mymodule.Spam is mock_spam
...     ...
>>> original = mymodule.Foo
>>> MyTest('test_foo').run()
>>> assert mymodule.Foo is original
```

### Mocking a dictionary with MagicMock

You may want to mock a dictionary, or other container object, recording all access to it whilst having it still behave like a dictionary.

We can do this with `MagicMock`, which will behave like a dictionary, and using `side_effect` to delegate dictionary access to a real underlying dictionary that is under our control.

When the `__getitem__()` and `__setitem__()` methods of our `MagicMock` are called (normal dictionary access) then `side_effect` is called with the key (and in the case of `__setitem__` the value too). We can also control what is returned.

After the `MagicMock` has been used we can use attributes like `call_args_list` to assert about how the dictionary was used:

```python
>>> my_dict = {'a': 1, 'b': 2, 'c': 3}
>>> def getitem(name):
...     return my_dict[name]
... >>> def setitem(name, val):
...     my_dict[name] = val
... >>> mock = MagicMock()
>>> mock.__getitem__.side_effect = getitem
>>> mock.__setitem__.side_effect = setitem
```

**Note:** An alternative to using `MagicMock` is to use `Mock` and only provide the magic methods you specifically want:

```python
>>> mock = Mock()
>>> mock.__getitem__ = Mock(side_effect=getitem)
>>> mock.__setitem__ = Mock(side_effect=setitem)
```

A third option is to use `MagicMock` but passing in `dict` as the `spec` (or `spec_set`) argument so that the `MagicMock` created only has dictionary magic methods available:
With these side effect functions in place, the mock will behave like a normal dictionary but recording the access. It even raises a `KeyError` if you try to access a key that doesn’t exist.

```python
>>> mock['a']
1
>>> mock['c']
3
>>> mock['d']
Traceback (most recent call last):
  ... 
KeyError: 'd'
```

After it has been used you can make assertions about the access using the normal mock methods and attributes:

```python
>>> mock._getitem__call_args_list
[call('a'), call('c'), call('d'), call('b'), call('d')]
>>> mock._setitem__call_args_list
[call('b', 'fish'), call('d', 'eggs')]
>>> my_dict
{'a': 1, 'b': 'fish', 'c': 3, 'd': 'eggs'}
```

### Mock subclasses and their attributes

There are various reasons why you might want to subclass `Mock`. One reason might be to add helper methods. Here’s a silly example:

```python
>>> class MyMock(MagicMock):
    ...
    def hasBeenCalled(self):
        ... return self.called
    ...
>>> mymock = MyMock(return_value=None)
>>> mymock
<MyMock id='...'>
>>> mymock.hasBeenCalled()
False
>>> mymock()  # (continues on next page)
>>> mymock.hasBeenCalled()
True
```

The standard behaviour for `Mock` instances is that attributes and the return value mocks are of the same type as the mock they are accessed on. This ensures that `Mock` attributes are `Mocks` and `MagicMock` attributes are `MagicMocks`². So if you’re subclassing to add helper methods then they’ll also be available on the attributes and return value mock of instances of your subclass.

```python
>>> mymock.foo
<MyMock name='mock.foo' id='...'>
```

² An exception to this rule are the non-callable mocks. Attributes use the callable variant because otherwise non-callable mocks couldn’t have callable methods.
Sometimes this is inconvenient. For example, one user is subclassing mock to created a Twisted adaptor. Having this applied to attributes too actually causes errors.

Mock (in all its flavours) uses a method called \_get\_child\_mock to create these “sub-mocks” for attributes and return values. You can prevent your subclass being used for attributes by overriding this method. The signature is that it takes arbitrary keyword arguments (**kwargs) which are then passed onto the mock constructor:

```
>>> class Subclass(MagicMock):
...     def _get_child_mock(self, /, **kwargs):
...         return MagicMock(**kwargs)
...
>>> mymock = Subclass()
>>> mymock.foo
<Mock name='mock.foo' id='...'>
>>> assert isinstance(mymock, Subclass)
>>> assert not isinstance(mymock.foo, Subclass)
>>> assert not isinstance(mymock(), Subclass)
```

Mocking imports with patch.dict

One situation where mocking can be hard is where you have a local import inside a function. These are harder to mock because they aren’t using an object from the module namespace that we can patch out.

Generally local imports are to be avoided. They are sometimes done to prevent circular dependencies, for which there is usually a much better way to solve the problem (refactor the code) or to prevent “up front costs” by delaying the import. This can also be solved in better ways than an unconditional local import (store the module as a class or module attribute and only do the import on first use).

That aside there is a way to use mock to affect the results of an import. Importing fetches an object from the sys.modules dictionary. Note that it fetches an object, which need not be a module. Importing a module for the first time results in a module object being put in sys.modules, so usually when you import something you get a module back. This need not be the case however.

This means you can use patch.dict() to temporarily put a mock in place in sys.modules. Any imports whilst this patch is active will fetch the mock. When the patch is complete (the decorated function exits, the with statement body is complete or patcher.stop() is called) then whatever was there previously will be restored safely.

Here’s an example that mocks out the ‘fooble’ module.

```
>>> import sys
>>> mock = Mock()
>>> with patch.dict('sys.modules', {'fooble': mock}):
...     import fooble
...     fooble.blob()
...<Mock name='mock.blob()' id='...'>
>>> assert 'fooble' not in sys.modules
>>> mock.blob.assert_called_once_with()
```

As you can see the import fooble succeeds, but on exit there is no ‘fooble’ left in sys.modules.

This also works for the from module import name form:
>>> mock = Mock()
>>> with patch.dict('sys.modules', {'fooble': mock}):
...     from fooble import blob
...     blob.blip()
...<Mock name='mock.blob.blip()' id='...'>
>>> mock.blob.blip.assert_called_once_with()

With slightly more work you can also mock package imports:

>>> mock = Mock()
>>> modules = {'package': mock, 'package.module': mock.module}
>>> with patch.dict('sys.modules', modules):
...     from package.module import fooble
...     fooble()
...<Mock name='mock.module.fooble()' id='...'>
>>> mock.module.fooble.assert_called_once_with()

Tracking order of calls and less verbose call assertions

The Mock class allows you to track the order of method calls on your mock objects through the method_calls attribute. This doesn’t allow you to track the order of calls between separate mock objects, however we can use mock_calls to achieve the same effect.

Because mocks track calls to child mocks in mock_calls, and accessing an arbitrary attribute of a mock creates a child mock, we can create our separate mocks from a parent one. Calls to those child mock will then all be recorded, in order, in the mock_calls of the parent:

>>> manager = Mock()
>>> mock_foo = manager.foo
>>> mock_bar = manager.bar

>>> mock_foo.something()
<Mock name='mock.foo.something()' id='...'>
>>> mock_bar.other.thing()
<Mock name='mock.bar.other.thing()' id='...'>

>>> manager.mock_calls
[call.foo.something(), call.bar.other.thing()]

We can then assert about the calls, including the order, by comparing with the mock_calls attribute on the manager mock:

>>> expected_calls = [call.foo.something(), call.bar.other.thing()]
>>> manager.mock_calls == expected_calls
True

If patch is creating, and putting in place, your mocks then you can attach them to a manager mock using the attach_mock() method. After attaching calls will be recorded in mock_calls of the manager.

>>> manager = MagicMock()
>>> with patch('mymodule.Class1') as MockClass1:
...     with patch('mymodule.Class2') as MockClass2:
...         manager.attach_mock(MockClass1, 'MockClass1')
...         manager.attach_mock(MockClass2, 'MockClass2')
...         MockClass1().foo()
...         MockClass2().bar()
<MockMock name='mock.MockClass1().foo()' id='...'>
(continues on next page)
If many calls have been made, but you’re only interested in a particular sequence of them then an alternative is to use the `assert_has_calls()` method. This takes a list of calls (constructed with the `call` object). If that sequence of calls are in `mock_calls` then the assert succeeds.

```python
>>> m = MagicMock()
>>> m().foo().bar().baz()
<MagicMock name='mock().foo().bar().baz()' id='...'>
```

Even though the chained call `m.one().two().three()` aren’t the only calls that have been made to the mock, the assert still succeeds.

Sometimes a mock may have several calls made to it, and you are only interested in asserting about some of those calls. You may not even care about the order. In this case you can pass `any_order=True` to `assert_has_calls`:

```python
>>> m.assert_has_calls([call.fifty('50'), call(1), call.seven(7)], any_order=True)
```

More complex argument matching

Using the same basic concept as `ANY` we can implement matchers to do more complex assertions on objects used as arguments to mocks.

Suppose we expect some object to be passed to a mock that by default compares equal based on object identity (which is the Python default for user defined classes). To use `assert_called_with()` we would need to pass in the exact same object. If we are only interested in some of the attributes of this object then we can create a matcher that will check these attributes for us.

You can see in this example how a ‘standard’ call to `assert_called_with` isn’t sufficient:

```python
>>> class Foo:
...     ...     def __init__(self, a, b):
...         self.a, self.b = a, b
...     ...
>>> mock = Mock(return_value=None)
>>> mock(Foo(1, 2))
>>> mock.assert_called_with(Foo(1, 2))
Traceback (most recent call last):
  ...
AssertionError: Expected: call(<__main__.Foo object at 0x...>)
Actual call: call(<__main__.Foo object at 0x...>)
```

A comparison function for our `Foo` class might look something like this:

```python
>>> def compare(self, other):
...     ...     if not type(self) == type(other):
...         return False
```
... if self.a != other.a:
...     return False
... if self.b != other.b:
...     return False
... return True

And a matcher object that can use comparison functions like this for its equality operation would look something like this:

```python
>>> class Matcher:
...     def __init__(self, compare, some_obj):
...         self.compare = compare
...         self.some_obj = some_obj
...     def __eq__(self, other):
...         return self.compare(self.some_obj, other)
```

Putting all this together:

```python
>>> match_foo = Matcher(compare, Foo(1, 2))
>>> mock.assert_called_with(match_foo)

The Matcher is instantiated with our compare function and the Foo object we want to compare against. In assert_called_with the Matcher equality method will be called, which compares the object the mock was called with against the one we created our matcher with. If they match then assert_called_with passes, and if they don’t an AssertionError is raised:

```python
>>> match_wrong = Matcher(compare, Foo(3, 4))
>>> mock.assert_called_with(match_wrong)
AssertionError: Expected: ((<Matcher object at 0x...>,), {})
Called with: ((<Foo object at 0x...>,), {})
```

With a bit of tweaking you could have the comparison function raise the AssertionError directly and provide a more useful failure message.

As of version 1.5, the Python testing library PyHamcrest provides similar functionality, that may be useful here, in the form of its equality matcher (hamcrest.library.integration.match_equality).

### 26.11 2to3 - Automated Python 2 to 3 code translation

2to3 is a Python program that reads Python 2.x source code and applies a series of fixers to transform it into valid Python 3.x code. The standard library contains a rich set of fixers that will handle almost all code. 2to3 supporting library `lib2to3` is, however, a flexible and generic library, so it is possible to write your own fixers for 2to3.
26.11.1 Using 2to3

2to3 will usually be installed with the Python interpreter as a script. It is also located in the \texttt{Tools/scripts} directory of the Python root.

2to3's basic arguments are a list of files or directories to transform. The directories are recursively traversed for Python sources.

Here is a sample Python 2.x source file, \texttt{example.py}:

```python
def greet(name):
    print "Hello, {0}!".format(name)
print "What's your name?"
name = raw_input()
greet(name)
```

It can be converted to Python 3.x code via 2to3 on the command line:

```
$ 2to3 example.py
```

A diff against the original source file is printed. 2to3 can also write the needed modifications right back to the source file. (A backup of the original file is made unless \texttt{-n} is also given.) Writing the changes back is enabled with the \texttt{-w} flag:

```
$ 2to3 -w example.py
```

After transformation, \texttt{example.py} looks like this:

```python
def greet(name):
    print("Hello, {0}!").format(name)
print("What's your name?")
name = input()
greet(name)
```

Comments and exact indentation are preserved throughout the translation process.

By default, 2to3 runs a set of \textit{predefined fixers}. The \texttt{-l} flag lists all available fixers. An explicit set of fixers to run can be given with \texttt{-f}. Likewise the \texttt{-x} explicitly disables a fixer. The following example runs only the \texttt{imports} and \texttt{has_key} fixers:

```
$ 2to3 -f imports -f has_key example.py
```

This command runs every fixer except the \texttt{apply} fixer:

```
$ 2to3 -x apply example.py
```

Some fixers are \textit{explicit}, meaning they aren't run by default and must be listed on the command line to be run. Here, in addition to the default fixers, the \texttt{idioms} fixer is run:

```
$ 2to3 -f all -f idioms example.py
```

Notice how passing \texttt{all} enables all default fixers.

Sometimes 2to3 will find a place in your source code that needs to be changed, but 2to3 cannot fix automatically. In this case, 2to3 will print a warning beneath the diff for a file. You should address the warning in order to have compliant 3.x code.

2to3 can also refactor doctests. To enable this mode, use the \texttt{-d} flag. Note that \textit{only} doctests will be refactored. This also doesn't require the module to be valid Python. For example, doctest like examples in a reST document could also be refactored with this option.

The \texttt{-v} option enables output of more information on the translation process.
Since some print statements can be parsed as function calls or statements, 2to3 cannot always read files containing the print function. When 2to3 detects the presence of the from __future__ import print_function compiler directive, it modifies its internal grammar to interpret print() as a function. This change can also be enabled manually with the -p flag. Use -p to run fixers on code that already has had its print statements converted. Also -q can be used to make exec() a function.

The -o or --output-dir option allows specification of an alternate directory for processed output files to be written to. The -n flag is required when using this as backup files do not make sense when not overwriting the input files.

New in version 3.2.3: The -o option was added.

The -w or --write-unchanged-files flag tells 2to3 to always write output files even if no changes were required to the file. This is most useful with -o so that an entire Python source tree is copied with translation from one directory to another. This option implies the -w flag as it would not make sense otherwise.

New in version 3.2.3: The -w flag was added.

The --add-suffix option specifies a string to append to all output filenames. The -n flag is required when specifying this as backups are not necessary when writing to different filenames. Example:

```
$ 2to3 -n -W --add-suffix=3 example.py
```

Will cause a converted file named example.py3 to be written.

New in version 3.2.3: The --add-suffix option was added.

To translate an entire project from one directory tree to another use:

```
$ 2to3 --output-dir=python3-version/mycode -W -n python2-version/mycode
```

### 26.11.2 Fixers

Each step of transforming code is encapsulated in a fixer. The command 2to3 -l lists them. As documented above, each can be turned on and off individually. They are described here in more detail.

**apply**

Removes usage of apply(). For example apply(function, *args, **kwargs) is converted to function(*args, **kwargs).

**asserts**

Replaces deprecated unittest method names with the correct ones.

```
<table>
<thead>
<tr>
<th>From</th>
<th>To</th>
</tr>
</thead>
<tbody>
<tr>
<td>failUnlessEqual(a, b)</td>
<td>assertEqual(a, b)</td>
</tr>
<tr>
<td>assertEqual(a, b)</td>
<td></td>
</tr>
<tr>
<td>failIfEqual(a, b)</td>
<td>assertNotEqual(a, b)</td>
</tr>
<tr>
<td>assertNotEqual(a, b)</td>
<td></td>
</tr>
<tr>
<td>failUnless(a)</td>
<td>assertTrue(a)</td>
</tr>
<tr>
<td>assert_(a)</td>
<td></td>
</tr>
<tr>
<td>failIf(a)</td>
<td>assertFalse(a)</td>
</tr>
<tr>
<td>failUnlessRaises(exc, cal)</td>
<td>assertRaises(exc, cal)</td>
</tr>
<tr>
<td>failUnlessAlmostEqual(a, b)</td>
<td>assertAlmostEqual(a, b)</td>
</tr>
<tr>
<td>assertAlmostEqual(a, b)</td>
<td></td>
</tr>
<tr>
<td>failIfAlmostEqual(a, b)</td>
<td>assertNotAlmostEqual(a, b)</td>
</tr>
<tr>
<td>assertNotAlmostEqual(a, b)</td>
<td></td>
</tr>
<tr>
<td>failUnlessAlmostEqual(a, b)</td>
<td>assertAlmostEqual(a, b)</td>
</tr>
<tr>
<td>assertAlmostEqual(a, b)</td>
<td></td>
</tr>
<tr>
<td>failIfAlmostEqual(a, b)</td>
<td>assertNotAlmostEqual(a, b)</td>
</tr>
<tr>
<td>assertNotAlmostEqual(a, b)</td>
<td></td>
</tr>
</tbody>
</table>
```

**basestring**

Converts basestring to str.
buffer
Converting buffer to memoryview. This fixer is optional because the memoryview API is similar but not exactly the same as that of buffer.

dict
Fixes dictionary iteration methods. dict.iteritems() is converted to dict.items(), dict. iterkeys() to dict.keys(), and dict.itervalues() to dict.values(). Similarly, dict. viewitems(), dict.viewkeys() and dict.viewvalues() are converted respectively to dict. items(), dict.keys() and dict.values(). It also wraps existing usages of dict.items(), dict.keys(), and dict.values() in a call to list.

except
Converts except X, T to except X as T.
exec
Converts the exec statement to the exec() function.
execfile
Removes usage of execfile(). The argument to execfile() is wrapped in calls to open(), compile(), and exec().
exitfunc
Changes assignment of sys.exitfunc to use of the atexit module.
filter
Wraps filter() usage in a list call.
funcattrs
Fixes function attributes that have been renamed. For example, my_function.func_closure is converted to my_function.__closure__.
future
Removes from __future__ import new_feature statements.
getcwdu
Renames os.getcwdu() to os.getcwd().
has_key
Changes dict.has_key(key) to key in dict.

idioms
This optional fixer performs several transformations that make Python code more idiomatic. Type comparisons like type(x) is SomeClass and type(x) == SomeClass are converted to isinstance(x, SomeClass). while 1 becomes while True. This fixer also tries to make use of sorted() in appropriate places. For example, this block

```python
L = list(some_iterable)
L.sort()
```

is changed to

```python
L = sorted(some_iterable)
```

import
Detects sibling imports and converts them to relative imports.

import2
Handles module renames in the standard library.

import2
Handles other modules renames in the standard library. It is separate from the imports fixer only because of technical limitations.

input
Converts input(prompt) to eval(input(prompt)).
The Python Library Reference, Release 3.10.4

**intern**
Converts `intern()` to `sys.intern()`.

**isinstance**
Fixes duplicate types in the second argument of `isinstance()`. For example, `isinstance(x, (int, int))` is converted to `isinstance(x, int)` and `isinstance(x, (int, float, int))` is converted to `isinstance(x, (int, float))`.

**itertools_imports**
Removes imports of `itertools.ifilter()`, `itertools.izip()`, and `itertools.imap()`. Imports of `itertools.ifilterfalse()` are also changed to `itertools.filterfalse()`.

**itertools**
Changes usage of `itertools.ifilter()`, `itertools.izip()`, and `itertools.imap()` to their built-in equivalents. `itertools.ifilterfalse()` is changed to `itertools.filterfalse()`.

**long**
Renames `long` to `int`.

**map**
Wraps `map()` in a `list` call. It also changes `map(NoNone, x)` to `list(x)`. Using `from future.builtins import map` disables this fixer.

**metaclass**
Converts the old metaclass syntax (`__metaclass__ = Meta` in the class body) to the new (`class X(metaclass=Meta)`).

**methodattrs**
Fixes old method attribute names. For example, `meth.im_func` is converted to `meth.__func__`.

**ne**
Converts the old not-equal syntax, `<>`, to `!`.

**next**
Converts the use of iterator’s `next()` methods to the `next()` function. It also renames `next()` methods to `__next__()`.

**nonzero**
Renames definitions of methods called `__nonzero__()` to `__bool__()`.

**numliterals**
Converts octal literals into the new syntax.

**operator**
Converts calls to various functions in the `operator` module to other, but equivalent, function calls. When needed, the appropriate `import` statements are added, e.g. `import collections.abc`. The following mapping are made:

<table>
<thead>
<tr>
<th>From</th>
<th>To</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>operator.isCallable(obj)</code></td>
<td><code>callable(obj)</code></td>
</tr>
<tr>
<td><code>operator.sequenceIncludes(obj)</code></td>
<td><code>operator.contains(obj)</code></td>
</tr>
<tr>
<td><code>operator.isSequenceType(obj)</code></td>
<td><code>isinstance(obj, collections.abc.Sequence)</code></td>
</tr>
<tr>
<td><code>operator.isMappingType(obj)</code></td>
<td><code>isinstance(obj, collections.abc.Mapping)</code></td>
</tr>
<tr>
<td><code>operator.isNumberType(obj)</code></td>
<td><code>isinstance(obj, numbers.Number)</code></td>
</tr>
<tr>
<td><code>operator.repeat(obj, n)</code></td>
<td><code>operator.mul(obj, n)</code></td>
</tr>
<tr>
<td><code>operator.irepeat(obj, n)</code></td>
<td><code>operator.imul(obj, n)</code></td>
</tr>
</tbody>
</table>

**paren**
Add extra parenthesis where they are required in list comprehensions. For example, `[x for x in 1, 2]`
becomes `[x for x in (1, 2)]`.

**print**

Converts the `print` statement to the `print()` function.

**raise**

Converts `raise E, V` to `raise E(V)` and `raise E, V, T` to `raise E(V)`.

If `E` is a tuple, the translation will be incorrect because substituting tuples for exceptions has been removed in 3.0.

**raw_input**

Converts `raw_input()` to `input()`.

**reduce**

Handles the move of `reduce()` to `functools.reduce()`.

**reload**

Converts `reload()` to `importlib.reload()`.

**renames**

Changes `sys.maxint` to `sys.maxsize`.

**repr**

Replaces backtick `repr` with the `repr()` function.

**set_literal**

Replaces use of the `set` constructor with set literals. This fixer is optional.

**standarderror**

Renames `StandardError` to `Exception`.

**sys_exc**

Changes the deprecated `sys.exc_value`, `sys.exc_type`, `sys.exc_traceback` to use `sys.exc_info()`.

**throw**

Fixes the API change in generator’s `throw()` method.

**tuple_params**

Removes implicit tuple parameter unpacking. This fixer inserts temporary variables.

**types**

Fixes code broken from the removal of some members in the `types` module.

**unicode**

Renames `unicode` to `str`.

**urllib**

Handles the rename of `urllib` and `urllib2` to the `urllib` package.

**ws_comma**

Removes excess whitespace from comma separated items. This fixer is optional.

**xrange**

Renames `xrange()` to `range()` and wraps existing `range()` calls with `list`.

**xreadlines**

Changes `for x in file.xreadlines()` to `for x in file`.

**zip**

Wraps `zip()` usage in a `list` call. This is disabled when `from future_builtins import zip` appears.
26.11.3 lib2to3 - 2to3’s library

Source code: Lib/lib2to3/

Deprecated since version 3.11, will be removed in version 3.13: Python 3.9 switched to a PEG parser (see PEP 617) while lib2to3 is using a less flexible LL(1) parser. Python 3.10 includes new language syntax that is not parsable by lib2to3’s LL(1) parser (see PEP 634). The lib2to3 module was marked pending for deprecation in Python 3.9 (raising PendingDeprecationWarning on import) and fully deprecated in Python 3.11 (raising DeprecationWarning). It will be removed from the standard library in Python 3.13. Consider third-party alternatives such as LibCST or parso.

Note: The lib2to3 API should be considered unstable and may change drastically in the future.

26.12 test — Regression tests package for Python

Note: The test package is meant for internal use by Python only. It is documented for the benefit of the core developers of Python. Any use of this package outside of Python’s standard library is discouraged as code mentioned here can change or be removed without notice between releases of Python.

The test package contains all regression tests for Python as well as the modules test.support and test. regrtest. test.support is used to enhance your tests while test.regrtest drives the testing suite.

Each module in the test package whose name starts with test_ is a testing suite for a specific module or feature. All new tests should be written using the unittest or doctest module. Some older tests are written using a “traditional” testing style that compares output printed to sys.stdout; this style of test is considered deprecated.

See also:

Module unittest Writing PyUnit regression tests.

Module doctest Tests embedded in documentation strings.

26.12.1 Writing Unit Tests for the test package

It is preferred that tests that use the unittest module follow a few guidelines. One is to name the test module by starting it with test_ and end it with the name of the module being tested. The test methods in the test module should start with test_ and end with a description of what the method is testing. This is needed so that the methods are recognized by the test driver as test methods. Also, no documentation string for the method should be included. A comment (such as # Tests function returns only True or False) should be used to provide documentation for test methods. This is done because documentation strings get printed out if they exist and thus what test is being run is not stated.

A basic boilerplate is often used:

```python
import unittest
from test import support

class MyTestCase(unittest.TestCase):
    # Only use setUp() and tearDown() if necessary
    def setUp(self):
```

(continues on next page)
This code pattern allows the testing suite to be run by `test.regrtest`, on its own as a script that supports the `unittest` CLI, or via the `python -m unittest` CLI.

The goal for regression testing is to try to break code. This leads to a few guidelines to be followed:

- The testing suite should exercise all classes, functions, and constants. This includes not just the external API that is to be presented to the outside world but also “private” code.

- Whitebox testing (examining the code being tested when the tests are being written) is preferred. Blackbox testing (testing only the published user interface) is not complete enough to make sure all boundary and edge cases are tested.

- Make sure all possible values are tested including invalid ones. This makes sure that not only all valid values are acceptable but also that improper values are handled correctly.

- Exhaust as many code paths as possible. Test where branching occurs and thus tailor input to make sure as many different paths through the code are taken.

- Add an explicit test for any bugs discovered for the tested code. This will make sure that the error does not crop up again if the code is changed in the future.

- Make sure to clean up after your tests (such as close and remove all temporary files).

- If a test is dependent on a specific condition of the operating system then verify the condition already exists before attempting the test.

- Import as few modules as possible and do it as soon as possible. This minimizes external dependencies of tests and also minimizes possible anomalous behavior from side-effects of importing a module.

- Try to maximize code reuse. On occasion, tests will vary by something as small as what type of input is used. Minimize code duplication by subclassing a basic test class with a class that specifies the input:

```python
class TestFuncAcceptsSequencesMixin:
    func = mySuperWhammyFunction

    def test_func(self):
        self.func(self.arg)

class AcceptLists(TestFuncAcceptsSequencesMixin, unittest.TestCase):
    arg = [1, 2, 3]
```

(continues on next page)
class AcceptStrings (TestFuncAcceptsSequencesMixin, unittest.TestCase):
    arg = 'abc'

class AcceptTuples (TestFuncAcceptsSequencesMixin, unittest.TestCase):
    arg = (1, 2, 3)

When using this pattern, remember that all classes that inherit from unittest.TestCase are run as tests. The Mixin class in the example above does not have any data and so can’t be run by itself, thus it does not inherit from unittest.TestCase.

See also:
Test Driven Development  A book by Kent Beck on writing tests before code.

26.12.2 Running tests using the command-line interface

The test package can be run as a script to drive Python’s regression test suite, thanks to the -m option: python -m test. Under the hood, it uses test.regrtest; the call python -m test.regrtest used in previous Python versions still works. Running the script by itself automatically starts running all regression tests in the test package. It does this by finding all modules in the package whose name starts with test_, importing them, and executing the function test_main() if present or loading the tests via unittest.TestLoader.loadTestsFromModule if test_main does not exist. The names of tests to execute may also be passed to the script. Specifying a single regression test (python -m test test_spam) will minimize output and only print whether the test passed or failed.

Running test directly allows what resources are available for tests to use to be set. You do this by using the -u command-line option. Specifying all as the value for the -u option enables all possible resources: python -m test -u all. If all but one resource is desired (a more common case), a comma-separated list of resources that are not desired may be listed after all. The command python -m test -u all,-audio,-largefile will run test with all resources except the audio and largefile resources. For a list of all resources and more command-line options, run python -m test -h.

Some other ways to execute the regression tests depend on what platform the tests are being executed on. On Unix, you can run make test at the top-level directory where Python was built. On Windows, executing rt.bat from your PCbuild directory will run all regression tests.

26.13 test.support — Utilities for the Python test suite

The test.support module provides support for Python’s regression test suite.

Note: test.support is not a public module. It is documented here to help Python developers write tests. The API of this module is subject to change without backwards compatibility concerns between releases.

This module defines the following exceptions:

exception test.support.TestFailed
    Exception to be raised when a test fails. This is deprecated in favor of unittest-based tests and unittest.TestCase’s assertion methods.

exception test.support.ResourceDenied
    Subclass of unittest.SkipTest. Raised when a resource(s) such as a network connection is not available. Raised by the requires() function.

The test.support module defines the following constants:
test.support.verbose
   True when verbose output is enabled. Should be checked when more detailed information is desired about a running test. verbose is set by test.regrtest.

test.support.is_jython
   True if the running interpreter is Jython.

test.support.is_android
   True if the system is Android.

test.support.unix_shell
   Path for shell if not on Windows; otherwise None.

test.support.LOOPBACK_TIMEOUT
   Timeout in seconds for tests using a network server listening on the network local loopback interface like 127.0.0.1.
   The timeout is long enough to prevent test failure: it takes into account that the client and the server can run in
different threads or even different processes.
   The timeout should be long enough for connect(), recv() and send() methods of socket.socket.
   Its default value is 5 seconds.
   See also INTERNET_TIMEOUT.

test.supportINTERNET_TIMEOUT
   Timeout in seconds for network requests going to the internet.
   The timeout is short enough to prevent a test to wait for too long if the internet request is blocked for whatever
reason.
   Usually, a timeout using INTERNET_TIMEOUT should not mark a test as failed, but skip the test instead: see transient_internet().
   Its default value is 1 minute.
   See also LOOPBACK_TIMEOUT.

test.support.SHORT_TIMEOUT
   Timeout in seconds to mark a test as failed if the test takes “too long”.
   The timeout value depends on the regrtest --timeout command line option.
   If a test using SHORT_TIMEOUT starts to fail randomly on slow buildbots, use LONG_TIMEOUT instead.
   Its default value is 30 seconds.

test.support.LONG_TIMEOUT
   Timeout in seconds to detect when a test hangs.
   It is long enough to reduce the risk of test failure on the slowest Python buildbots. It should not be used to mark
a test as failed if the test takes “too long”. The timeout value depends on the regrtest --timeout command
line option.
   Its default value is 5 minutes.
   See also LOOPBACK_TIMEOUT, INTERNET_TIMEOUT and SHORT_TIMEOUT.

test.support.PGO
   Set when tests can be skipped when they are not useful for PGO.

test.support.PIPE_MAX_SIZE
   A constant that is likely larger than the underlying OS pipe buffer size, to make writes blocking.

test.support.SOCK_MAX_SIZE
   A constant that is likely larger than the underlying OS socket buffer size, to make writes blocking.

test.support.TEST_SUPPORT_DIR
   Set to the top level directory that contains test.support.
test.support.TEST_HOME_DIR
Set to the top level directory for the test package.

test.support.TEST_DATA_DIR
Set to the data directory within the test package.

test.support.MAX_Py_size_t
Set to sys.maxsize for big memory tests.

test.support.max_memuse
Set by set_memlimit() as the memory limit for big memory tests. Limited by MAX_Py_size_t.

test.support.real_max_memuse
Set by set_memlimit() as the memory limit for big memory tests. Not limited by MAX_Py_size_t.

test.support.MISSING_C_DOCSTRINGS
Return True if running on CPython, not on Windows, and configuration not set with WITH_DOC_STRINGS.

test.support.HAVE_DOCSTRINGS
Check for presence of docstrings.

test.support.TEST_HTTP_URL
Define the URL of a dedicated HTTP server for the network tests.

test.support.ALWAYS_EQ
Object that is equal to anything. Used to test mixed type comparison.

test.support.NEVER_EQ
Object that is not equal to anything (even to ALWAYS_EQ). Used to test mixed type comparison.

test.support.LARGEST
Object that is greater than anything (except itself). Used to test mixed type comparison.

test.support.SMALLEST
Object that is less than anything (except itself). Used to test mixed type comparison.

The test.support module defines the following functions:

test.support.is_resource_enabled(resource)
Return True if resource is enabled and available. The list of available resources is only set when test.regrtest is executing the tests.

test.support.python_is_optimized()
Return True if Python was not built with -O0 or -Og.

test.support.with_pymalloc()
Return _testcapi.WITH_PYMALLOC.

test.support.requires(resource, msg=None)
Raise ResourceDenied if resource is not available. msg is the argument to ResourceDenied if it is raised. Always returns True if called by a function whose __name__ is '__main__'. Used when tests are executed by test.regrtest.

test.support.system_must_validate_cert(f)
Raise unittest.SkipTest on TLS certification validation failures.

test.support.sortdict(dict)
Return a repr of dict with keys sorted.

test.support.findfile(filename, subdir=None)
Return the path to the file named filename. If no match is found filename is returned. This does not equal a failure since it could be the path to the file.

Setting subdir indicates a relative path to use to find the file rather than looking directly in the path directories.

test.support.match_test(test)
Match test to patterns set in set_match_tests().
test.support.set_match_tests(patterns)
Define match test with regular expression patterns.

test.support.run_unittest(*classes)
Execute unittest.TestCase subclasses passed to the function. The function scans the classes for methods starting with the prefix test_ and executes the tests individually.

It is also legal to pass strings as parameters; these should be keys in sys.modules. Each associated module will be scanned by unittest.TestLoader.loadTestsFromModule(). This is usually seen in the following test_main() function:

```python
def test_main():
    support.run_unittest(__name__)
```

This will run all tests defined in the named module.

test.support.run_doctest(module, verbosity=None, optionflags=0)
Run doctest.testmod() on the given module. Return (failure_count, test_count).

If verbosity is None, doctest.testmod() is run with verbosity set to verbose. Otherwise, it is run with verbosity set to None. optionflags is passed as optionflags to doctest.testmod().

test.support.setswitchinterval(interval)
Set the sys.setswitchinterval() to the given interval. Defines a minimum interval for Android systems to prevent the system from hanging.

test.support.check_impl_detail(**guards)
Use this check to guard CPython’s implementation-specific tests or to run them only on the implementations guarded by the arguments:

```ini
check_impl_detail()  # Only on CPython (default).
cHECK_IMPL_DETAIL(jython=True)  # Only on Jython.
cHECK_IMPL_DETAIL(cpython=False)  # Everywhere except CPython.
```

test.support.set_memlimit(limit)
Set the values for max_memuse and real_max_memuse for big memory tests.

```ini
test.support.record_original_stdout(stdout)
Store the value from stdout. It is meant to hold the stdout at the time the regtest began.

test.support.get_original_stdout()
Return the original stdout set by record_original_stdout() or sys.stdout if it's not set.

```ini
test.support.args_from_interpreter_flags()
Return a list of command line arguments reproducing the current settings in sys.flags and sys.warnoptions.

test.support.optim_args_from_interpreter_flags()
Return a list of command line arguments reproducing the current optimization settings in sys.flags.

test.support.captured_stdin()
test.support.captured_stdout()
test.support.captured_stderr()
A context manager that temporarily replaces the named stream with io.StringIO object.

Example use with output streams:

```python
with captured_stdout() as stdout, captured_stderr() as stderr:
    print("hello")
    print("error", file=sys.stderr)
assert stdout.getvalue() == "hello\n"
assert stderr.getvalue() == "error\n"
```

Example use with input stream:
with captured_stdin() as stdin:
    stdin.write('hello
    stdin.seek(0)
    # call test code that consumes from sys.stdin
    captured = input()
self.assertEqual(captured, "hello")

test.support.disable_faulthandler()  
A context manager that replaces sys.stderr with sys.__stderr__.

test.support.gc_collect()  
Force as many objects as possible to be collected. This is needed because timely deallocation is not guaranteed by the garbage collector. This means that __del__ methods may be called later than expected and weakrefs may remain alive for longer than expected.

test.support.disable_gc()  
A context manager that disables the garbage collector upon entry and reenables it upon exit.

test.support.swap_attr(obj, attr, new_val)  
Context manager to swap out an attribute with a new object.

Usage:

    with swap_attr(obj, "attr", 5):
        ...

This will set obj.attr to 5 for the duration of the with block, restoring the old value at the end of the block. If attr doesn't exist on obj, it will be created and then deleted at the end of the block.

The old value (or None if it doesn't exist) will be assigned to the target of the "as" clause, if there is one.

test.support.swap_item(obj, attr, new_val)  
Context manager to swap out an item with a new object.

Usage:

    with swap_item(obj, "item", 5):
        ...

This will set obj["item"] to 5 for the duration of the with block, restoring the old value at the end of the block. If item doesn't exist on obj, it will be created and then deleted at the end of the block.

The old value (or None if it doesn't exist) will be assigned to the target of the "as" clause, if there is one.

test.support.print_warning(msg)  
Print a warning into sys.__stderr__. Format the message as: f"Warning -- {msg}". If msg is made of multiple lines, add "Warning -- " prefix to each line.

New in version 3.9.

test.support.wait_process(pid, *, exitcode, timeout=None)  
Wait until process pid completes and check that the process exit code is exitcode.

Raise an AssertionError if the process exit code is not equal to exitcode.

If the process runs longer than timeout seconds (SHORT_TIMEOUT by default), kill the process and raise an AssertionError. The timeout feature is not available on Windows.

New in version 3.9.

test.support.calcobjsize(fmt)  
Return struct.calcsize() for nP{fmt}0n or, if gettotalrefcount exists, 2nPn{fmt}0P.

test.support.calkobjectsize(fmt)  
Return struct.calcsize() for nP{fmt}0n or, if gettotalrefcount exists, 2nPn{fmt}0P.
test.support.checksizeof(test, o, size)
    For test case test, assert that the sys.getsizeof for o plus the GC header size equals size.

@test.support.anticipate_failure(condition)
    A decorator to conditionally mark tests with unittest.expectedFailure(). Any use of this decorator
    should have an associated comment identifying the relevant tracker issue.

@test.support.run_with_locale(catstr, *locales)
    A decorator for running a function in a different locale, correctly resetting it after it has finished. catstr
    is the locale category as a string (for example "LC_ALL"). The locales passed will be tried sequentially,
    and the first valid locale will be used.

@test.support.run_with_tz(tz)
    A decorator for running a function in a specific timezone, correctly resetting it after it has finished.

@test.support.requires_freebsd_version(*min_version)
    Decorator for the minimum version when running test on FreeBSD. If the FreeBSD version is less than
    the minimum, raise unittest.SkipTest.

@test.support.requires_linux_version(*min_version)
    Decorator for the minimum version when running test on Linux. If the Linux version is less than the
    minimum, raise unittest.SkipTest.

@test.support.requires_mac_version(*min_version)
    Decorator for the minimum version when running test on macOS. If the macOS version is less than the
    minimum, raise unittest.SkipTest.

@test.support.requires_IEEE_754
    Decorator for skipping tests on non-IEEE 754 platforms.

@test.support.requires_zlib
    Decorator for skipping tests if zlib doesn’t exist.

@test.support.requires_gzip
    Decorator for skipping tests if gzip doesn’t exist.

@test.support.requires_bz2
    Decorator for skipping tests if bz2 doesn’t exist.

@test.support.requires_lzma
    Decorator for skipping tests if lzma doesn’t exist.

@test.support.requires_resource(resource)
    Decorator for skipping tests if resource is not available.

@test.support.requires_docstrings
    Decorator for only running the test if HAVE_DOCSTRINGS.

@test.support.cpython_only(test)
    Decorator for tests only applicable to CPython.

@test.support.impl_detail(msg=None, **guards)
    Decorator for invoking check_impl_detail() on guards. If that returns False, then uses msg as
    the reason for skipping the test.

@test.support.no_tracing(func)
    Decorator to temporarily turn off tracing for the duration of the test.

@test.support.refcount_test(test)
    Decorator for tests which involve reference counting. The decorator does not run the test if it is not run
    by CPython. Any trace function is unset for the duration of the test to prevent unexpected refcounts caused
    by the trace function.

@test.support.bigmemtest(size, memuse, dry_run=True)
    Decorator for bigmem tests.
size is a requested size for the test (in arbitrary, test-interpreted units.) memuse is the number of bytes per unit for the test, or a good estimate of it. For example, a test that needs two byte buffers, of 4 GiB each, could be decorated with @bigmemtest(size=_4G, memuse=2).

The size argument is normally passed to the decorated test method as an extra argument. If dry_run is True, the value passed to the test method may be less than the requested value. If dry_run is False, it means the test doesn’t support dummy runs when -M is not specified.

@test.support.bigaddspacetest(f)
Decorator for tests that fill the address space. f is the function to wrap.

test.support.check_syntax_error(testcase, statement, errtext='', *, lineno=None, offset=None)
Test for syntax errors in statement by attempting to compile statement. testcase is the unittest instance for the test. errtext is the regular expression which should match the string representation of the raised SyntaxError. If lineno is not None, compares to the line of the exception. If offset is not None, compares to the offset of the exception.

test.support.open_urlresource(url, *args, **kw)
Open url. If open fails, raises TestFailed.

test.support.reap_children()
Use this at the end of test_main whenever sub-processes are started. This will help ensure that no extra children (zombies) stick around to hog resources and create problems when looking for refleaks.

test.support.get_attribute(obj, name)
Get an attribute, raising unittest.SkipTest if AttributeError is raised.

test.support.catch_unraisable_exception()
Context manager catching unraisable exception using sys.unraisablehook(). Storing the exception value (cm.unraisable.exc_value) creates a reference cycle. The reference cycle is broken explicitly when the context manager exits.

Storing the object (cm.unraisable.object) can resurrect it if it is set to an object which is being finalized. Exiting the context manager clears the stored object.

Usage:

```python
with support.catch_unraisable_exception() as cm:
    # code creating an "unraisable exception"
    ...
    cm.unraisable = ...
    # cm.unraisable attribute no longer exists at this point
    # (to break a reference cycle)
```

New in version 3.8.

test.support.load_package_tests(pkg_dir, loader, standard_tests, pattern)
Generic implementation of the unittest load_tests protocol for use in test packages. pkg_dir is the root directory of the package; loader, standard_tests, and pattern are the arguments expected by load_tests. In simple cases, the test package’s __init__.py can be the following:

```python
import os
from test.support import load_package_tests

def load_tests(*args):
    return load_package_tests(os.path.dirname(__file__), *args)
```

test.support.detect_api_mismatch(ref_api, other_api, *, ignore=())
Returns the set of attributes, functions or methods of ref_api not found on other_api, except for a defined list of items to be ignored in this check specified in ignore.
By default this skips private attributes beginning with `'_` but includes all magic methods, i.e. those starting and ending in `''__'``.

New in version 3.5.

**test.support.patch** *(test_instance, object_to_patch, attr_name, new_value)*

Override `object_to_patch.attr_name` with `new_value`. Also add cleanup procedure to `test_instance` to restore `object_to_patch` for `attr_name`. The `attr_name` should be a valid attribute for `object_to_patch`.

**test.support.run_in_subinterp** *(code)*

Run `code` in subinterpreter. Raise `unittest.SkipTest` if `tracemalloc` is enabled.

**test.support.check_free_after_iterating** *(test, iter, cls, args=())*

Assert that `iter` is deallocated after iterating.

**test.support.missing_compiler_executable** *(cmd_names=[])*

Check for the existence of the compiler executables whose names are listed in `cmd_names` or all the compiler executables when `cmd_names` is empty and return the first missing executable or `None` when none is found missing.

**test.support.check__all__** *(test_case, module, name_of_module=None, extra=(), not_exported=())*

Assert that the `__all__` variable of `module` contains all public names.

The module’s public names (its API) are detected automatically based on whether they match the public name convention and were defined in `module`.

The `name_of_module` argument can specify (as a string or tuple thereof) what module(s) an API could be defined in order to be detected as a public API. One case for this is when `module` imports part of its public API from other modules, possibly a C backend (like `csv` and its `_csv`).

The `extra` argument can be a set of names that wouldn’t otherwise be automatically detected as “public”, like objects without a proper `__module__` attribute. If provided, it will be added to the automatically detected ones.

The `not_exported` argument can be a set of names that must not be treated as part of the public API even though their names indicate otherwise.

Example use:

```python
import bar
import foo
import unittest
from test import support

class MiscTestCase(unittest.TestCase):
    def test__all__(self):
        support.check__all__(self, foo)

class OtherTestCase(unittest.TestCase):
    def test__all__(self):
        extra = {'BAR_CONST', 'FOO_CONST'}
        not_exported = {'baz'}  # Undocumented name.
        # bar imports part of its API from _bar.
        support.check__all__(self, bar, ('bar', '_bar'),
                             extra=extra, not_exported=not_exported)
```

New in version 3.6.

**test.support.skip_if_broken_multiprocessing_synchronize** ()

Skip tests if the `multiprocessing.synchronize` module is missing, if there is no available semaphore implementation, or if creating a lock raises an `OSError`.

New in version 3.10.

**test.support.check_disallow_instantiation** *(test_case, tp, *args, **kwds)*

Assert that type `tp` cannot be instantiated using `args` and `kwds`.

---

**26.13. test.support — Utilities for the Python test suite**
New in version 3.10.

The `test.support` module defines the following classes:

**class test.support.SuppressCrashReport**

A context manager used to try to prevent crash dialog popups on tests that are expected to crash a subprocess.

On Windows, it disables Windows Error Reporting dialogs using `SetErrorMode`.

On UNIX, `resource.setrlimit()` is used to set `resource.RLIMIT_CORE`'s soft limit to 0 to prevent coredump file creation.

On both platforms, the old value is restored by `__exit__(...)`.

**class test.support.SaveSignals**

Class to save and restore signal handlers registered by the Python signal handler.

**class test.support.Matcher**

`matches(self, d, **kwargs)`

Try to match a single dict with the supplied arguments.

`match_value(self, k, dv, v)`

Try to match a single stored value (`dv`) with a supplied value (`v`).

**class test.support.BasicTestRunner**

`run(test)`

Run `test` and return the result.

### 26.14 test.support.socket_helper — Utilities for socket tests

The `test.support.socket_helper` module provides support for socket tests.

New in version 3.9.

`test.support.socket_helper.IPV6_ENABLED`  
Set to `True` if IPv6 is enabled on this host, `False` otherwise.

`test.support.socket_helper.find_unused_port(family=socket.AF_INET, socktype=socket.SOCK_STREAM)`

Returns an unused port that should be suitable for binding. This is achieved by creating a temporary socket with the same family and type as the `sock` parameter (default is `AF_INET, SOCK_STREAM`), and binding it to the specified host address (defaults to `0.0.0.0`) with the port set to 0, eliciting an unused ephemeral port from the OS. The temporary socket is then closed and deleted, and the ephemeral port is returned.

Either this method or `bind_port()` should be used for any tests where a server socket needs to be bound to a particular port for the duration of the test. Which one to use depends on whether the calling code is creating a Python socket, or if an unused port needs to be provided in a constructor or passed to an external program (i.e. the `-accept` argument to openssl's `s_server` mode). Always prefer `bind_port()` over `find_unused_port()` where possible. Using a hard coded port is discouraged since it can make multiple instances of the test impossible to run simultaneously, which is a problem for buildsbots.

`test.support.socket_helper.bind_port(sock, host=HOST)`

Bind the socket to a free port and return the port number. Relies on ephemeral ports in order to ensure we are using an unbound port. This is important as many tests may be running simultaneously, especially in a buildbot environment. This method raises an exception if the `sock.family` is `AF_INET` and `sock.type` is `SOCK_STREAM`, and the socket has `SO_REUSEADDR` or `SO_REUSEPORT` set on it. Tests should never set these socket options for TCP/IP sockets. The only case for setting these options is testing multicasting via multiple UDP sockets.

Additionally, if the `SO_EXCLUSIVEADDRUSE` socket option is available (i.e. on Windows), it will be set on the socket. This will prevent anyone else from binding to our host/port for the duration of the test.
test.support.socket_helper.bind_unix_socket(sock, addr)
Bind a unix socket, raising unittest.SkipTest if PermissionError is raised.

@test.support.socket_helper.skip_unless_bind_unix_socket
A decorator for running tests that require a functional bind() for Unix sockets.

test.support.socket_helper.transient_internet(resource_name, *, timeout=30.0, errno=())
A context manager that raises ResourceDenied when various issues with the internet connection manifest themselves as exceptions.

26.15 test.support.script_helper — Utilities for the Python execution tests

The test.support.script_helper module provides support for Python’s script execution tests.

test.support.script_helper.interpreter_requires_environment()
Return True if sys.executable interpreter requires environment variables in order to be able to run at all.

This is designed to be used with @unittest.skipIf() to annotate tests that need to use an assert_python*() function to launch an isolated mode (-I) or no environment mode (-E) sub-interpreter process.

A normal build & test does not run into this situation but it can happen when trying to run the standard library test suite from an interpreter that doesn’t have an obvious home with Python’s current home finding logic.

Setting PYTHONHOME is one way to get most of the testsuite to run in that situation. PYTHONPATH or PYTHONUSERSITE are other common environment variables that might impact whether or not the interpreter can start.

test.support.script_helper.run_python_until_end(*args, **env_vars)
Set up the environment based on env_vars for running the interpreter in a subprocess. The values can include __isolated, __cleanenv, __cwd, and TERM.

Changed in version 3.9: The function no longer strips whitespaces from stderr.

test.support.script_helper.assert_python_ok(*args, **env_vars)
Assert that running the interpreter with args and optional environment variables env_vars succeeds (rc == 0) and return a (return code, stdout, stderr) tuple.

If the __cleanenv keyword is set, env_vars is used as a fresh environment.

Python is started in isolated mode (command line option -I), except if the __isolated keyword is set to False.

Changed in version 3.9: The function no longer strips whitespaces from stderr.

 teste.support.script_helper.assert_python_failure(*args, **env_vars)
Assert that running the interpreter with args and optional environment variables env_vars fails (rc != 0) and return a (return code, stdout, stderr) tuple.

See assert_python_ok() for more options.

Changed in version 3.9: The function no longer strips whitespaces from stderr.

test.support.script_helper.spawn_python(*args, stdout=subprocess.PIPE, stderr=subprocess.STDOUT, **kw)
Run a Python subprocess with the given arguments.

kw is extra keyword args to pass to subprocess.Popen(). Returns a subprocess.Popen object.

test.support.script_helper.kill_python(p)
Run the given subprocess.Popen process until completion and return stdout.
test.support.script_helper.make_script(script_dir, script_basename, source, omit_suffix=False)

Create script containing source in path script_dir and script_basename. If omit_suffix is False, append .py to the name. Return the full script path.

test.support.script_helper.make_zip_script(zip_dir, zip_basename, script_name, name_in_zip=None)

Create zip file at zip_dir and zip_basename with extension zip which contains the files in script_name. name_in_zip is the archive name. Return a tuple containing (full path, full path of archive name).

test.support.script_helper.make_pkg(pkg_dir, init_source='')

Create a directory named pkg_dir containing an __init__ file with init_source as its contents.

test.support.script_helper.make_zip_pkg(zip_dir, zip_basename, pkg_name, script_basename, source, depth=1, compiled=False)

Create a zip package directory with a path of zip_dir and zip_basename containing an empty __init__ file and a file script_basename containing the source. If compiled is True, both source files will be compiled and added to the zip package. Return a tuple of the full zip path and the archive name for the zip file.

26.16 test.support.bytecode_helper — Support tools for testing correct bytecode generation

The test.support.bytecode_helper module provides support for testing and inspecting bytecode generation.

New in version 3.9.

The module defines the following class:

class test.support.bytecode_helper.BytecodeTestCase(unittest.TestCase)

This class has custom assertion methods for inspecting bytecode.

BytecodeTestCase.get_disassembly_as_string(co)

Return the disassembly of co as string.

BytecodeTestCase.assertInBytecode(x, opname, argval=_UNSPECIFIED)

Return instr if opname is found, otherwise throws AssertionError.

BytecodeTestCase.assertNotInBytecode(x, opname, argval=_UNSPECIFIED)

Throws AssertionError if opname is found.

26.17 test.support.threading_helper — Utilities for threading tests

The test.support.threading_helper module provides support for threading tests.

New in version 3.10.

test.support.threading_helper.join_thread(thread, timeout=None)

Join a thread within timeout. Raise an AssertionError if thread is still alive after timeout seconds.

@test.support.threading_helper.reap_threads(func)

Decorator to ensure the threads are cleaned up even if the test fails.

test.support.threading_helper.start_threads(threads, unlock=None)

Context manager to start threads. It attempts to join the threads upon exit.
test.support.threading_helper.threading_cleanup(*original_values)
Cleanup up threads not specified in original_values. Designed to emit a warning if a test leaves running threads in the background.

test.support.threading_helper.threading_setup()
Return current thread count and copy of dangling threads.

test.support.threading_helper.wait_threads_exit(timeout=None)
Context manager to wait until all threads created in the with statement exit.

test.support.threading_helper.catch_threading_exception()
Context manager catching threading.Thread exception using threading.excepthook().

Attributes set when an exception is caught:

• exc_type
• exc_value
• exc_traceback
• thread

See threading.excepthook() documentation.

These attributes are deleted at the context manager exit.

Usage:

```python
with threading_helper.catch_threading_exception() as cm:
    # code spawning a thread which raises an exception
    ...

    # check the thread exception, use cm attributes:
    # exc_type, exc_value, exc_traceback, thread
    ...

    # exc_type, exc_value, exc_traceback, thread attributes of cm no longer
    # exists at this point
    # (to avoid reference cycles)
```

New in version 3.8.

## 26.18 test.support.os_helper — Utilities for os tests

The test.support.os_helper module provides support for os tests.

New in version 3.10.

test.support.os_helper.FS_NONASCII
A non-ASCII character encodable by os.fsencode().

test.support.os_helper.SAVEDCWD
Set to os.getcwd().

test.support.os_helper.TESTFN
Set to a name that is safe to use as the name of a temporary file. Any temporary file that is created should be closed and unlinked (removed).

test.support.os_helper.TESTFN_NONASCII
Set to a filename containing the FS_NONASCII character.

test.support.os_helper.TESTFN_UNENCODABLE
Set to a filename (str type) that should not be able to be encoded by file system encoding in strict mode. It may be None if it’s not possible to generate such a filename.
test.support.os_helper.TESTFN_UNDECODABLE
Set to a filename (bytes type) that should not be able to be decoded by file system encoding in strict mode. It may be None if it’s not possible to generate such a filename.

test.support.os_helper.TESTFN_UNICODE
Set to a non-ASCII name for a temporary file.

class test.support.os_helper.EnvironmentVarGuard
Class used to temporarily set or unset environment variables. Instances can be used as a context manager and have a complete dictionary interface for querying/modifying the underlying os.environ. After exit from the context manager all changes to environment variables done through this instance will be rolled back.

Changed in version 3.1: Added dictionary interface.

class test.support.os_helper.FakePath(path)
Simple path-like object. It implements the __fspath__() method which just returns the path argument. If path is an exception, it will be raised in __fspath__().

EnvironmentVarGuard.set(envvar, value)
Temporarily set the environment variable envvar to the value of value.

EnvironmentVarGuard.unset(envvar)
Temporarily unset the environment variable envvar.

test.support.os_helper.can_symlink()
Return True if the OS supports symbolic links, False otherwise.

test.support.os_helper.can_xattr()
Return True if the OS supports xattr, False otherwise.

test.support.os_helper.change_cwd(path, quiet=False)
A context manager that temporarily changes the current working directory to path and yields the directory.

If quiet is False, the context manager raises an exception on error. Otherwise, it issues only a warning and keeps the current working directory the same.

test.support.os_helper.create_empty_file(filename)
Create an empty file with filename. If it already exists, truncate it.

test.support.os_helper.fd_count()
Count the number of open file descriptors.

test.support.os_helper.fs_is_case_insensitive(directory)
Return True if the file system for directory is case-insensitive.

test.support.os_helper.make_bad_fd()
Create an invalid file descriptor by opening and closing a temporary file, and returning its descriptor.

test.support.os_helper.rmdir(filename)
Call os.rmdir() on filename. On Windows platforms, this is wrapped with a wait loop that checks for the existence of the file.

test.support.os_helper.rmtree(path)
Call shutil.rmtree() on path or call os.lstat() and os.rmdir() to remove a path and its contents. On Windows platforms, this is wrapped with a wait loop that checks for the existence of the files.

@test.support.os_helper.skip_unless_symlink
A decorator for running tests that require support for symbolic links.

@test.support.os_helper.skip_unless_xattr
A decorator for running tests that require support for xattr.

test.support.os_helper.temp_cwd(name=‘tempcwd’, quiet=False)
A context manager that temporarily creates a new directory and changes the current working directory (CWD).

The context manager creates a temporary directory in the current directory with name name before temporarily changing the current working directory. If name is None, the temporary directory is created using tempfile.mkdtemp().
If `quiet` is `False` and it is not possible to create or change the CWD, an error is raised. Otherwise, only a warning is raised and the original CWD is used.

test.support.os_helper.temp_dir(path=None, quiet=False)

A context manager that creates a temporary directory at `path` and yields the directory.

If `path` is `None`, the temporary directory is created using `tempfile.mkdtemp()`. If `quiet` is `False`, the context manager raises an exception on error. Otherwise, if `path` is specified and cannot be created, only a warning is issued.

test.support.os_helper.temp_umask(umask)

A context manager that temporarily sets the process umask.

test.support.os_helper.unlink(filename)

Call `os.unlink()` on `filename`. On Windows platforms, this is wrapped with a wait loop that checks for the existence of the file.

26.19 test.support.import_helper — Utilities for import tests

The `test.support.import_helper` module provides support for import tests.

New in version 3.10.

test.support.import_helper.forget(module_name)

Remove the module named `module_name` from `sys.modules` and delete any byte-compiled files of the module.

test.support.import_helper.import_fresh_module(name, fresh=(), blocked=(), deprecated=False)

This function imports and returns a fresh copy of the named Python module by removing the named module from `sys.modules` before doing the import. Note that unlike `reload()`, the original module is not affected by this operation.

`fresh` is an iterable of additional module names that are also removed from the `sys.modules` cache before doing the import.

`blocked` is an iterable of module names that are replaced with `None` in the module cache during the import to ensure that attempts to import them raise `ImportError`.

The named module and any modules named in the `fresh` and `blocked` parameters are saved before starting the import and then reinserted into `sys.modules` when the fresh import is complete.

Module and package deprecation messages are suppressed during this import if `deprecated` is `True`.

This function will raise `ImportError` if the named module cannot be imported.

Example use:

```python
# Get copies of the warnings module for testing without affecting the
# version being used by the rest of the test suite. One copy uses the
# C implementation, the other is forced to use the pure Python fallback
# implementation
py_warnings = import_fresh_module('warnings', fresh=['.warnings'])
c_warnings = import_fresh_module('warnings', fresh=['.warnings'])
```

New in version 3.1.

test.support.import_helper.import_module(name, deprecated=False, *, required_on())

This function imports and returns the named module. Unlike a normal import, this function raises `unittest.SkipTest` if the module cannot be imported.

Module and package deprecation messages are suppressed during this import if `deprecated` is `True`. If a module is required on a platform but optional for others, set `required_on` to an iterable of platform prefixes which will be compared against `sys.platform`.

26.19. test.support.import_helper — Utilities for import tests 1589
New in version 3.1.

```python
test.support.import_helper.modules_setup()
```

Return a copy of `sys.modules`.

```python
test.support.import_helper.modules_cleanup(oldmodules)
```

Remove modules except for `oldmodules` and `encodings` in order to preserve internal cache.

```python
test.support.import_helper.unload(name)
```

Delete `name` from `sys.modules`.

```python
test.support.import_helper.make_legacy_pyc(source)
```

Move a PEP 3147/PEP 488 pyc file to its legacy pyc location and return the file system path to the legacy pyc file. The `source` value is the file system path to the source file. It does not need to exist, however the PEP 3147/488 pyc file must exist.

```python
class test.support.import_helper.CleanImport(*module_names)
```

A context manager to force import to return a new module reference. This is useful for testing module-level behaviors, such as the emission of a DeprecationWarning on import. Example usage:

```python
with CleanImport('foo'):
    importlib.import_module('foo')  # New reference.
```

```python
class test.support.import_helper.DirsOnSysPath(*paths)
```

A context manager to temporarily add directories to `sys.path`.

This makes a copy of `sys.path`, appends any directories given as positional arguments, then reverts `sys.path` to the copied settings when the context ends.

Note that all `sys.path` modifications in the body of the context manager, including replacement of the object, will be reverted at the end of the block.

### 26.20 test.support.warnings_helper — Utilities for warnings tests

The `test.support.warnings_helper` module provides support for warnings tests.

New in version 3.10.

```python
test.support.warnings_helper.check_no_resource_warning(testcase)
```

Context manager to check that no `ResourceWarning` was raised. You must remove the object which may emit `ResourceWarning` before the end of the context manager.

```python
test.support.warnings_helper.check_syntax_warning(testcase, statement, errtext='', *, lineno=1, offset=None)
```

Test for syntax warning in `statement` by attempting to compile `statement`. Test also that the `SyntaxWarning` is emitted only once, and that it will be converted to a `SyntaxError` when turned into error. `testcase` is the `unittest` instance for the test. `errtext` is the regular expression which should match the string representation of the emitted `SyntaxWarning` and raised `SyntaxError`. If `lineno` is not `None`, compares to the line of the warning and exception. If `offset` is not `None`, compares to the offset of the exception.

New in version 3.8.

```python
test.support.warnings_helper.check_warnings(*filters, quiet=True)
```

A convenience wrapper for `warnings.catch_warnings()` that makes it easier to test that a warning was correctly raised. It is approximately equivalent to calling `warnings.catch_warnings(record=True)` with `warnings.simplefilter()` set to `always` and with the option to automatically validate the results that are recorded.

`check_warnings` accepts 2-tuples of the form `("message regexp", WarningCategory)` as positional arguments. If one or more `filters` are provided, or if the optional keyword argument `quiet` is `False`, it checks to make sure the warnings are as expected: each specified filter must match at least one of the warnings.
raised by the enclosed code or the test fails, and if any warnings are raised that do not match any of the specified filters the test fails. To disable the first of these checks, set quiet to True.

If no arguments are specified, it defaults to:

```python
check_warnings(("", Warning), quiet=True)
```

In this case all warnings are caught and no errors are raised.

On entry to the context manager, a `WarningRecorder` instance is returned. The underlying warnings list from `catch_warnings()` is available via the recorder object’s `warnings` attribute. As a convenience, the attributes of the object representing the most recent warning can also be accessed directly through the recorder object (see example below). If no warning has been raised, then any of the attributes that would otherwise be expected on an object representing a warning will return `None`.

The recorder object also has a `reset()` method, which clears the warnings list.

The context manager is designed to be used like this:

```python
with check_warnings(("assertion is always true", SyntaxWarning),
                   ("", UserWarning)):
    exec('assert(False, "Hey!")')
    warnings.warn(UserWarning("Hide me!"))
```

In this case if either warning was not raised, or some other warning was raised, `check_warnings()` would raise an error.

When a test needs to look more deeply into the warnings, rather than just checking whether or not they occurred, code like this can be used:

```python
with check_warnings(quiet=True) as w:
    warnings.warn("foo")
    assert str(w.args[0]) == "foo"
    warnings.warn("bar")
    assert str(w.args[0]) == "bar"
    assert str(w.warnings[0].args[0]) == "foo"
    assert str(w.warnings[1].args[0]) == "bar"
    w.reset()
    assert len(w.warnings) == 0
```

Here all warnings will be caught, and the test code tests the captured warnings directly.

Changed in version 3.2: New optional arguments `filters` and `quiet`.

```python
class test.support.warnings_helper.WarningsRecorder

Class used to record warnings for unit tests. See documentation of `check_warnings()` above for more details.
```
These libraries help you with Python development: the debugger enables you to step through code, analyze stack frames and set breakpoints etc., and the profilers run code and give you a detailed breakdown of execution times, allowing you to identify bottlenecks in your programs. Auditing events provide visibility into runtime behaviors that would otherwise require intrusive debugging or patching.

### 27.1 Audit events table

This table contains all events raised by `sys.audit()` or `PySys_Audit()` calls throughout the CPython runtime and the standard library. These calls were added in 3.8.0 or later (see PEP 578).

See `sys.addaudithook()` and `PySys_AddAuditHook()` for information on handling these events.

**CPython implementation detail**: This table is generated from the CPython documentation, and may not represent events raised by other implementations. See your runtime specific documentation for actual events raised.

27.2 `bdb` — Debugger framework

Source code: Lib/bdb.py

The `bdb` module handles basic debugger functions, like setting breakpoints or managing execution via the debugger.

The following exception is defined:

**exception** `bdb.BdbQuit`

Exception raised by the `Bdb` class for quitting the debugger.

The `bdb` module also defines two classes:

**class** `bdb.Breakpoint`

This class implements temporary breakpoints, ignore counts, disabling and (re-)enabling, and conditionals.

Breakpoints are indexed by number through a list called `bpbynumber` and by `(file, line)` pairs through `bplist`. The former points to a single instance of class `Breakpoint`. The latter points to a list of such instances since there may be more than one breakpoint per line.

When creating a breakpoint, its associated filename should be in canonical form. If a `funcname` is defined, a breakpoint hit will be counted when the first line of that function is executed. A conditional breakpoint always counts a hit.

`Breakpoint` instances have the following methods:

**deleteMe()**

Delete the breakpoint from the list associated to a file/line. If it is the last breakpoint in that position, it also deletes the entry for the file/line.

**enable()**

Mark the breakpoint as enabled.

**disable()**

Mark the breakpoint as disabled.

**bpformat()**

Return a string with all the information about the breakpoint, nicely formatted:

- The breakpoint number.
- If it is temporary or not.
- Its file/line position.
- The condition that causes a break.
- If it must be ignored the next N times.
- The breakpoint hit count.

New in version 3.2.
**bprint** *(out=None)*

Print the output of `bpformat()` to the file `out`, or if it is `None`, to standard output.

**class** `bdb.Bdb`(skip=None)

The `Bdb` class acts as a generic Python debugger base class.

This class takes care of the details of the trace facility; a derived class should implement user interaction. The standard debugger class (`pdb.Pdb`) is an example.

The `skip` argument, if given, must be an iterable of glob-style module name patterns. The debugger will not step into frames that originate in a module that matches one of these patterns. Whether a frame is considered to originate in a certain module is determined by the `__name__` in the frame globals.

New in version 3.1: The `skip` argument.

The following methods of `Bdb` normally don’t need to be overridden.

**canonic** *(filename)*

Auxiliary method for getting a filename in a canonical form, that is, as a case-normalized (on case-insensitive filesystems) absolute path, stripped of surrounding angle brackets.

**reset** ()

Set the `botframe`, `stopframe`, `returnframe` and `quitting` attributes with values ready to start debugging.

**trace_dispatch** *(frame, event, arg)*

This function is installed as the trace function of debugged frames. Its return value is the new trace function (in most cases, that is, itself).

The default implementation decides how to dispatch a frame, depending on the type of event (passed as a string) that is about to be executed. `event` can be one of the following:

- "line": A new line of code is going to be executed.
- "call": A function is about to be called, or another code block entered.
- "return": A function or other code block is about to return.
- "exception": An exception has occurred.
- "c_call": A C function is about to be called.
- "c_return": A C function has returned.
- "c_exception": A C function has raised an exception.

For the Python events, specialized functions (see below) are called. For the C events, no action is taken.

The `arg` parameter depends on the previous event.

See the documentation for `sys.settrace()` for more information on the trace function. For more information on code and frame objects, refer to types.

**dispatch_line** *(frame)*

If the debugger should stop on the current line, invoke the `user_line()` method (which should be overridden in subclasses). Raise a `BdbQuit` exception if the `Bdb.quitting` flag is set (which can be set from `user_line()`). Return a reference to the `trace_dispatch()` method for further tracing in that scope.

**dispatch_call** *(frame, arg)*

If the debugger should stop on this function call, invoke the `user_call()` method (which should be overridden in subclasses). Raise a `BdbQuit` exception if the `Bdb.quitting` flag is set (which can be set from `user_call()`). Return a reference to the `trace_dispatch()` method for further tracing in that scope.

**dispatch_return** *(frame, arg)*

If the debugger should stop on this function return, invoke the `user_return()` method (which should be overridden in subclasses). Raise a `BdbQuit` exception if the `Bdb.quitting` flag is set (which can...
be set from \texttt{user\_return()}. Return a reference to the \texttt{trace\_dispatch()} method for further tracing in that scope.

\textbf{dispatch\_exception (frame, arg)}

If the debugger should stop at this exception, invokes the \texttt{user\_exception()} method (which should be overridden in subclasses). Raise a \texttt{BdbQuit} exception if the \texttt{Bdb.quitting} flag is set (which can be set from \texttt{user\_exception()}). Return a reference to the \texttt{trace\_dispatch()} method for further tracing in that scope.

Normally derived classes don’t override the following methods, but they may if they want to redefine the definition of stopping and breakpoints.

\textbf{stop\_here (frame)}

This method checks if the \texttt{frame} is somewhere below \texttt{botframe} in the call stack. \texttt{botframe} is the frame in which debugging started.

\textbf{break\_here (frame)}

This method checks if there is a breakpoint in the filename and line belonging to \texttt{frame} or, at least, in the current function. If the breakpoint is a temporary one, this method deletes it.

\textbf{break\_anywhere (frame)}

This method checks if there is a breakpoint in the filename of the current frame.

Derived classes should override these methods to gain control over debugger operation.

\textbf{user\_call (frame, argument\_list)}

This method is called from \texttt{dispatch\_call()} when there is the possibility that a break might be necessary anywhere inside the called function.

\textbf{user\_line (frame)}

This method is called from \texttt{dispatch\_line()} when either \texttt{stop\_here()} or \texttt{break\_here()} yields True.

\textbf{user\_return (frame, return\_value)}

This method is called from \texttt{dispatch\_return()} when \texttt{stop\_here()} yields True.

\textbf{user\_exception (frame, exc\_info)}

This method is called from \texttt{dispatch\_exception()} when \texttt{stop\_here()} yields True.

\textbf{do\_clear (arg)}

Handle how a breakpoint must be removed when it is a temporary one.

This method must be implemented by derived classes.

Derived classes and clients can call the following methods to affect the stepping state.

\textbf{set\_step ()}

Stop after one line of code.

\textbf{set\_next (frame)}

Stop on the next line in or below the given frame.

\textbf{set\_return (frame)}

Stop when returning from the given frame.

\textbf{set\_until (frame)}

Stop when the line with the line no greater than the current one is reached or when returning from current frame.

\textbf{set\_trace ([frame ])}

Start debugging from \texttt{frame}. If \texttt{frame} is not specified, debugging starts from caller’s frame.

\textbf{set\_continue ()}

Stop only at breakpoints or when finished. If there are no breakpoints, set the system trace function to None.
**set_quit()**
Set the quitting attribute to True. This raises `BdbQuit` in the next call to one of the `dispatch_*()` methods.

Derived classes and clients can call the following methods to manipulate breakpoints. These methods return a string containing an error message if something went wrong, or `None` if all is well.

**set_break (filename, lineno, temporary=0, cond, funcname)**
Set a new breakpoint. If the `lineno` line doesn’t exist for the `filename` passed as argument, return an error message. The `filename` should be in canonical form, as described in the `canonic()` method.

**clear_break (filename, lineno)**
Delete the breakpoints in `filename` and `lineno`. If none were set, an error message is returned.

**clear_bpbynumber (arg)**
Delete the breakpoint which has the index `arg` in the `Breakpoint.bpbynumber`. If `arg` is not numeric or out of range, return an error message.

**clear_all_file_breaks (filename)**
Delete all breakpoints in `filename`. If none were set, an error message is returned.

**clear_all_breaks ()**
Delete all existing breakpoints.

**get_bpbynumber (arg)**
Return a breakpoint specified by the given number. If `arg` is a string, it will be converted to a number. If `arg` is a non-numeric string, if the given breakpoint never existed or has been deleted, a `ValueError` is raised.

New in version 3.2.

**get_break (filename, lineno)**
Check if there is a breakpoint for `lineno` of `filename`.

**get_breaks (filename, lineno)**
Return all breakpoints for `lineno` in `filename`, or an empty list if none are set.

**get_file_breaks (filename)**
Return all breakpoints in `filename`, or an empty list if none are set.

**get_all_breaks ()**
Return all breakpoints that are set.

Derived classes and clients can call the following methods to get a data structure representing a stack trace.

**get_stack (f, t)**
Get a list of records for a frame and all higher (calling) and lower frames, and the size of the higher part.

**format_stack_entry (frame_lineno, lprefix=’’)**
Return a string with information about a stack entry, identified by a `(frame, lineno)` tuple:

- The canonical form of the filename which contains the frame.
- The function name, or "<lambda>".
- The input arguments.
- The return value.
- The line of code (if it exists).

The following two methods can be called by clients to use a debugger to debug a `statement`, given as a string.

**run (cmd, globals=None, locals=None)**
Debug a statement executed via the `exec()` function. `globals` defaults to `__main__.__dict__`, `locals` defaults to `globals`.

**runeval (expr, globals=None, locals=None)**
Debug an expression executed via the `eval()` function. `globals` and `locals` have the same meaning as in `run()`.
**runctx** *(cmd, globals, locals)*
For backwards compatibility. Calls the `run()` method.

**runcall** *(func, /, *args, **kwargs)*
Debug a single function call, and return its result.

Finally, the module defines the following functions:

**bdb.** *checkfuncname* *(b, frame)*
Check whether we should break here, depending on the way the breakpoint `b` was set.

- If it was set via line number, it checks if `b.line` is the same as the one in the frame also passed as argument.
- If the breakpoint was set via function name, we have to check we are in the right frame (the right function) and if we are in its first executable line.

**bdb.** *effective* *(file, line, frame)*
Determine if there is an effective (active) breakpoint at this line of code. Return a tuple of the breakpoint and a boolean that indicates if it is ok to delete a temporary breakpoint. Return `(None, None)` if there is no matching breakpoint.

**bdb.** *set_trace*
Start debugging with a `Bdb` instance from caller’s frame.

### 27.3 faulthandler — Dump the Python traceback

New in version 3.3.

This module contains functions to dump Python backtraces explicitly, on a fault, after a timeout, or on a user signal. Call `faulthandler.enable()` to install fault handlers for the `SIGSEGV`, `SIGFPE`, `SIGABRT`, `SIGBUS`, and `SIGILL` signals. You can also enable them at startup by setting the `PYTHONFAULTHANDLER` environment variable or by using the `-X faulthandler` command line option.

The fault handler is compatible with system fault handlers like Apport or the Windows fault handler. The module uses an alternative stack for signal handlers if the `sigaltstack()` function is available. This allows it to dump the traceback even on a stack overflow.

The fault handler is called on catastrophic cases and therefore can only use signal-safe functions (e.g. it cannot allocate memory on the heap). Because of this limitation traceback dumping is minimal compared to normal Python backtraces:

- Only ASCII is supported. The `backslashreplace` error handler is used on encoding.
- Each string is limited to 500 characters.
- Only the filename, the function name and the line number are displayed. (no source code)
- It is limited to 100 frames and 100 threads.
- The order is reversed: the most recent call is shown first.

By default, the Python traceback is written to `sys.stderr`. To see backtraces, applications must be run in the terminal. A log file can alternatively be passed to `faulthandler.enable()`.

The module is implemented in C, so backtraces can be dumped on a crash or when Python is deadlocked.

The `Python Development Mode` calls `faulthandler.enable()` at Python startup.
27.3.1 Dumping the traceback

```python
default_handler.dump_traceback(file=sys.stderr, all_threads=True)
```
Dump the tracebacks of all threads into `file`. If `all_threads` is `False`, dump only the current thread.

Changed in version 3.5: Added support for passing file descriptor to this function.

27.3.2 Fault handler state

```python
default_handler.enable(file=sys.stderr, all_threads=True)
```
Enable the fault handler: install handlers for the SIGSEGV, SIGFPE, SIGABRT, SIGBUS and SIGILL signals to dump the Python traceback. If `all_threads` is `True`, produce tracebacks for every running thread. Otherwise, dump only the current thread.

The `file` must be kept open until the fault handler is disabled: see issue with file descriptors.

Changed in version 3.5: Added support for passing file descriptor to this function.

Changed in version 3.6: On Windows, a handler for Windows exception is also installed.

Changed in version 3.10: The dump now mentions if a garbage collector collection is running if `all_threads` is true.

```python
default_handler.disable()
```
Disable the fault handler: uninstall the signal handlers installed by `enable()`.

```python
default_handler.is_enabled()
```
Check if the fault handler is enabled.

27.3.3 Dumping the tracebacks after a timeout

```python
default_handler.dump_traceback_later(timeout, repeat=False, file=sys.stderr, exit=False)
```
Dump the tracebacks of all threads, after a timeout of `timeout` seconds, or every `timeout` seconds if `repeat` is `True`. If `exit` is `True`, call `_exit()` with `status=1` after dumping the tracebacks. (Note `_exit()` exits the process immediately, which means it doesn’t do any cleanup like flushing file buffers.) If the function is called twice, the new call replaces previous parameters and resets the timeout. The timer has a sub-second resolution.

The `file` must be kept open until the traceback is dumped or `cancel_dump_traceback_later()` is called: see issue with file descriptors.

This function is implemented using a watchdog thread.

Changed in version 3.7: This function is now always available.

Changed in version 3.5: Added support for passing file descriptor to this function.

```python
default_handler.cancel_dump_traceback_later()
```
Cancel the last call to `dump_traceback_later()`.

27.3.4 Dumping the traceback on a user signal

```python
default_handler.register(signum, file=sys.stderr, all_threads=True, chain=False)
```
Register a user signal: install a handler for the `signum` signal to dump the traceback of all threads, or of the current thread if `all_threads` is `False`, into `file`. Call the previous handler if chain is `True`.

The `file` must be kept open until the signal is unregistered by `unregister(): see issue with file descriptors`.

Not available on Windows.

Changed in version 3.5: Added support for passing file descriptor to this function.
faulthandler.unregister(signum)

Unregister a user signal: uninstall the handler of the *signum* signal installed by *register()*.

Return *True* if the signal was registered, *False* otherwise.

Not available on Windows.

### 27.3.5 Issue with file descriptors

*enable(), dump_traceback_later()*, and *register()* keep the file descriptor of their *file* argument. If the file is closed and its file descriptor is reused by a new file, or if *os.dup2()* is used to replace the file descriptor, the traceback will be written into a different file. Call these functions again each time that the file is replaced.

### 27.3.6 Example

Example of a segmentation fault on Linux with and without enabling the fault handler:

```
$ python3 -c "import ctypes; ctypes.string_at(0)"
Segmentation fault

$ python3 -q -X faulthandler
>>> import ctypes
>>> ctypes.string_at(0)
Fatal Python error: Segmentation fault
```

Current thread 0x00007fb8a9f39700 (most recent call first):
  File "/home/python/cpython/Lib/ctypes/__init__.py", line 486 in string_at
  File ":<stdin>", line 1 in <module>

```
Segmentation fault
```

### 27.4 pdb — The Python Debugger

**Source code:** Lib/pdb.py

The module *pdb* defines an interactive source code debugger for Python programs. It supports setting (conditional) breakpoints and single stepping at the source line level, inspection of stack frames, source code listing, and evaluation of arbitrary Python code in the context of any stack frame. It also supports post-mortem debugging and can be called under program control.

The debugger is extensible – it is actually defined as the class *Pdb*. This is currently undocumented but easily understood by reading the source. The extension interface uses the modules *bdb* and *cmd*.

The debugger’s prompt is *(Pdb)*. Typical usage to run a program under control of the debugger is:

```
>>> import pdb
>>> import mymodule
>>> pdb.run('mymodule.test()')
> <string>(0)?()
(Pdb) continue
> <string>(1)?()
(Pdb) continue
NameError: 'spam'
> <string>(1)?()
(Pdb)
```

Changed in version 3.3: Tab-completion via the *readline* module is available for commands and command arguments, e.g. the current global and local names are offered as arguments of the *p* command.

*pdb*.py can also be invoked as a script to debug other scripts. For example:
When invoked as a script, pdb will automatically enter post-mortem debugging if the program being debugged exits abnormally. After post-mortem debugging (or after normal exit of the program), pdb will restart the program. Automatic restarting preserves pdb’s state (such as breakpoints) and in most cases is more useful than quitting the debugger upon program’s exit.

New in version 3.2: pdb.py now accepts a -c option that executes commands as if given in a .pdbrc file, see Debugger Commands.

New in version 3.7: pdb.py now accepts a -m option that execute modules similar to the way python3 -m does. As with a script, the debugger will pause execution just before the first line of the module.

The typical usage to break into the debugger is to insert:

```python
import pdb; pdb.set_trace()
```

at the location you want to break into the debugger, and then run the program. You can then step through the code following this statement, and continue running without the debugger using the continue command.

New in version 3.7: The built-in breakpoint(), when called with defaults, can be used instead of import pdb; pdb.set_trace().

The typical usage to inspect a crashed program is:

```python
>>> import pdb
>>> import mymodule
>>> mymodule.test()
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "./mymodule.py", line 4, in test2
    test2()
  File "./mymodule.py", line 3, in test2
    print(spam)
NameError: spam
>>> pdb.pm()
> ./mymodule.py(3)test2()
  -> print(spam)
(Pdb)
```

The module defines the following functions; each enters the debugger in a slightly different way:

`pdb.run(statement, globals=None, locals=None)`

Execute the statement (given as a string or a code object) under debugger control. The debugger prompt appears before any code is executed; you can set breakpoints and type continue, or you can step through the statement using step or next (all these commands are explained below). The optional globals and locals arguments specify the environment in which the code is executed; by default the dictionary of the module __main__ is used. (See the explanation of the built-in exec() or eval() functions.)

`pdb.runeval(expression, globals=None, locals=None)`

Evaluate the expression (given as a string or a code object) under debugger control. When runeval() returns, it returns the value of the expression. Otherwise this function is similar to run().

`pdb.runcall(function, *args, **kwargs)`

Call the function (a function or method object, not a string) with the given arguments. When runcall() returns, it returns whatever the function call returned. The debugger prompt appears as soon as the function is entered.

`pdb.set_trace(*, header=None)`

Enter the debugger at the calling stack frame. This is useful to hard-code a breakpoint at a given point in a program, even if the code is not otherwise being debugged (e.g. when an assertion fails). If given, header is printed to the console just before debugging begins.

Changed in version 3.7: The keyword-only argument header.
pdb.post_mortem (traceback=None)

Enter post-mortem debugging of the given traceback object. If no traceback is given, it uses the one of the exception that is currently being handled (an exception must be being handled if the default is to be used).

pdb.pm ()

Enter post-mortem debugging of the traceback found in sys.last_traceback.

The run* functions and set_trace() are aliases for instantiating the Pdb class and calling the method of the same name. If you want to access further features, you have to do this yourself:

class pdb.Pdb (completekey='tab', stdin=None, stdout=None, skip=None, nosigint=False, readrc=True)

Pdb is the debugger class.

The completekey, stdin and stdout arguments are passed to the underlying cmd.Cmd class; see the description there.

The skip argument, if given, must be an iterable of glob-style module name patterns. The debugger will not step into frames that originate in a module that matches one of these patterns.1

By default, Pdb sets a handler for the SIGINT signal (which is sent when the user presses Ctrl-C on the console) when you give a continue command. This allows you to break into the debugger again by pressing Ctrl-C. If you want Pdb not to touch the SIGINT handler, set nosigint to true.

The readrc argument defaults to true and controls whether Pdb will load .pdbrc files from the filesystem.

Example call to enable tracing with skip:

```python
import pdb; pdb.Pdb(skip=['django.*']).set_trace()
```

Raises an auditing event pdb.Pdb with no arguments.

New in version 3.1: The skip argument.

New in version 3.2: The nosigint argument. Previously, a SIGINT handler was never set by Pdb.

Changed in version 3.6: The readrc argument.

run (statement, globals=None, locals=None)
runeval (expression, globals=None, locals=None)
runcall (function, *args, **kwds)
set_trace ()

See the documentation for the functions explained above.

### 27.4.1 Debugger Commands

The commands recognized by the debugger are listed below. Most commands can be abbreviated to one or two letters as indicated; e.g. h(elp) means that either h or help can be used to enter the help command (but not he or hel, nor H or Help or HELP). Arguments to commands must be separated by whitespace (spaces or tabs). Optional arguments are enclosed in square brackets ([ ]) in the command syntax; the square brackets must not be typed. Alternatives in the command syntax are separated by a vertical bar (|).

Entering a blank line repeats the last command entered. Exception: if the last command was a list command, the next 11 lines are listed.

Commands that the debugger doesn’t recognize are assumed to be Python statements and are executed in the context of the program being debugged. Python statements can also be prefixed with an exclamation point (!). This is a powerful way to inspect the program being debugged; it is even possible to change a variable or call a function. When an exception occurs in such a statement, the exception name is printed but the debugger's state is not changed.

The debugger supports aliases. Aliases can have parameters which allows one a certain level of adaptability to the context under examination.

---

1 Whether a frame is considered to originate in a certain module is determined by the __name__ in the frame globals.
Multiple commands may be entered on a single line, separated by `;`. (A single `;` is not used as it is the separator for multiple commands in a line that is passed to the Python parser.) No intelligence is applied to separating the commands; the input is split at the first `;` pair, even if it is in the middle of a quoted string.

If a file `.pdbrc` exists in the user’s home directory or in the current directory, it is read in and executed as if it had been typed at the debugger prompt. This is particularly useful for aliases. If both files exist, the one in the home directory is read first and aliases defined there can be overridden by the local file.

Changed in version 3.2: `.pdbrc` can now contain commands that continue debugging, such as `continue` or `next`. Previously, these commands had no effect.

h(elp) `[command]`
Without argument, print the list of available commands. With a `command` as argument, print help about that command. `help pdb` displays the full documentation (the docstring of the `pdb` module). Since the `command` argument must be an identifier, `help exec` must be entered to get help on the `!` command.

w(here)
Print a stack trace, with the most recent frame at the bottom. An arrow indicates the current frame, which determines the context of most commands.

d(own) `[count]`
Move the current frame `count` (default one) levels down in the stack trace (to a newer frame).

u(p) `[count]`
Move the current frame `count` (default one) levels up in the stack trace (to an older frame).

b(reak) `[[filename: lineno | function] [, condition]]`
With a `lineno` argument, set a break there in the current file. With a `function` argument, set a break at the first executable statement within that function. The line number may be prefixed with a filename and a colon, to specify a breakpoint in another file (probably one that hasn’t been loaded yet). The file is searched on `sys.path`. Note that each breakpoint is assigned a number to which all the other breakpoint commands refer.

If a second argument is present, it is an expression which must evaluate to true before the breakpoint is honored.

Without argument, list all breaks, including for each breakpoint, the number of times that breakpoint has been hit, the current ignore count, and the associated condition if any.

tbreak `[[filename: lineno | function] [, condition]]`
Temporary breakpoint, which is removed automatically when it is first hit. The arguments are the same as for `break`.

cl(ear) `[[filename:lineno | bpnumber ...]]`
With a `filename:lineno` argument, clear all the breakpoints at this line. With a space separated list of breakpoint numbers, clear those breakpoints. Without argument, clear all breaks (but first ask confirmation).

disable `bpnumber ...`
Disable the breakpoints given as a space separated list of breakpoint numbers. Disabling a breakpoint means it cannot cause the program to stop execution, but unlike clearing a breakpoint, it remains in the list of breakpoints and can be (re-)enabled.

enable `bpnumber ...`
Enable the breakpoints specified.

ignore `bpnumber [count]`
Set the ignore count for the given breakpoint number. If count is omitted, the ignore count is set to 0. A breakpoint becomes active when the ignore count is zero. When non-zero, the count is decremented each time the breakpoint is reached and the breakpoint is not disabled and any associated condition evaluates to true.

condition `bpnumber [condition]`
Set a new condition for the breakpoint, an expression which must evaluate to true before the breakpoint is honored. If `condition` is absent, any existing condition is removed; i.e., the breakpoint is made unconditional.

commands `bpnumber`
Specify a list of commands for breakpoint number `bpnumber`. The commands themselves appear on the following lines. Type a line containing just `end` to terminate the commands. An example:
To remove all commands from a breakpoint, type `commands` and follow it immediately with `end`; that is, give no commands.

With no `bpnumber` argument, `commands` refers to the last breakpoint set.

You can use breakpoint commands to start your program up again. Simply use the `continue` command, or `step`, or any other command that resumes execution.

Specifying any command resuming execution (currently `continue`, `step`, `next`, `return`, `jump`, `quit` and their abbreviations) terminates the command list (as if that command was immediately followed by end). This is because any time you resume execution (even with a simple next or step), you may encounter another breakpoint—which could have its own command list, leading to ambiguities about which list to execute.

If you use the ‘silent’ command in the command list, the usual message about stopping at a breakpoint is not printed. This may be desirable for breakpoints that are to print a specific message and then continue. If none of the other commands print anything, you see no sign that the breakpoint was reached.

`s tep`

Execute the current line, stop at the first possible occasion (either in a function that is called or on the next line in the current function).

`n ext`

Continue execution until the next line in the current function is reached or it returns. (The difference between `next` and `step` is that `step` stops inside a called function, while `next` executes called functions at (nearly) full speed, only stopping at the next line in the current function.)

`unt il [lineno]`

Without argument, continue execution until the line with a number greater than the current one is reached.

With a line number, continue execution until a line with a number greater or equal to that is reached. In both cases, also stop when the current frame returns.

Changed in version 3.2: Allow giving an explicit line number.

`r eturn`

Continue execution until the current function returns.

`c ont inue)`

Continue execution, only stop when a breakpoint is encountered.

`j ump lineno`

Set the next line that will be executed. Only available in the bottom-most frame. This lets you jump back and execute code again, or jump forward to skip code that you don’t want to run.

It should be noted that not all jumps are allowed – for instance it is not possible to jump into the middle of a `for` loop or out of a `finally` clause.

`l ist [first[, last]]`

List source code for the current file. Without arguments, list 11 lines around the current line or continue the previous listing. With . as argument, list 11 lines around the current line. With one argument, list 11 lines around at that line. With two arguments, list the given range; if the second argument is less than the first, it is interpreted as a count.

The current line in the current frame is indicated by `->`. If an exception is being debugged, the line where the exception was originally raised or propagated is indicated by `>>`, if it differs from the current line.

New in version 3.2: The `>>` marker.

`ll | longlist`

List all source code for the current function or frame. Interesting lines are marked as for `list`.

New in version 3.2.
a(rgs)
    Print the argument list of the current function.

p expression
    Evaluate the expression in the current context and print its value.

Note: print() can also be used, but is not a debugger command — this executes the Python print() function.

PP expression
    Like the p command, except the value of the expression is pretty-printed using the pprint module.

whatis expression
    Print the type of the expression.

source expression
    Try to get source code for the given object and display it.
    New in version 3.2.

display [expression]
    Display the value of the expression if it changed, each time execution stops in the current frame.
    Without expression, list all display expressions for the current frame.
    New in version 3.2.

undisplay [expression]
    Do not display the expression any more in the current frame. Without expression, clear all display expressions
    for the current frame.
    New in version 3.2.

interact
    Start an interactive interpreter (using the code module) whose global namespace contains all the (global and
    local) names found in the current scope.
    New in version 3.2.

alias [name [command]]
    Create an alias called name that executes command. The command must not be enclosed in quotes. Replaceable
    parameters can be indicated by %1, %2, and so on, while %* is replaced by all the parameters. If no command
    is given, the current alias for name is shown. If no arguments are given, all aliases are listed.

    Aliases may be nested and can contain anything that can be legally typed at the pdb prompt. Note that internal
    pdb commands can be overridden by aliases. Such a command is then hidden until the alias is removed.

    As an example, here are two useful aliases (especially when placed in the .pdbrc file):

    # Print instance variables (usage "pi classInst")
    alias pi for k in %1.__dict__.keys(): print("%1.%s",%1,%1.__dict__[k])
    # Print instance variables in self
    alias ps pi self

unalias name
    Delete the specified alias.

! statement
    Execute the (one-line) statement in the context of the current stack frame. The exclamation point can be omitted
    unless the first word of the statement resembles a debugger command. To set a global variable, you can prefix
    the assignment command with a global statement on the same line, e.g.:

    (Pdb) global list_options; list_options = ['-l']
    (Pdb)
run [args ...]
restart [args ...]

Restart the debugged Python program. If an argument is supplied, it is split with `shlex` and the result is used as the new `sys.argv`. History, breakpoints, actions and debugger options are preserved. `restart` is an alias for `run`.

quit

Quit from the debugger. The program being executed is aborted.

debug code

Enter a recursive debugger that steps through the code argument (which is an arbitrary expression or statement to be executed in the current environment).

retval

Print the return value for the last return of a function.

### 27.5 The Python Profilers

**Source code:** Lib/profile.py and Lib/pstats.py

#### 27.5.1 Introduction to the profilers

`cProfile` and `profile` provide deterministic profiling of Python programs. A `profile` is a set of statistics that describes how often and for how long various parts of the program executed. These statistics can be formatted into reports via the `pstats` module.

The Python standard library provides two different implementations of the same profiling interface:

1. `cProfile` is recommended for most users; it's a C extension with reasonable overhead that makes it suitable for profiling long-running programs. Based on `lsprof`, contributed by Brett Rosen and Ted Czotter.

2. `profile`, a pure Python module whose interface is imitated by `cProfile`, but which adds significant overhead to profiled programs. If you’re trying to extend the profiler in some way, the task might be easier with this module. Originally designed and written by Jim Roskind.

**Note:** The profiler modules are designed to provide an execution profile for a given program, not for benchmarking purposes (for that, there is `timeit` for reasonably accurate results). This particularly applies to benchmarking Python code against C code: the profilers introduce overhead for Python code, but not for C-level functions, and so the C code would seem faster than any Python one.

#### 27.5.2 Instant User’s Manual

This section is provided for users that “don’t want to read the manual.” It provides a very brief overview, and allows a user to rapidly perform profiling on an existing application.

To profile a function that takes a single argument, you can do:

```python
import cProfile
import re

re.compile("foo|bar")
```

(Use `profile` instead of `cProfile` if the latter is not available on your system.)

The above action would run `re.compile()` and print profile results like the following:
197 function calls (192 primitive calls) in 0.002 seconds

Ordered by: standard name

<table>
<thead>
<tr>
<th>ncalls</th>
<th>tottime</th>
<th>percall</th>
<th>cumtime</th>
<th>percall</th>
<th>filename:lineno(function)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>0.000</td>
<td>0.000</td>
<td>0.001</td>
<td>0.0001</td>
<td>&lt;string&gt;:1(&lt;module&gt;)</td>
</tr>
<tr>
<td>1</td>
<td>0.000</td>
<td>0.000</td>
<td>0.001</td>
<td>0.0001</td>
<td>re.py:212(compile)</td>
</tr>
<tr>
<td>1</td>
<td>0.000</td>
<td>0.000</td>
<td>0.001</td>
<td>0.0001</td>
<td>re.py:268(_compile)</td>
</tr>
<tr>
<td>1</td>
<td>0.000</td>
<td>0.000</td>
<td>0.000</td>
<td>0.000</td>
<td>sre_compile.py:172(_compile_charset)</td>
</tr>
<tr>
<td>1</td>
<td>0.000</td>
<td>0.000</td>
<td>0.000</td>
<td>0.000</td>
<td>sre_compile.py:201(_optimize_charset)</td>
</tr>
<tr>
<td>4</td>
<td>0.000</td>
<td>0.000</td>
<td>0.000</td>
<td>0.000</td>
<td>sre_compile.py:25(_identityfunction)</td>
</tr>
<tr>
<td>3/1</td>
<td>0.000</td>
<td>0.000</td>
<td>0.000</td>
<td>0.000</td>
<td>sre_compile.py:33(_compile)</td>
</tr>
</tbody>
</table>

The first line indicates that 197 calls were monitored. Of those calls, 192 were primitive, meaning that the call was not induced via recursion. The next line: Ordered by: standard name, indicates that the text string in the far right column was used to sort the output. The column headings include:

ncalls for the number of calls.

tottime for the total time spent in the given function (and excluding time made in calls to sub-functions)

percall is the quotient of tottime divided by ncalls

cumtime is the cumulative time spent in this and all subfunctions (from invocation till exit). This figure is accurate even for recursive functions.

percall is the quotient of cumtime divided by primitive calls

filename:lineno(function) provides the respective data of each function

When there are two numbers in the first column (for example 3/1), it means that the function recursed. The second value is the number of primitive calls and the former is the total number of calls. Note that when the function does not recurse, these two values are the same, and only the single figure is printed.

Instead of printing the output at the end of the profile run, you can save the results to a file by specifying a filename to the run() function:

```python
import cProfile
import re
cProfile.run('re.compile("foo|bar"), 'restats')
```

The `pstats.Stats` class reads profile results from a file and formats them in various ways. The files `cProfile` and `profile` can also be invoked as a script to profile another script. For example:

```bash
python -m cProfile [-o output_file] [-s sort_order] [-m module | myscript.py]
```

- `-o` writes the profile results to a file instead of to stdout
- `-s` specifies one of the `sort_stats()` sort values to sort the output by. This only applies when `-o` is not supplied.
- `-m` specifies that a module is being profiled instead of a script.

New in version 3.7: Added the `-m` option to `cProfile`.

New in version 3.8: Added the `-m` option to `profile`.

The `pstats` module's `Stats` class has a variety of methods for manipulating and printing the data saved into a profile results file:

```python
import pstats
from pstats import SortKey
p = pstats.Stats('restats')
p.strip_dirs().sort_stats(-1).print_stats()
```
The `strip_dirs()` method removed the extraneous path from all the module names. The `sort_stats()` method sorted all the entries according to the standard module/line/name string that is printed. The `print_stats()` method printed out all the statistics. You might try the following sort calls:

```python
p.sort_stats(SortKey.NAME)
p.print_stats()
```

The first call will actually sort the list by function name, and the second call will print out the statistics. The following are some interesting calls to experiment with:

```python
p.sort_stats(SortKey.CUMULATIVE).print_stats(10)
```

This sorts the profile by cumulative time in a function, and then only prints the ten most significant lines. If you want to understand what algorithms are taking time, the above line is what you would use.

If you were looking to see what functions were looping a lot, and taking a lot of time, you would do:

```python
p.sort_stats(SortKey.TIME).print_stats(10)
```

to sort according to time spent within each function, and then print the statistics for the top ten functions.

You might also try:

```python
p.sort_stats(SortKey.FILENAME).print_stats('__init__')
```

This will sort all the statistics by file name, and then print out statistics for only the class init methods (since they are spelled with `__init__` in them). As one final example, you could try:

```python
p.sort_stats(SortKey.TIME, SortKey.CUMULATIVE).print_stats(.5, 'init')
```

This line sorts statistics with a primary key of time, and a secondary key of cumulative time, and then prints out some of the statistics. To be specific, the list is first culled down to 50% (re: .5) of its original size, then only lines containing `init` are maintained, and that sub-sub-list is printed.

If you wondered what functions called the above functions, you could now (p is still sorted according to the last criteria) do:

```python
p.print_callers(.5, 'init')
```

and you would get a list of callers for each of the listed functions.

If you want more functionality, you’re going to have to read the manual, or guess what the following functions do:

```python
p.print_callees()
p.add('restats')
```

Invoked as a script, the `pstats` module is a statistics browser for reading and examining profile dumps. It has a simple line-oriented interface (implemented using `cmd`) and interactive help.

### 27.5.3 profile and cProfile Module Reference

Both the `profile` and `cProfile` modules provide the following functions:

```python
profile.run(command, filename=None, sort=-1)
```

This function takes a single argument that can be passed to the `exec()` function, and an optional file name. In all cases this routine executes:

```python
exec(command, __main__.__dict__, __main__.__dict__)
```

and gathers profiling statistics from the execution. If no file name is present, then this function automatically creates a `Stats` instance and prints a simple profiling report. If the sort value is specified, it is passed to this `Stats` instance to control how the results are sorted.
profile.runctx(command, globals, locals, filename=None, sort=-1)

This function is similar to run(), with added arguments to supply the globals and locals dictionaries for the command string. This routine executes:

```python
eval(command, globals, locals)
```

and gathers profiling statistics as in the run() function above.

class profile.Profile (timer=None, timeunit=0.0, subcalls=True, builtins=True)

This class is normally only used if more precise control over profiling is needed than what the cProfile.run() function provides.

A custom timer can be supplied for measuring how long code takes to run via the timer argument. This must be a function that returns a single number representing the current time. If the number is an integer, the timeunit specifies a multiplier that specifies the duration of each unit of time. For example, if the timer returns times measured in thousands of seconds, the time unit would be .001.

Directly using the Profile class allows formatting profile results without writing the profile data to a file:

```python
import cProfile, pstats, io
from pstats import SortKey
pr = cProfile.Profile()
pr.enable()
# ... do something ...
pr.disable()
s = io.StringIO()
sortby = SortKey.CUMULATIVE
ps = pstats.Stats(pr, stream=s).sort_stats(sortby)
ps.print_stats()
print(s.getvalue())
```

The Profile class can also be used as a context manager (supported only in cProfile module. see Context Manager Types):

```python
import cProfile

with cProfile.Profile() as pr:
    # ... do something ...
pr.print_stats()
```

Changed in version 3.8: Added context manager support.

enable ()

Start collecting profiling data. Only in cProfile.

disable ()

Stop collecting profiling data. Only in cProfile.

create_stats ()

Stop collecting profiling data and record the results internally as the current profile.

print_stats (sort=-1)

Create a Stats object based on the current profile and print the results to stdout.

dump_stats (filename)

Write the results of the current profile to filename.

run (cmd)

Profile the cmd via exec().

runctx (cmd, globals, locals)

Profile the cmd via exec() with the specified global and local environment.

runcall (func, /, *args, **kwargs)

Profile func(*args, **kwargs)
Note that profiling will only work if the called command/function actually returns. If the interpreter is terminated (e.g. via a `sys.exit()` call during the called command/function execution) no profiling results will be printed.

27.5.4 The Stats Class

Analysis of the profiler data is done using the `Stats` class.

```python
class pstats.Stats(*filenames or profile, stream=sys.stdout)
```

This class constructor creates an instance of a “statistics object” from a `filename` (or list of filenames) or from a `Profile` instance. Output will be printed to the stream specified by `stream`.

The file selected by the above constructor must have been created by the corresponding version of `profile` or `cProfile`. To be specific, there is no file compatibility guaranteed with future versions of this profiler, and there is no compatibility with files produced by other profilers, or the same profiler run on a different operating system. If several files are provided, all the statistics for identical functions will be coalesced, so that an overall view of several processes can be considered in a single report. If additional files need to be combined with data in an existing `Stats` object, the `add()` method can be used.

Instead of reading the profile data from a file, a `cProfile.Profile` or `profile.Profile` object can be used as the profile data source.

`Stats` objects have the following methods:

- **`strip_dirs()`**
  
  This method for the `Stats` class removes all leading path information from file names. It is very useful in reducing the size of the printout to fit within (close to) 80 columns. This method modifies the object, and the stripped information is lost. After performing a strip operation, the object is considered to have its entries in a “random” order, as it was just after object initialization and loading. If `strip_dirs()` causes two function names to be indistinguishable (they are on the same line of the same filename, and have the same function name), then the statistics for these two entries are accumulated into a single entry.

- **`add(*filenames)`**
  
  This method of the `Stats` class accumulates additional profiling information into the current profiling object. Its arguments should refer to filenames created by the corresponding version of `profile.run()` or `cProfile.run()`. Statistics for identically named (re: file, line, name) functions are automatically accumulated into single function statistics.

- **`dump_stats(filename)`**
  
  Save the data loaded into the `Stats` object to a file named `filename`. The file is created if it does not exist, and is overwritten if it already exists. This is equivalent to the method of the same name on the `profile.Profile` and `cProfile.Profile` classes.

- **`sort_stats(*keys)`**
  
  This method modifies the `Stats` object by sorting it according to the supplied criteria. The argument can be either a string or a SortKey enum identifying the basis of a sort (example: `'time', 'name', SortKey.TIME or SortKey.NAME). The SortKey enums argument have advantage over the string argument in that it is more robust and less error prone.

  When more than one key is provided, then additional keys are used as secondary criteria when there is equality in all keys selected before them. For example, `sort_stats(SortKey.NAME, SortKey.FILE)` will sort all the entries according to their function name, and resolve all ties (identical function names) by sorting by file name.

  For the string argument, abbreviations can be used for any key names, as long as the abbreviation is unambiguous.

  The following are the valid string and SortKey:
Valid String Arg | Valid enum Arg       | Meaning
---|-------------------|------------------
'calls'  | SortKey.CALLS     | call count
'cumulative' | SortKey.CUMULATIVE | cumulative time
'cumtime' | N/A               | cumulative time
'file'    | N/A               | file name
'filename' | SortKey.FILENAME  | file name
'module'  | N/A               | file name
'ncalls'  | N/A               | call count
'pcalls'  | SortKey.PCALLS    | primitive call count
'line'    | SortKey.LINE      | line number
'name'    | SortKey.NAME      | function name
'nfl'     | SortKey.NFL       | name/file/line
'stdname' | SortKey.STDNAME   | standard name
'time'    | SortKey.TIME      | internal time
'tottime' | N/A               | internal time

Note that all sorts on statistics are in descending order (placing most time consuming items first), where as name, file, and line number searches are in ascending order (alphabetical). The subtle distinction between SortKey.NFL and SortKey.STDNAME is that the standard name is a sort of the name as printed, which means that the embedded line numbers get compared in an odd way. For example, lines 3, 20, and 40 would (if the file names were the same) appear in the string order 20, 3 and 40. In contrast, SortKey.NFL does a numeric compare of the line numbers. In fact, sort_stats(SortKey.NFL) is the same as sort_stats(SortKey.NAME, SortKey.FILENAME, SortKey.LINE).

For backward-compatibility reasons, the numeric arguments -1, 0, 1, and 2 are permitted. They are interpreted as 'stdname', 'calls', 'time', and 'cumulative' respectively. If this old style format (numeric) is used, only one sort key (the numeric key) will be used, and additional arguments will be silently ignored.

New in version 3.7: Added the SortKey enum.

reverse_order ()
This method for the Stats class reverses the ordering of the basic list within the object. Note that by default ascending vs descending order is properly selected based on the sort key of choice.

print_stats (*restrictions)
This method for the Stats class prints out a report as described in the profile.run() definition.

The order of the printing is based on the last sort_stats() operation done on the object (subject to caveats in add() and strip_dirs()).

The arguments provided (if any) can be used to limit the list down to the significant entries. Initially, the list is taken to be the complete set of profiled functions. Each restriction is either an integer (to select a count of lines), or a decimal fraction between 0.0 and 1.0 inclusive (to select a percentage of lines), or a string that will interpreted as a regular expression (to pattern match the standard name that is printed). If several restrictions are provided, then they are applied sequentially. For example:

```python
print_stats(.1, 'foo:')
```

would first limit the printing to first 10% of list, and then only print functions that were part of filename .*foo:. In contrast, the command:

```python
print_stats('foo:', .1)
```

would list the file to all functions having file names .*foo:, and then proceed to only print the first 10% of them.

print_callers (*restrictions)
This method for the Stats class prints a list of all functions that called each function in the profiled database. The ordering is identical to that provided by print_stats(), and the definition of the
restricting argument is also identical. Each caller is reported on its own line. The format differs slightly depending on the profiler that produced the stats:

- With `profile`, a number is shown in parentheses after each caller to show how many times this specific call was made. For convenience, a second non-parenthesized number repeats the cumulative time spent in the function at the right.
- With `cProfile`, each caller is preceded by three numbers: the number of times this specific call was made, and the total and cumulative times spent in the current function while it was invoked by this specific caller.

```
print_callees(*restrictions)
```

This method for the `Stats` class prints a list of all function that were called by the indicated function. Aside from this reversal of direction of calls (re: called vs was called by), the arguments and ordering are identical to the `print_callers()` method.

```
get_stats_profile()
```

This method returns an instance of StatsProfile, which contains a mapping of function names to instances of FunctionProfile. Each FunctionProfile instance holds information related to the function's profile such as how long the function took to run, how many times it was called, etc…

New in version 3.9: Added the following dataclasses: StatsProfile, FunctionProfile. Added the following function: `get_stats_profile`.

### 27.5.5 What Is Deterministic Profiling?

Deterministic profiling is meant to reflect the fact that all function call, function return, and exception events are monitored, and precise timings are made for the intervals between these events (during which time the user’s code is executing). In contrast, statistical profiling (which is not done by this module) randomly samples the effective instruction pointer, and deduces where time is being spent. The latter technique traditionally involves less overhead (as the code does not need to be instrumented), but provides only relative indications of where time is being spent.

In Python, since there is an interpreter active during execution, the presence of instrumented code is not required in order to do deterministic profiling. Python automatically provides a hook (optional callback) for each event. In addition, the interpreted nature of Python tends to add so much overhead to execution, that deterministic profiling tends to only add small processing overhead in typical applications. The result is that deterministic profiling is not that expensive, yet provides extensive run time statistics about the execution of a Python program.

Call count statistics can be used to identify bugs in code (surprising counts), and to identify possible inline-expansion points (high call counts). Internal time statistics can be used to identify “hot loops” that should be carefully optimized. Cumulative time statistics should be used to identify high level errors in the selection of algorithms. Note that the unusual handling of cumulative times in this profiler allows statistics for recursive implementations of algorithms to be directly compared to iterative implementations.

### 27.5.6 Limitations

One limitation has to do with accuracy of timing information. There is a fundamental problem with deterministic profilers involving accuracy. The most obvious restriction is that the underlying “clock” is only ticking at a rate (typically) of about .001 seconds. Hence no measurements will be more accurate than the underlying clock. If enough measurements are taken, then the “error” will tend to average out. Unfortunately, removing this first error induces a second source of error.

The second problem is that it “takes a while” from when an event is dispatched until the profiler’s call to get the time actually gets the state of the clock. Similarly, there is a certain lag when exiting the profiler event handler from the time that the clock’s value was obtained (and then squreiled away), until the user’s code is once again executing. As a result, functions that are called many times, or call many functions, will typically accumulate this error. The error that accumulates in this fashion is typically less than the accuracy of the clock (less than one clock tick), but it can accumulate and become very significant.

The problem is more important with `profile` than with the lower-overhead `cProfile`. For this reason, `profile` provides a means of calibrating itself for a given platform so that this error can be probabilistically (on the
average) removed. After the profiler is calibrated, it will be more accurate (in a least square sense), but it will sometimes produce negative numbers (when call counts are exceptionally low, and the gods of probability work against you :-). ) Do not be alarmed by negative numbers in the profile. They should only appear if you have calibrated your profiler, and the results are actually better than without calibration.

27.5.7 Calibration

The profiler of the profile module subtracts a constant from each event handling time to compensate for the overhead of calling the time function, and socking away the results. By default, the constant is 0. The following procedure can be used to obtain a better constant for a given platform (see Limitations).

```python
import profile
pr = profile.Profile()
for i in range(5):
    print(pr.calibrate(10000))
```

The method executes the number of Python calls given by the argument, directly and again under the profiler, measuring the time for both. It then computes the hidden overhead per profiler event, and returns that as a float. For example, on a 1.8Ghz Intel Core i5 running macOS, and using Python's time.process_time() as the timer, the magical number is about 4.04e-6.

The object of this exercise is to get a fairly consistent result. If your computer is very fast, or your timer function has poor resolution, you might have to pass 100000, or even 1000000, to get consistent results.

When you have a consistent answer, there are three ways you can use it:

```python
import profile

# 1. Apply computed bias to all Profile instances created hereafter.
profile.Profile.bias = your_computed_bias

# 2. Apply computed bias to a specific Profile instance.
pr = profile.Profile()
pr.bias = your_computed_bias

# 3. Specify computed bias in instance constructor.
pr = profile.Profile(bias=your_computed_bias)
```

If you have a choice, you are better off choosing a smaller constant, and then your results will “less often” show up as negative in profile statistics.

27.5.8 Using a custom timer

If you want to change how current time is determined (for example, to force use of wall-clock time or elapsed process time), pass the timing function you want to the Profile class constructor:

```python
pr = profile.Profile(your_time_func)
```

The resulting profiler will then call your_time_func. Depending on whether you are using profile.Profile or cProfile.Profile, your_time_func's return value will be interpreted differently:

profile.Profile your_time_func should return a single number, or a list of numbers whose sum is the current time (like what os.times() returns). If the function returns a single time number, or the list of returned numbers has length 2, then you will get an especially fast version of the dispatch routine.

Be warned that you should calibrate the profiler class for the timer function that you choose (see Calibration). For most machines, a timer that returns a lone integer value will provide the best results in terms of low overhead during profiling. (os.times() is pretty bad, as it returns a tuple of floating point values). If you want to substitute a better timer in the cleanest fashion, derive a class and hardwire a replacement dispatch method that best handles your timer call, along with the appropriate calibration constant.
cProfile.Profile your_time_func should return a single number. If it returns integers, you can also invoke the class constructor with a second argument specifying the real duration of one unit of time. For example, if your_integer_time_func returns times measured in thousands of seconds, you would construct the Profile instance as follows:

```python
pr = cProfile.Profile(your_integer_time_func, 0.001)
```

As the cProfile.Profile class cannot be calibrated, custom timer functions should be used with care and should be as fast as possible. For the best results with a custom timer, it might be necessary to hard-code it in the C source of the internal _lsprof module.

Python 3.3 adds several new functions in time that can be used to make precise measurements of process or wall-clock time. For example, see time.perf_counter().

### 27.6 timeit — Measure execution time of small code snippets

**Source code:** Lib/timeit.py

This module provides a simple way to time small bits of Python code. It has both a Command-Line Interface as well as a callable one. It avoids a number of common traps for measuring execution times. See also Tim Peters’ introduction to the “Algorithms” chapter in the second edition of *Python Cookbook*, published by O’Reilly.

#### 27.6.1 Basic Examples

The following example shows how the Command-Line Interface can be used to compare three different expressions:

```
$ python3 -m timeit '"-.join(str(n) for n in range(100))'  
10000 loops, best of 5: 30.2 usec per loop
$ python3 -m timeit '"-.join([str(n) for n in range(100)])'  
10000 loops, best of 5: 27.5 usec per loop
$ python3 -m timeit '"-.join(map(str, range(100)))'  
10000 loops, best of 5: 23.2 usec per loop
```

This can be achieved from the Python Interface with:

```
>>> import timeit
>>> timeit.timeit('"-.join(str(n) for n in range(100))"', number=10000)
0.3018611848820001
>>> timeit.timeit('"-.join([str(n) for n in range(100)])"', number=10000)
0.2727368790656328
>>> timeit.timeit('"-.join(map(str, range(100)))"', number=10000)
0.23702679807320237
```

A callable can also be passed from the Python Interface:

```
>>> timeit.timeit(lambda: '"-.join(map(str, range(100)))"', number=10000)
0.19665591977536678
```

Note however that timeit() will automatically determine the number of repetitions only when the command-line interface is used. In the Examples section you can find more advanced examples.
27.6.2 Python Interface

The module defines three convenience functions and a public class:

```python
timeit.timeit(stmt='pass', setup='pass', timer=<default timer>, number=1000000, globals=None)
```

Create a `Timer` instance with the given statement, setup code and timer function and run its `timeit()` method with `number` executions. The optional `globals` argument specifies a namespace in which to execute the code.

Changed in version 3.5: The optional `globals` parameter was added.

```python
timeit.repeat(stmt='pass', setup='pass', timer=<default timer>, repeat=5, number=1000000, globals=None)
```

Create a `Timer` instance with the given statement, setup code and timer function and run its `repeat()` method with the given `repeat` count and `number` executions. The optional `globals` argument specifies a namespace in which to execute the code.

Changed in version 3.5: The optional `globals` parameter was added.

Changed in version 3.7: Default value of `repeat` changed from 3 to 5.

```python
timeit.default_timer()
```

The default timer, which is always `time.perf_counter()`.

Changed in version 3.3: `time.perf_counter()` is now the default timer.

```python
class timeit.Timer(stmt='pass', setup='pass', timer=<timer function>, globals=None)
```

Class for timing execution speed of small code snippets.

The constructor takes a statement to be timed, an additional statement used for setup, and a timer function. Both statements default to `'pass'`; the timer function is platform-dependent (see the module doc string). `stmt` and `setup` may also contain multiple statements separated by `;` or newlines, as long as they don’t contain multi-line string literals. The statement will by default be executed within `timeit`’s namespace; this behavior can be controlled by passing a namespace to `globals`.

To measure the execution time of the first statement, use the `timeit()` method. The `repeat()` and `autorange()` methods are convenience methods to call `timeit()` multiple times.

The execution time of `setup` is excluded from the overall timed execution run.

The `stmt` and `setup` parameters can also take objects that are callable without arguments. This will embed calls to them in a timer function that will then be executed by `timeit()`. Note that the timing overhead is a little larger in this case because of the extra function calls.

Changed in version 3.5: The optional `globals` parameter was added.

```python
timeit(number=1000000)
```

Time `number` executions of the main statement. This executes the setup statement once, and then returns the time it takes to execute the main statement a number of times, measured in seconds as a float. The argument is the number of times through the loop, defaulting to one million. The main statement, the setup statement and the timer function to be used are passed to the constructor.

Note: By default, `timeit()` temporarily turns off garbage collection during the timing. The advantage of this approach is that it makes independent timings more comparable. The disadvantage is that GC may be an important component of the performance of the function being measured. If so, GC can be re-enabled as the first statement in the `setup` string. For example:

```python
timeit.Timer('for i in range(10): oct(i)', 'gc.enable()').timeit()
```

```python
timeit.autorange(callback=None)
```

Automatically determine how many times to call `timeit()`.

This is a convenience function that calls `timeit()` repeatedly so that the total time >= 0.2 second, returning the eventual (number of loops, time taken for that number of loops). It calls `timeit()` with increasing numbers from the sequence 1, 2, 5, 10, 20, 50, … until the time taken is at least 0.2 second.
If `callback` is given and is not `None`, it will be called after each trial with two arguments: `callback(number, time_taken)`.

New in version 3.6.

**repeat** *(repeat=5, number=1000000)*

Call `timeit()` a few times.

This is a convenience function that calls the `timeit()` repeatedly, returning a list of results. The first argument specifies how many times to call `timeit()`. The second argument specifies the `number` argument for `timeit()`.

---

**Note:** It’s tempting to calculate mean and standard deviation from the result vector and report these. However, this is not very useful. In a typical case, the lowest value gives a lower bound for how fast your machine can run the given code snippet; higher values in the result vector are typically not caused by variability in Python’s speed, but by other processes interfering with your timing accuracy. So the `min()` of the result is probably the only number you should be interested in. After that, you should look at the entire vector and apply common sense rather than statistics.

Changed in version 3.7: Default value of `repeat` changed from 3 to 5.

**print_exc** *(file=None)*

Helper to print a traceback from the timed code.

Typical use:

```python

t = Timer(...)  # outside the try/except
try:
t.timeit(...)  # or t.repeat(...)
except Exception:
t.print_exc()
```

The advantage over the standard traceback is that source lines in the compiled template will be displayed. The optional `file` argument directs where the traceback is sent; it defaults to `sys.stderr`.

---

### 27.6.3 Command-Line Interface

When called as a program from the command line, the following form is used:

```
python -m timeit [-n N] [-r N] [-u U] [-s S] [-h] [statement ...]
```

Where the following options are understood:

- **-n N, --number=N**
  how many times to execute ‘statement’

- **-r N, --repeat=N**
  how many times to repeat the timer (default 5)

- **-s S, --setup=S**
  statement to be executed once initially (default `pass`)

- **-p, --process**
  measure process time, not wallclock time, using `time.process_time()` instead of `time.perf_counter()`, which is the default

  New in version 3.3.

- **-u, --unit=U**
  specify a time unit for timer output; can select nsec, usec, msec, or sec

  New in version 3.5.
-v, --verbose
    print raw timing results; repeat for more digits precision

-h, --help
    print a short usage message and exit

A multi-line statement may be given by specifying each line as a separate statement argument; indented lines are
possible by enclosing an argument in quotes and using leading spaces. Multiple -s options are treated similarly.

If -n is not given, a suitable number of loops is calculated by trying increasing numbers from the sequence 1, 2, 5,
10, 20, 50, ... until the total time is at least 0.2 seconds.

default_timer() measurements can be affected by other programs running on the same machine, so the best
ting is necessary to repeat the timing a few times and use the best time. The -r option is
good for this; the default of 5 repetitions is probably enough in most cases. You can use time.process_time()
to measure CPU time.

Note: There is a certain baseline overhead associated with executing a pass statement. The code here doesn't try
to hide it, but you should be aware of it. The baseline overhead can be measured by invoking the program without
arguments, and it might differ between Python versions.

27.6.4 Examples

It is possible to provide a setup statement that is executed only once at the beginning:

```bash
$ python -m timeit -s 'text = "sample string"; char = "g"' 'char in text'
5000000 loops, best of 5: 0.0877 usec per loop
$ python -m timeit -s 'text = "sample string"; char = "g"' 'text.find(char)'
1000000 loops, best of 5: 0.342 usec per loop
```

In the output, there are three fields. The loop count, which tells you how many times the statement body was run per
timing loop repetition. The repetition count ('best of 5') which tells you how many times the timing loop was
repeated, and finally the time the statement body took on average within the best repetition of the timing loop. That
is, the time the fastest repetition took divided by the loop count.

```
>>> import timeit
>>> timeit.timeit('char in text', setup='text = "sample string"; char = "g"')
0.41440500499993504
>>> timeit.timeit('text.find(char)', setup='text = "sample string"; char = "g"')
1.7246671520006203
```

The same can be done using the Timer class and its methods:

```
>>> import timeit
>>> t = timeit.Timer('char in text', setup='text = "sample string"; char = "g"')
>>> t.timeit()
0.3955516149999312
>>> t.repeat()
[0.40183617287970225, 0.37027556854118704, 0.3834867356679524, 0.3712595970846668, 0.37866875250654886]
```

The following examples show how to time expressions that contain multiple lines. Here we compare the cost of using
hasattr() vs. try/except to test for missing and present object attributes:

```
$ python -m timeit 'try:' str.__bool__' except AttributeError:' 'pass'
20000 loops, best of 5: 15.7 usec per loop
$ python -m timeit 'if hasattr(str, "__bool__"):' pass'
50000 loops, best of 5: 4.26 usec per loop
```

(continues on next page)
To give the timeit module access to functions you define, you can pass a setup parameter which contains an import statement:

```python
def test():
    """Stupid test function""
    L = [i for i in range(100)]

if __name__ == '__main__':
    import timeit
    print(timeit.timeit("test()", setup="from __main__ import test"))
```

Another option is to pass globals() to the globals parameter, which will cause the code to be executed within your current global namespace. This can be more convenient than individually specifying imports:

```python
def f(x):
    return x**2
def g(x):
    return x**4
def h(x):
    return x**8

import timeit
print(timeit.timeit('[func(42) for func in (f,g,h)]', globals=globals()))
```
27.7 trace — Trace or track Python statement execution

Source code: Lib/trace.py

The `trace` module allows you to trace program execution, generate annotated statement coverage listings, print caller/callee relationships and list functions executed during a program run. It can be used in another program or from the command line.

See also:

Coverage.py A popular third-party coverage tool that provides HTML output along with advanced features such as branch coverage.

27.7.1 Command-Line Usage

The `trace` module can be invoked from the command line. It can be as simple as

```
python -m trace --count -C somefile.py ...
```

The above will execute `somefile.py` and generate annotated listings of all Python modules imported during the execution into the current directory.

--help
Display usage and exit.

--version
Display the version of the module and exit.

New in version 3.8: Added `--module` option that allows to run an executable module.

Main options

At least one of the following options must be specified when invoking `trace`. The `--listfuncs` option is mutually exclusive with the `--trace` and `--count` options. When `--listfuncs` is provided, neither `--count` nor `--trace` are accepted, and vice versa.

-c, --count
Produce a set of annotated listing files upon program completion that shows how many times each statement was executed. See also `--coverdir`, `--file` and `--no-report` below.

-t, --trace
Display lines as they are executed.

-l, --listfuncs
Display the functions executed by running the program.

-r, --report
Produce an annotated list from an earlier program run that used the `--count` and `--file` option. This does not execute any code.

-T, --trackcalls
Display the calling relationships exposed by running the program.
Modifiers

-f, --file=<file>
Name of a file to accumulate counts over several tracing runs. Should be used with the --count option.

-C, --coverdir=<dir>
Directory where the report files go. The coverage report for package.module is written to file dir/package/module.cover.

-m, --missing
When generating annotated listings, mark lines which were not executed with >>>>>>>.

-s, --summary
When using --count or --report, write a brief summary to stderr for each file processed.

-R, --no-report
Do not generate annotated listings. This is useful if you intend to make several runs with --count, and then produce a single set of annotated listings at the end.

-g, --timing
Prefix each line with the time since the program started. Only used while tracing.

Filters

These options may be repeated multiple times.

--ignore-module=<mod>
Ignore each of the given module names and its submodules (if it is a package). The argument can be a list of names separated by a comma.

--ignore-dir=<dir>
Ignore all modules and packages in the named directory and subdirectories. The argument can be a list of directories separated by os.pathsep.

27.7.2 Programmatic Interface

class trace.Trace(count=1, trace=1, countfuncs=0, countcallers=0, ignoremods=(), ignoredirs=(),
infile=None, outfile=None, timing=False)
Create an object to trace execution of a single statement or expression. All parameters are optional. count enables counting of line numbers. trace enables line execution tracing. countfuncs enables listing of the functions called during the run. countcallers enables call relationship tracking. ignoremods is a list of modules or packages to ignore. ignoredirs is a list of directories whose modules or packages should be ignored. infile is the name of the file from which to read stored count information. outfile is the name of the file in which to write updated count information. timing enables a timestamp relative to when tracing was started to be displayed.

run(cmd)
Execute the command and gather statistics from the execution with the current tracing parameters. cmd must be a string or code object, suitable for passing into exec().

runcxt(cmd, globals=None, locals=None)
Execute the command and gather statistics from the execution with the current tracing parameters, in the defined global and local environments. If not defined, globals and locals default to empty dictionaries.

runfunc(func, /, *args, **kwds)
Call func with the given arguments under control of the Trace object with the current tracing parameters.

results()
Return a CoverageResults object that contains the cumulative results of all previous calls to run, runcxt and runfunc for the given Trace instance. Does not reset the accumulated trace results.
class `trace.CoverageResults`
A container for coverage results, created by `Trace.results()`. Should not be created directly by the user.

```
update(other)
    Merge in data from another CoverageResults object.
```

```
write_results(show_missing=True, summary=False, coverdir=None)
    Write coverage results. Set `show_missing` to show lines that had no hits. Set `summary` to include in the output the coverage summary per module. `coverdir` specifies the directory into which the coverage result files will be output. If `None`, the results for each source file are placed in its directory.
```

A simple example demonstrating the use of the programmatic interface:

```
import sys
import trace

# create a Trace object, telling it what to ignore, and whether to
# do tracing or line-counting or both.
tracer = trace.Trace(
    ignoredirs=[sys.prefix, sys.exec_prefix],
    trace=0,
    count=1)

# run the new command using the given tracer
tracer.run('main()')

# make a report, placing output in the current directory
r = tracer.results()
r.write_results(show_missing=True, coverdir="")
```

## 27.8 tracemalloc — Trace memory allocations

New in version 3.4.

**Source code:** Lib/tracemalloc.py

The tracemalloc module is a debug tool to trace memory blocks allocated by Python. It provides the following information:

- Traceback where an object was allocated
- Statistics on allocated memory blocks per filename and per line number: total size, number and average size of allocated memory blocks
- Compute the differences between two snapshots to detect memory leaks

To trace most memory blocks allocated by Python, the module should be started as early as possible by setting the `PYTHONTRACEMALLOC` environment variable to 1, or by using `-X tracemalloc` command line option. The `tracemalloc.start()` function can be called at runtime to start tracing Python memory allocations.

By default, a trace of an allocated memory block only stores the most recent frame (1 frame). To store 25 frames at startup: set the `PYTHONTRACEMALLOC` environment variable to 25, or use the `-X tracemalloc=25` command line option.
27.8.1 Examples

Display the top 10

Display the 10 files allocating the most memory:

```python
import tracemalloc
tracemalloc.start()
# ... run your application ...
snapshot = tracemalloc.take_snapshot()
top_stats = snapshot.statistics('lineno')
print("[ Top 10 ]")
for stat in top_stats[:10]:
    print(stat)
```

Example of output of the Python test suite:

```
[ Top 10 ]
<frozen importlib._bootstrap>:716: size=4855 KiB, count=39328, average=126 B
<frozen importlib._bootstrap>:284: size=521 KiB, count=3199, average=167 B
/usr/lib/python3.4/collections/__init__.py:368: size=244 KiB, count=2315,
    → average=108 B
/usr/lib/python3.4/unittest/case.py:381: size=185 KiB, count=779, average=243 B
/usr/lib/python3.4/abc.py:133: size=88.7 KiB, count=347, average=262 B
<frozen importlib._bootstrap>:1446: size=70.4 KiB, count=911, average=79 B
<frozen importlib._bootstrap>:1454: size=52.0 KiB, count=25, average=2131 B
<string>:5: size=49.7 KiB, count=148, average=344 B
/usr/lib/python3.4/sysconfig.py:411: size=48.0 KiB, count=1, average=48.0 KiB
```

We can see that Python loaded 4855 KiB data (bytecode and constants) from modules and that the collections module allocated 244 KiB to build namedtuple types.

See `Snapshot.statistics()` for more options.

Compute differences

Take two snapshots and display the differences:

```python
import tracemalloc
tracemalloc.start()
# ... start your application ...
snapshot1 = tracemalloc.take_snapshot()
# ... call the function leaking memory ...
snapshot2 = tracemalloc.take_snapshot()
top_stats = snapshot2.compare_to(snapshot1, 'lineno')
print("[ Top 10 differences ]")
for stat in top_stats[:10]:
    print(stat)
```

Example of output before/after running some tests of the Python test suite:

```
[ Top 10 differences ]
<frozen importlib._bootstrap>:716: size=8173 KiB (+4428 KiB), count=71332 (+39369),
    average=117 B
```

(continues on next page)
We can see that Python has loaded 8173 KiB of module data (bytecode and constants), and that this is 4428 KiB more than had been loaded before the tests, when the previous snapshot was taken. Similarly, the linecache module has cached 940 KiB of Python source code to format traceback, all of it since the previous snapshot.

If the system has little free memory, snapshots can be written on disk using the `Snapshot.dump()` method to analyze the snapshot offline. Then use the `Snapshot.load()` method reload the snapshot.

### Get the traceback of a memory block

Code to display the traceback of the biggest memory block:

```
import tracemalloc

# Store 25 frames
tracemalloc.start(25)

# ... run your application ...

snapshot = tracemalloc.take_snapshot()
top_stats = snapshot.statistics('traceback')

# pick the biggest memory block
stat = top_stats[0]
print('%.2f memory blocks: %.1f KiB % (stat.count, stat.size / 1024))
for line in stat.traceback.format():
    print(line)
```

Example of output of the Python test suite (traceback limited to 25 frames):

```
903 memory blocks: 870.1 KiB
File "<frozen importlib._bootstrap>" line 716
File "<frozen importlib._bootstrap>" line 1036
File "<frozen importlib._bootstrap>" line 934
File "<frozen importlib._bootstrap>" line 1068
File "<frozen importlib._bootstrap>" line 619
File "<frozen importlib._bootstrap>" line 1581
File "<frozen importlib._bootstrap>" line 1614
File "/usr/lib/python3.4/doctest.py" line 101
  import pdb
File "<frozen importlib._bootstrap>" line 284
File "<frozen importlib._bootstrap>" line 938
```
We can see that the most memory was allocated in the `importlib` module to load data (bytecode and constants) from modules: 870.1 KiB. The traceback is where the `importlib` loaded data most recently: on the `import pdb` line of the `doctest` module. The traceback may change if a new module is loaded.

### Pretty top

Code to display the 10 lines allocating the most memory with a pretty output, ignoring `<frozen importlib._bootstrap>` and `<unknown>` files:

```python
import linecache
import os
import tracemalloc
def display_top(snapshot, key_type='lineno', limit=10):
    snapshot = snapshot.filter_traces(
        (tracemalloc.Filter(False, '<frozen importlib._bootstrap>'),),
        (tracemalloc.Filter(False, '<unknown>'),),
    )
    top_stats = snapshot.statistics(key_type)
    print("Top %s lines" % limit)
    for index, stat in enumerate(top_stats[:limit], 1):
        frame = stat.traceback[0]
        line = linecache.getline(frame.filename, frame.lineno).strip()
        print("%s: %s: %.1f KiB" % (index, frame.filename, frame.lineno, stat.size / 1024))
        if line:
            print("  %s" % line)
    other = top_stats[limit:]
    if other:
        size = sum(stat.size for stat in other)
        print("Other: %.1f KiB (%.1f%%)")
    total = sum(stat.size for stat in top_stats)
    print("Total allocated size: %.1f KiB")
tracemalloc.start()
```

(continues on next page)
# ... run your application ...

```python
snapshot = tracemalloc.take_snapshot()
display_top(snapshot)
```

Example of output of the Python test suite:

<table>
<thead>
<tr>
<th>#1: Lib/base64.py:414</th>
<th>419.8 KiB</th>
</tr>
</thead>
<tbody>
<tr>
<td>_b85chars2 = [(a + b) for a in _b85chars for b in _b85chars]</td>

See `Snapshot.statistics()` for more options.

**Record the current and peak size of all traced memory blocks**

The following code computes two sums like $0 + 1 + 2 + \ldots$ inefficiently, by creating a list of those numbers. This list consumes a lot of memory temporarily. We can use `get_traced_memory()` and `reset_peak()` to observe the small memory usage after the sum is computed as well as the peak memory usage during the computations:

```python
import tracemalloc

tracemalloc.start()

# Example code: compute a sum with a large temporary list
large_sum = sum(list(range(100000)))

first_size, first_peak = tracemalloc.get_traced_memory()
tracemalloc.reset_peak()

# Example code: compute a sum with a small temporary list
small_sum = sum(list(range(1000)))

second_size, second_peak = tracemalloc.get_traced_memory()

print(f"first_size={first_size}, first_peak={first_peak}")
print(f"second_size={second_size}, second_peak={second_peak}")
```

Output:
first_size=664, first_peak=3592984
second_size=804, second_peak=29704

Using `reset_peak()` ensured we could accurately record the peak during the computation of `small_sum`, even though it is much smaller than the overall peak size of memory blocks since the `start()` call. Without the call to `reset_peak()`, `second_peak` would still be the peak from the computation of `large_sum` (that is, equal to `first_peak`). In this case, both peaks are much higher than the final memory usage, and which suggests we could optimise (by removing the unnecessary call to `list`, and writing `sum(range(...))`).

### 27.8.2 API

#### Functions

- `tracemalloc.clear_traces()`  
  Clear traces of memory blocks allocated by Python.
  
  See also `stop()`.

- `tracemalloc.get_object_traceback(obj)`  
  Get the traceback where the Python object `obj` was allocated. Return a `Traceback` instance, or `None` if the `tracemalloc` module is not tracing memory allocations or did not trace the allocation of the object.
  
  See also `gc.get_referrers()` and `sys.getsizeof()` functions.

- `tracemalloc.get_traceback_limit()`  
  Get the maximum number of frames stored in the traceback of a trace.
  
  The `tracemalloc` module must be tracing memory allocations to get the limit, otherwise an exception is raised.
  
  The limit is set by the `start()` function.

- `tracemalloc.get_traced_memory()`  
  Get the current size and peak size of memory blocks traced by the `tracemalloc` module as a tuple: `current: int, peak: int`.

- `tracemalloc.reset_peak()`  
  Set the peak size of memory blocks traced by the `tracemalloc` module to the current size.
  
  Do nothing if the `tracemalloc` module is not tracing memory allocations.
  
  This function only modifies the recorded peak size, and does not modify or clear any traces, unlike `clear_traces()`. Snapshots taken with `take_snapshot()` before a call to `reset_peak()` can be meaningfully compared to snapshots taken after the call.
  
  See also `get_traced_memory()`.

  New in version 3.9.

- `tracemalloc.get_tracemalloc_memory()`  
  Get the memory usage in bytes of the `tracemalloc` module used to store traces of memory blocks. Return an `int`.

- `tracemalloc.is_tracing()`  
  True if the `tracemalloc` module is tracing Python memory allocations, `False` otherwise.
  
  See also `start()` and `stop()` functions.

- `tracemalloc.start(nframe: int = 1)`  
  Start tracing Python memory allocations: install hooks on Python memory allocators. Collected tracebacks of traces will be limited to `nframe` frames. By default, a trace of a memory block only stores the most recent frame: the limit is 1. `nframe` must be greater or equal to 1.
  
  You can still read the original number of total frames that composed the traceback by looking at the `Traceback.total_nframe` attribute.

---

**27.8. tracemalloc — Trace memory allocations**
Storing more than 1 frame is only useful to compute statistics grouped by 'traceback' or to compute cumulative statistics: see the `Snapshot.compare_to()` and `Snapshot.statistics()` methods.

Storing more frames increases the memory and CPU overhead of the `tracemalloc` module. Use the `get_tracemalloc_memory()` function to measure how much memory is used by the `tracemalloc` module.

The `PYTHONTRACEMALLOC` environment variable (`PYTHONTRACEMALLOC=NFRAME`) and the `-X tracemalloc=nframe` command line option can be used to start tracing at startup.

See also `stop()`, `is_tracing()` and `get_traceback_limit()` functions.

```python
tracemalloc.stop()
```

Stop tracing Python memory allocations: uninstall hooks on Python memory allocators. Also clears all previously collected traces of memory blocks allocated by Python.

Call `take_snapshot()` function to take a snapshot of traces before clearing them.

See also `start()`, `is_tracing()` and `clear_traces()` functions.

```python
tracemalloc.take_snapshot()
```

Take a snapshot of traces of memory blocks allocated by Python. Return a new `Snapshot` instance.

The snapshot does not include memory blocks allocated before the `tracemalloc` module started to trace memory allocations.

Tracebacks of traces are limited to `get_traceback_limit()` frames. Use the `nframe` parameter of the `start()` function to store more frames.

The `tracemalloc` module must be tracing memory allocations to take a snapshot, see the `start()` function.

See also the `get_object_traceback()` function.

**DomainFilter**

```python
class tracemalloc.DomainFilter (inclusive: bool, domain: int)
```

Filter traces of memory blocks by their address space (domain).

New in version 3.6.

- **inclusive**
  
  If `inclusive` is True (include), match memory blocks allocated in the address space `domain`.

  If `inclusive` is False (exclude), match memory blocks not allocated in the address space `domain`.

- **domain**
  
  Address space of a memory block (int). Read-only property.

**Filter**

```python
class tracemalloc.Filter (inclusive: bool, filename_pattern: str, lineno: int = None, all_frames: bool = False, domain: int = None)
```

Filter on traces of memory blocks.

See the `fnmatch.fnmatch()` function for the syntax of `filename_pattern`. The `.pyc` file extension is replaced with `.py`.

Examples:

- Filter(True, subprocess.__file__) only includes traces of the `subprocess` module
- Filter(False, tracemalloc.__file__) excludes traces of the `tracemalloc` module
- Filter(False, "<unknown>") excludes empty tracebacks
Changed in version 3.5: The '.pyo' file extension is no longer replaced with '.py'.

Changed in version 3.6: Added the `domain` attribute.

**domain**
Address space of a memory block (int or None).
tracemalloc uses the domain 0 to trace memory allocations made by Python. C extensions can use other domains to trace other resources.

**inclusive**
If `inclusive` is True (include), only match memory blocks allocated in a file with a name matching `filename_pattern` at line number `lineno`.

If `inclusive` is False (exclude), ignore memory blocks allocated in a file with a name matching `filename_pattern` at line number `lineno`.

**lineno**
Line number (int) of the filter. If `lineno` is None, the filter matches any line number.

**filename_pattern**
Filename pattern of the filter (str). Read-only property.

**all_frames**
If `all_frames` is True, all frames of the traceback are checked. If `all_frames` is False, only the most recent frame is checked.

This attribute has no effect if the traceback limit is 1. See the `get_traceback_limit()` function and `Snapshot.traceback_limit` attribute.

**Frame**

class tracemalloc.Frame
Frame of a traceback.

The `Traceback` class is a sequence of `Frame` instances.

**filename**
Filename (str).

**lineno**
Line number (int).

**Snapshot**

class tracemalloc.Snapshot
Snapshot of traces of memory blocks allocated by Python.

The `take_snapshot()` function creates a snapshot instance.

**compare_to**(old_snapshot: Snapshot, key_type: str, cumulative: bool = False)
Compute the differences with an old snapshot. Get statistics as a sorted list of `StatisticDiff` instances grouped by `key_type`.

See the `Snapshot.statistics()` method for `key_type` and `cumulative` parameters.

The result is sorted from the biggest to the smallest by: absolute value of `StatisticDiff.size_diff`, `StatisticDiff.size`, absolute value of `StatisticDiff.count_diff`, `StatisticDiff.count` and then by `StatisticDiff.traceback`.

**dump**(filename)
Write the snapshot into a file.

Use `load()` to reload the snapshot.
**filter_traces** (*filters*)
Create a new `Snapshot` instance with a filtered `traces` sequence. `filters` is a list of `DomainFilter` and `Filter` instances. If `filters` is an empty list, return a new `Snapshot` instance with a copy of the traces.

All inclusive filters are applied at once, a trace is ignored if no inclusive filters match it. A trace is ignored if at least one exclusive filter matches it.

Changed in version 3.6: `DomainFilter` instances are now also accepted in `filters`.

**classmethod load** (*filename*)
Load a snapshot from a file.

See also `dump()`.

**statistics** (*key_type: str, cumulative: bool = False*)
Get statistics as a sorted list of `Statistic` instances grouped by `key_type`.

<table>
<thead>
<tr>
<th>key_type</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>'filename'</td>
<td>filename</td>
</tr>
<tr>
<td>'lineno'</td>
<td>filename and line number</td>
</tr>
<tr>
<td>'traceback'</td>
<td>traceback</td>
</tr>
</tbody>
</table>

If `cumulative` is True, cumulate size and count of memory blocks of all frames of the traceback of a trace, not only the most recent frame. The cumulative mode can only be used with `key_type` equals to 'filename' and 'lineno'.

The result is sorted from the biggest to the smallest by: `Statistic.size, Statistic.count` and then by `Statistic.traceback`.

**traceback_limit**
Maximum number of frames stored in the traceback of `traces`: result of the `get_traceback_limit()` when the snapshot was taken.

**traces**
Traces of all memory blocks allocated by Python: sequence of `Trace` instances.

The sequence has an undefined order. Use the `Snapshot.statistics()` method to get a sorted list of statistics.

**Statistic**

**class** `tracemalloc.Statistic`
Statistic on memory allocations.

`Snapshot.statistics()` returns a list of `Statistic` instances.

See also the `StatisticDiff` class.

**count**
Number of memory blocks (int).

**size**
Total size of memory blocks in bytes (int).

**traceback**
Traceback where the memory block was allocated, `Traceback` instance.
The Python Library Reference, Release 3.10.4

StatisticDiff

class tracemalloc.StatisticDiff
Statistic difference on memory allocations between an old and a new Snapshot instance.

Snapshot.compare_to() returns a list of StatisticDiff instances. See also the Statistic class.

count
Number of memory blocks in the new snapshot (int): 0 if the memory blocks have been released in the new snapshot.

count_diff
Difference of number of memory blocks between the old and the new snapshots (int): 0 if the memory blocks have been allocated in the new snapshot.

size
Total size of memory blocks in bytes in the new snapshot (int): 0 if the memory blocks have been released in the new snapshot.

size_diff
Difference of total size of memory blocks in bytes between the old and the new snapshots (int): 0 if the memory blocks have been allocated in the new snapshot.

traceback
Traceback where the memory blocks were allocated, Traceback instance.

Trace

class tracemalloc.Trace
Trace of a memory block.

The Snapshot.traces attribute is a sequence of Trace instances.

Changed in version 3.6: Added the domain attribute.

domain
Address space of a memory block (int). Read-only property.

tracemalloc uses the domain 0 to trace memory allocations made by Python. C extensions can use other domains to trace other resources.

size
Size of the memory block in bytes (int).

traceback
Traceback where the memory blocks were allocated, Traceback instance.

Traceback

class tracemalloc.Traceback
Sequence of Frame instances sorted from the oldest frame to the most recent frame.

A traceback contains at least 1 frame. If the tracemalloc module failed to get a frame, the filename ":<unknown>" at line number 0 is used.

When a snapshot is taken, tracebacks of traces are limited to get_traceback_limit() frames. See the take_snapshot() function. The original number of frames of the traceback is stored in the Traceback.total_nframe attribute. That allows to know if a traceback has been truncated by the traceback limit.

The Trace.traceback attribute is an instance of Traceback instance.

Changed in version 3.7: Frames are now sorted from the oldest to the most recent, instead of most recent to oldest.
total_nframe
Total number of frames that composed the traceback before truncation. This attribute can be set to None if the information is not available.

Changed in version 3.9: The Traceback.total_nframe attribute was added.

format(limit=None, most_recent_first=False)
Format the traceback as a list of lines. Use the linecache module to retrieve lines from the source code. If limit is set, format the limit most recent frames if limit is positive. Otherwise, format the abs(limit) oldest frames. If most_recent_first is True, the order of the formatted frames is reversed, returning the most recent frame first instead of last.

Similar to the traceback.format_tb() function, except that format() does not include newlines.

Example:

```python
print("Traceback (most recent call first):")
for line in traceback:
    print(line)
```

Output:

```
Traceback (most recent call first):
  File "test.py", line 9
      obj = Object()
  File "test.py", line 12
      tb = tracemalloc.get_object_traceback(f())
```
These libraries help you with publishing and installing Python software. While these modules are designed to work in conjunction with the Python Package Index, they can also be used with a local index server, or without any index server at all.

28.1 distutils — Building and installing Python modules

`distutils` is deprecated with removal planned for Python 3.12. See the What’s New entry for more information.

The `distutils` package provides support for building and installing additional modules into a Python installation. The new modules may be either 100%-pure Python, or may be extension modules written in C, or may be collections of Python packages which include modules coded in both Python and C.

Most Python users will not want to use this module directly, but instead use the cross-version tools maintained by the Python Packaging Authority. In particular, `setuptools` is an enhanced alternative to `distutils` that provides:

- support for declaring project dependencies
- additional mechanisms for configuring which files to include in source releases (including plugins for integration with version control systems)
- the ability to declare project “entry points”, which can be used as the basis for application plugin systems
- the ability to automatically generate Windows command line executables at installation time rather than needing to prebuild them
- consistent behaviour across all supported Python versions

The recommended `pip` installer runs all `setup.py` scripts with `setuptools`, even if the script itself only imports `distutils`. Refer to the Python Packaging User Guide for more information.

For the benefits of packaging tool authors and users seeking a deeper understanding of the details of the current packaging and distribution system, the legacy `distutils` based user documentation and API reference remain available:

- install-index
- distutils-index
28.2 ensurepip — Bootstrapping the pip installer

New in version 3.4.

The ensurepip package provides support for bootstrapping the pip installer into an existing Python installation or virtual environment. This bootstrapping approach reflects the fact that pip is an independent project with its own release cycle, and the latest available stable version is bundled with maintenance and feature releases of the CPython reference interpreter.

In most cases, end users of Python shouldn’t need to invoke this module directly (as pip should be bootstrapped by default), but it may be needed if installing pip was skipped when installing Python (or when creating a virtual environment) or after explicitly un installing pip.

Note: This module does not access the internet. All of the components needed to bootstrap pip are included as internal parts of the package.

See also:
installing-index The end user guide for installing Python packages
PEP 453: Explicit bootstrapping of pip in Python installations The original rationale and specification for this module.

28.2.1 Command line interface

The command line interface is invoked using the interpreter’s -m switch.

The simplest possible invocation is:

```
python -m ensurepip
```

This invocation will install pip if it is not already installed, but otherwise does nothing. To ensure the installed version of pip is at least as recent as the one available in ensurepip, pass the --upgrade option:

```
python -m ensurepip --upgrade
```

By default, pip is installed into the current virtual environment (if one is active) or into the system site packages (if there is no active virtual environment). The installation location can be controlled through two additional command line options:

- `--root <dir>`: Installs pip relative to the given root directory rather than the root of the currently active virtual environment (if any) or the default root for the current Python installation.
- `--user`: Installs pip into the user site packages directory rather than globally for the current Python installation (this option is not permitted inside an active virtual environment).

By default, the scripts pipX and pipX.Y will be installed (where X.Y stands for the version of Python used to invoke ensurepip). The scripts installed can be controlled through two additional command line options:

- `--altinstall`: if an alternate installation is requested, the pipX script will not be installed.
- `--default-pip`: if a “default pip” installation is requested, the pip script will be installed in addition to the two regular scripts.

Providing both of the script selection options will trigger an exception.
28.2.2 Module API

`ensurepip` exposes two functions for programmatic use:

`ensurepip.version()`
Returns a string specifying the available version of pip that will be installed when bootstrapping an environment.

`ensurepip.bootstrap(root=None, upgrade=False, user=False, altinstall=False, default_pip=False, verbosity=0)`
Bootsrap `pip` into the current or designated environment.

- `root` specifies an alternative root directory to install relative to. If `root` is `None`, then installation uses the default install location for the current environment.
- `upgrade` indicates whether or not to upgrade an existing installation of an earlier version of `pip` to the available version.
- `user` indicates whether to use the user scheme rather than installing globally.

By default, the scripts `pipX` and `pipX.Y` will be installed (where `X.Y` stands for the current version of Python).

If `altinstall` is set, then `pipX` will *not* be installed.

If `default_pip` is set, then `pip` will be installed in addition to the two regular scripts.

Setting both `altinstall` and `default_pip` will trigger `ValueError`.

`verbosity` controls the level of output to `sys.stdout` from the bootstrapping operation.

Raises an auditing event `ensurepip.bootstrap` with argument `root`.

**Note:** The bootstrapping process has side effects on both `sys.path` and `os.environ`. Invoking the command line interface in a subprocess instead allows these side effects to be avoided.

**Note:** The bootstrapping process may install additional modules required by `pip`, but other software should not assume those dependencies will always be present by default (as the dependencies may be removed in a future version of `pip`).

28.3 `venv` — Creation of virtual environments

New in version 3.3.

**Source code:** `Lib/venv/`

The `venv` module provides support for creating lightweight “virtual environments” with their own site directories, optionally isolated from system site directories. Each virtual environment has its own Python binary (which matches the version of the binary that was used to create this environment) and can have its own independent set of installed Python packages in its site directories.

See PEP 405 for more information about Python virtual environments.

**See also:**

Python Packaging User Guide: Creating and using virtual environments
28.3.1 Creating virtual environments

Creation of virtual environments is done by executing the command `venv`:

```
python3 -m venv /path/to/new/virtual/environment
```

Running this command creates the target directory (creating any parent directories that don’t exist already) and places a `pyvenv.cfg` file in it with a `home` key pointing to the Python installation from which the command was run (a common name for the target directory is `.venv`). It also creates a `bin` (or `Scripts` on Windows) subdirectory containing a copy/symlink of the Python binary/binaries (as appropriate for the platform or arguments used at environment creation time). It also creates an (initially empty) `lib/pythonX.Y/site-packages` subdirectory (on Windows, this is `Lib/site-packages`). If an existing directory is specified, it will be re-used.

Deprecated since version 3.6: `pyvenv` was the recommended tool for creating virtual environments for Python 3.3 and 3.4, and is deprecated in Python 3.6.

Changed in version 3.5: The use of `venv` is now recommended for creating virtual environments.

On Windows, invoke the `venv` command as follows:

```
c:\> c:\Python35\python -m venv c:\path\to\myenv
```

Alternatively, if you configured the `PATH` and `PATHEXT` variables for your Python installation:

```
c:\> python -m venv c:\path\to\myenv
```

The command, if run with `-h`, will show the available options:

```
usage: venv [-h] [--system-site-packages] [--symlinks | --copies] [--clear]
            ENV_DIR [ENV_DIR ...]

Creates virtual Python environments in one or more target directories.

positional arguments:
  ENV_DIR A directory to create the environment in.

optional arguments:
  -h, --help     show this help message and exit
  --system-site-packages
                 Give the virtual environment access to the system
                 site-packages dir.
  --symlinks     Try to use symlinks rather than copies, when symlinks
                 are not the default for the platform.
  --copies       Try to use copies rather than symlinks, even when
                 symlinks are the default for the platform.
  --clear        Delete the contents of the environment directory if it
                 already exists, before environment creation.
  --upgrade      Upgrade the environment directory to use this version
                 of Python, assuming Python has been upgraded in-place.
  --without-pip  Skips installing or upgrading pip in the virtual
                 environment (pip is bootstrapped by default)
  --prompt PROMPT Provides an alternative prompt prefix for this
                 environment.
  --upgrade-deps Upgrade core dependencies: pip setuptools to the
                 latest version in PyPI
```

Once an environment has been created, you may wish to activate it, e.g. by sourcing an activate script in its bin directory.

Changed in version 3.9: Add `--upgrade-deps` option to upgrade pip + setuptools to the latest on PyPI

Changed in version 3.4: Installs pip by default, added the `--without-pip` and `--copies` options
Changed in version 3.4: In earlier versions, if the target directory already existed, an error was raised, unless the --clear or --upgrade option was provided.

**Note:** While symlinks are supported on Windows, they are not recommended. Of particular note is that double-clicking python.exe in File Explorer will resolve the symlink eagerly and ignore the virtual environment.

**Note:** On Microsoft Windows, it may be required to enable the `Activate.ps1` script by setting the execution policy for the user. You can do this by issuing the following PowerShell command:

```
```

See About Execution Policies for more information.

The created `pyvenv.cfg` file also includes the `include-system-site-packages` key, set to `true` if `venv` is run with the `--system-site-packages` option, false otherwise.

Unless the `--without-pip` option is given, `ensurepip` will be invoked to bootstrap `pip` into the virtual environment.

Multiple paths can be given to `venv`, in which case an identical virtual environment will be created, according to the given options, at each provided path.

Once a virtual environment has been created, it can be “activated” using a script in the virtual environment's binary directory. The invocation of the script is platform-specific (`<venv>` must be replaced by the path of the directory containing the virtual environment):

<table>
<thead>
<tr>
<th>Platform</th>
<th>Shell</th>
<th>Command to activate virtual environment</th>
</tr>
</thead>
<tbody>
<tr>
<td>POSIX</td>
<td>bash/zsh</td>
<td>$ source &lt;venv&gt;/bin/activate</td>
</tr>
<tr>
<td></td>
<td>fish</td>
<td>$ source &lt;venv&gt;/bin/activate.fish</td>
</tr>
<tr>
<td></td>
<td>csh/tcsh</td>
<td>$ source &lt;venv&gt;/bin/activate.csh</td>
</tr>
<tr>
<td>PowerShell Core</td>
<td>PowerShe</td>
<td>$ &lt;venv&gt;/bin/Activate.ps1</td>
</tr>
<tr>
<td>Windows</td>
<td>cmd.exe</td>
<td>C:&gt; &lt;venv&gt;\Scripts\Activate.bat</td>
</tr>
<tr>
<td></td>
<td>PowerShell</td>
<td>PS C:&gt; &lt;venv&gt;\Scripts\Activate.ps1</td>
</tr>
</tbody>
</table>

When a virtual environment is active, the `VIRTUAL_ENV` environment variable is set to the path of the virtual environment. This can be used to check if one is running inside a virtual environment.

You don’t specifically need to activate an environment; activation just prepends the virtual environment’s binary directory to your path, so that “python” invokes the virtual environment’s Python interpreter and you can run installed scripts without having to use their full path. However, all scripts installed in a virtual environment should be runnable without activating it, and run with the virtual environment’s Python automatically.

You can deactivate a virtual environment by typing “deactivate” in your shell. The exact mechanism is platform-specific and is an internal implementation detail (typically a script or shell function will be used).

New in version 3.4: fish and csh activation scripts.

New in version 3.8: PowerShell activation scripts installed under POSIX for PowerShell Core support.

**Note:** A virtual environment is a Python environment such that the Python interpreter, libraries and scripts installed into it are isolated from those installed in other virtual environments, and (by default) any libraries installed in a “system” Python, i.e., one which is installed as part of your operating system.

A virtual environment is a directory tree which contains Python executable files and other files which indicate that it is a virtual environment.

Common installation tools such as setuptools and pip work as expected with virtual environments. In other words, when a virtual environment is active, they install Python packages into the virtual environment without needing to be told to do so explicitly.
When a virtual environment is active (i.e., the virtual environment’s Python interpreter is running), the attributes `sys.prefix` and `sys.exec_prefix` point to the base directory of the virtual environment, whereas `sys.base_prefix` and `sys.base_exec_prefix` point to the non-virtual environment Python installation which was used to create the virtual environment. If a virtual environment is not active, then `sys.prefix` is the same as `sys.base_prefix` and `sys.exec_prefix` is the same as `sys.base_exec_prefix` (they all point to a non-virtual environment Python installation).

When a virtual environment is active, any options that change the installation path will be ignored from all `distutils` configuration files to prevent projects being inadvertently installed outside of the virtual environment.

When working in a command shell, users can make a virtual environment active by running an `activate` script in the virtual environment’s executables directory (the precise filename and command to use the file is shell-dependent), which prepends the virtual environment’s directory for executables to the `PATH` environment variable for the running shell. There should be no need in other circumstances to activate a virtual environment; scripts installed into virtual environments have a “shebang” line which points to the virtual environment’s Python interpreter. This means that the script will run with that interpreter regardless of the value of `PATH`. On Windows, “shebang” line processing is supported if you have the Python Launcher for Windows installed (this was added to Python in 3.3 - see PEP 397 for more details). Thus, double-clicking an installed script in a Windows Explorer window should run the script with the correct interpreter without there needing to be any reference to its virtual environment in `PATH`.

### 28.3.2 API

The high-level method described above makes use of a simple API which provides mechanisms for third-party virtual environment creators to customize environment creation according to their needs, the `EnvBuilder` class.

```python
class venv.EnvBuilder (system_site_packages=False, clear=False, symlinks=False, upgrade=False, with_pip=False, prompt=None, upgrade_deps=False)
```

The `EnvBuilder` class accepts the following keyword arguments on instantiation:

- `system_site_packages` – a Boolean value indicating that the system Python site-packages should be available to the environment (defaults to `False`).
- `clear` – a Boolean value which, if true, will delete the contents of any existing target directory, before creating the environment.
- `symlinks` – a Boolean value indicating whether to attempt to symlink the Python binary rather than copying.
- `upgrade` – a Boolean value which, if true, will upgrade an existing environment with the running Python - for use when that Python has been upgraded in-place (defaults to `False`).
- `with_pip` – a Boolean value which, if true, ensures pip is installed in the virtual environment. This uses `ensurepip` with the `--default-pip` option.
- `prompt` – a String to be used after virtual environment is activated (defaults to `None` which means directory name of the environment would be used). If the special string "." is provided, the basename of the current directory is used as the prompt.
- `upgrade_deps` – Update the base venv modules to the latest on PyPI

Changed in version 3.4: Added the `with_pip` parameter

New in version 3.6: Added the `prompt` parameter

New in version 3.9: Added the `upgrade_deps` parameter

Creators of third-party virtual environment tools will be free to use the provided `EnvBuilder` class as a base class.

The returned env-builder is an object which has a method, `create`:

```python
create (env_dir)
```

Create a virtual environment by specifying the target directory (absolute or relative to the current direc-
The `create` method of the `EnvBuilder` class illustrates the hooks available for subclass customization:

```python
def create(self, env_dir):
    """
    Create a virtualized Python environment in a directory.
    env_dir is the target directory to create an environment in.
    """
    env_dir = os.path.abspath(env_dir)
    context = self.ensure_directories(env_dir)
    self.create_configuration(context)
    self.setup_python(context)
    self.setup_scripts(context)
    self.post_setup(context)
```

Each of the methods `ensure_directories()`, `create_configuration()`, `setup_python()`, `setup_scripts()` and `post_setup()` can be overridden.

**ensure_directories**(env_dir)

Creates the environment directory and all necessary directories, and returns a context object. This is just a holder for attributes (such as paths), for use by the other methods. The directories are allowed to exist already, as long as either `clear` or `upgrade` were specified to allow operating on an existing environment directory.

**create_configuration**(context)

Creates the `pyvenv.cfg` configuration file in the environment.

**setup_python**(context)

Creates a copy or symlink to the Python executable in the environment. On POSIX systems, if a specific executable `python3.x` was used, symlinks to `python` and `python3` will be created pointing to that executable, unless files with those names already exist.

**setup_scripts**(context)

Installs activation scripts appropriate to the platform into the virtual environment.

**upgrade_dependencies**(context)

Upgrades the core venv dependency packages (currently `pip` and `setuptools`) in the environment. This is done by shelling out to the `pip` executable in the environment.

New in version 3.9.

**post_setup**(context)

A placeholder method which can be overridden in third party implementations to pre-install packages in the virtual environment or perform other post-creation steps.

Changed in version 3.7.2: Windows now uses redirector scripts for `python[w].exe` instead of copying the actual binaries. In 3.7.2 only `setup_python()` does nothing unless running from a build in the source tree.

Changed in version 3.7.3: Windows copies the redirector scripts as part of `setup_python()` instead of `setup_scripts()`. This was not the case in 3.7.2. When using symlinks, the original executables will be linked.

In addition, `EnvBuilder` provides this utility method that can be called from `setup_scripts()` or `post_setup()` in subclasses to assist in installing custom scripts into the virtual environment.

**install_scripts**(context, path)

`path` is the path to a directory that should contain subdirectories “common”, “posix”, “nt”, each containing scripts destined for the bin directory in the environment. The contents of “common” and the directory corresponding to `os.name` are copied after some text replacement of placeholders:

- `__VENV_DIR__` is replaced with the absolute path of the environment directory.
The directories are allowed to exist (for when an existing environment is being upgraded).

There is also a module-level convenience function:

```python
venv.create(env_dir, system_site_packages=False, clear=False, symlinks=False, with_pip=False, prompt=None, upgrade_deps=False)
```

Create an `EnvBuilder` with the given keyword arguments, and call its `create()` method with the `env_dir` argument.

New in version 3.3.

Changed in version 3.4: Added the `with_pip` parameter

Changed in version 3.6: Added the `prompt` parameter

Changed in version 3.9: Added the `upgrade_deps` parameter

### 28.3.3 An example of extending `EnvBuilder`

The following script shows how to extend `EnvBuilder` by implementing a subclass which installs setuptools and pip into a created virtual environment:

```python
import os
import os.path
from subprocess import Popen, PIPE
import sys
from threading import Thread
from urllib.parse import urlparse
from urllib.request import urlretrieve
import venv

class ExtendedEnvBuilder(venv.EnvBuilder):
    
    """
    This builder installs setuptools and pip so that you can pip or
    easy_install other packages into the created virtual environment.
    
    :param nodist: If true, setuptools and pip are not installed into the
    created virtual environment.
    :param nopip: If true, pip is not installed into the created
    virtual environment.
    :param progress: If setuptools or pip are installed, the progress of the
    installation can be monitored by passing a progress
    callable. If specified, it is called with two
    arguments: a string indicating some progress, and a
    context indicating where the string is coming from.
    The context argument can have one of three values:
    'main', indicating that it is called from virtualize()
    itself, and 'stdout' and 'stderr', which are obtained
    by reading lines from the output streams of a subprocess
    which is used to install the app.
    
    If a callable is not specified, default progress
    information is output to sys.stderr.
    """
```

(continues on next page)
def __init__(self, *args, **kwargs):
    self.nodist = kwargs.pop('nodist', False)
    self.nopip = kwargs.pop('nopip', False)
    self.progress = kwargs.pop('progress', None)
    self.verbose = kwargs.pop('verbose', False)
    super().__init__(*args, **kwargs)

def post_setup(self, context):
    """Set up any packages which need to be pre-installed into
    the virtual environment being created.
    """
    os.environ['VIRTUAL_ENV'] = context.env_dir
    if not self.nodist:
        self.install_setuptools(context)
    # Can't install pip without setuptools
    if not self.nopip and not self.nodist:
        self.install_pip(context)

def reader(self, stream, context):
    """Read lines from a subprocess' output stream and either pass to a progress
    callable (if specified) or write progress information to sys.stderr.
    """
    progress = self.progress
    while True:
        s = stream.readline()
        if not s:
            break
        if progress is not None:
            progress(s, context)
        else:
            if not self.verbose:
                sys.stderr.write('.')
            else:
                sys.stderr.write(s.decode('utf-8'))
                sys.stderr.flush()
        stream.close()

def install_script(self, context, name, url):
    _, _, path, _, _, _ = urlparse(url)

This script is also available for download online.
28.4 zipapp — Manage executable Python zip archives

New in version 3.5.

Source code: Lib/zipapp.py

This module provides tools to manage the creation of zip files containing Python code, which can be executed directly by the Python interpreter. The module provides both a Command-Line Interface and a Python API.

28.4.1 Basic Example

The following example shows how the Command-Line Interface can be used to create an executable archive from a directory containing Python code. When run, the archive will execute the main function from the module myapp in the archive.

```bash
$ python -m zipapp myapp -m "myapp:main"
$ python myapp.pyz
<output from myapp>
```

28.4.2 Command-Line Interface

When called as a program from the command line, the following form is used:

```bash
$ python -m zipapp source [options]
```

If source is a directory, this will create an archive from the contents of source. If source is a file, it should be an archive, and it will be copied to the target archive (or the contents of its shebang line will be displayed if the –info option is specified).

The following options are understood:

- **-o**, **--output**
  Write the output to a file named output. If this option is not specified, the output filename will be the same as the input source, with the extension .pyz added. If an explicit filename is given, it is used as is (so a .pyz extension should be included if required).
  An output filename must be specified if the source is an archive (and in that case, output must not be the same as source).

- **-p**, **--python**
  Add a #! line to the archive specifying interpreter as the command to run. Also, on POSIX, make the archive executable. The default is to write no #! line, and not make the file executable.

- **-m**, **--main**
  Write a __main__.py file to the archive that executes mainfn. The mainfn argument should have the form “pkg.mod:fn”, where “pkg.mod” is a package/module in the archive, and “fn” is a callable in the given module. The __main__.py file will execute that callable.
  --main cannot be specified when copying an archive.

- **-c**, **--compress**
  Compress files with the deflate method, reducing the size of the output file. By default, files are stored uncompressed in the archive.
  --compress has no effect when copying an archive.

New in version 3.7.
--info
  Display the interpreter embedded in the archive, for diagnostic purposes. In this case, any other options are
  ignored and SOURCE must be an archive, not a directory.

-h, --help
  Print a short usage message and exit.

28.4.3 Python API

The module defines two convenience functions:

```python
zipapp.create_archive(source, target=None, interpreter=None, main=None, filter=None, compressed=False)
```

Create an application archive from `source`. The source can be any of the following:

- The name of a directory, or a `path-like object` referring to a directory, in which case a new application
  archive will be created from the content of that directory.
- The name of an existing application archive file, or a `path-like object` referring to such a file, in which case
  the file is copied to the target (modifying it to reflect the value given for the `interpreter` argument). The
  file name should include the `.pyz` extension, if required.
- A file object open for reading in bytes mode. The content of the file should be an application archive, and
  the file object is assumed to be positioned at the start of the archive.

The `target` argument determines where the resulting archive will be written:

- If it is the name of a file, or a `path-like object`, the archive will be written to that file.
- If it is an open file object, the archive will be written to that file object, which must be open for writing
  in bytes mode.
- If the target is omitted (or `None`), the source must be a directory and the target will be a file with the
  same name as the source, with a `.pyz` extension added.

The `interpreter` argument specifies the name of the Python interpreter with which the archive will be executed.
It is written as a “shebang” line at the start of the archive. On POSIX, this will be interpreted by the OS, and
on Windows it will be handled by the Python launcher. Omitting the `interpreter` results in no shebang line being
written. If an interpreter is specified, and the target is a filename, the executable bit of the target file will be
set.

The `main` argument specifies the name of a callable which will be used as the main program for the archive.
It can only be specified if the source is a directory, and the source does not already contain a `__main__.py` file.
The `main` argument should take the form “pkg.module:callable” and the archive will be run by importing
“pkg.module” and executing the given callable with no arguments. It is an error to omit `main` if the source
is a directory and does not contain a `__main__.py` file, as otherwise the resulting archive would not be executable.

The optional `filter` argument specifies a callback function that is passed a Path object representing the path to
the file being added (relative to the source directory). It should return `True` if the file is to be added.

The optional `compressed` argument determines whether files are compressed. If set to `True`, files in the archive
are compressed with the deflate method; otherwise, files are stored uncompressed. This argument has no effect
when copying an existing archive.

If a file object is specified for `source` or `target`, it is the caller’s responsibility to close it after calling `create_archive`.

When copying an existing archive, file objects supplied only need `read` and `readline`, or `write` methods.
When creating an archive from a directory, if the target is a file object it will be passed to the `zipfile.ZipFile` class,
and must supply the methods needed by that class.

New in version 3.7: Added the `filter` and `compressed` arguments.
zipapp.get_interpreter(archive)

Return the interpreter specified in the `#!` line at the start of the archive. If there is no `#!` line, return None. The `archive` argument can be a filename or a file-like object open for reading in bytes mode. It is assumed to be at the start of the archive.

### 28.4.4 Examples

Pack up a directory into an archive, and run it.

```
$ python -m zipapp myapp
$ python myapp.pyz
<output from myapp>
```

The same can be done using the `create_archive()` function:

```python
>>> import zipapp
>>> zipapp.create_archive('myapp', 'myapp.pyz')
```

To make the application directly executable on POSIX, specify an interpreter to use.

```
$ python -m zipapp myapp -p "/usr/bin/env python"
$ ./myapp.pyz
<output from myapp>
```

To replace the shebang line on an existing archive, create a modified archive using the `create_archive()` function:

```python
>>> import zipapp
>>> zipapp.create_archive('old_archive.pyz', 'new_archive.pyz', '/usr/bin/python3')
```

To update the file in place, do the replacement in memory using a `BytesIO` object, and then overwrite the source afterwards. Note that there is a risk when overwriting a file in place that an error will result in the loss of the original file. This code does not protect against such errors, but production code should do so. Also, this method will only work if the archive fits in memory:

```python
>>> import zipapp
>>> import io
>>> temp = io.BytesIO()
>>> zipapp.create_archive('myapp.pyz', temp, '/usr/bin/python2')
>>> with open('myapp.pyz', 'wb') as f:
...    f.write(temp.getvalue())
```

### 28.4.5 Specifying the Interpreter

Note that if you specify an interpreter and then distribute your application archive, you need to ensure that the interpreter used is portable. The Python launcher for Windows supports most common forms of POSIX `#!` line, but there are other issues to consider:

- If you use "/usr/bin/env python" (or other forms of the "python" command, such as "/usr/bin/python"), you need to consider that your users may have either Python 2 or Python 3 as their default, and write your code to work under both versions.
- If you use an explicit version, for example "/usr/bin/env python3" your application will not work for users who do not have that version. (This may be what you want if you have not made your code Python 2 compatible).
- There is no way to say "python X.Y or later", so be careful of using an exact version like "/usr/bin/env python3.4" as you will need to change your shebang line for users of Python 3.5, for example.

Typically, you should use an "/usr/bin/env python2" or "/usr/bin/env python3", depending on whether your code is written for Python 2 or 3.
28.4.6 Creating Standalone Applications with zipapp

Using the `zipapp` module, it is possible to create self-contained Python programs, which can be distributed to end users who only need to have a suitable version of Python installed on their system. The key to doing this is to bundle all of the application’s dependencies into the archive, along with the application code.

The steps to create a standalone archive are as follows:

1. Create your application in a directory as normal, so you have a `myapp` directory containing a `__main__.py` file, and any supporting application code.

2. Install all of your application’s dependencies into the `myapp` directory, using pip:

   ```
   $ python -m pip install -r requirements.txt --target myapp
   ```

   (this assumes you have your project requirements in a `requirements.txt` file - if not, you can just list the dependencies manually on the pip command line).

3. Optionally, delete the `.dist-info` directories created by pip in the `myapp` directory. These hold metadata for pip to manage the packages, and as you won’t be making any further use of pip they aren’t required - although it won’t do any harm if you leave them.

4. Package the application using:

   ```
   $ python -m zipapp -p "interpreter" myapp
   ```

This will produce a standalone executable, which can be run on any machine with the appropriate interpreter available. See Specifying the Interpreter for details. It can be shipped to users as a single file.

On Unix, the `myapp.pyz` file is executable as it stands. You can rename the file to remove the `.pyz` extension if you prefer a “plain” command name. On Windows, the `myapp.pyz[w]` file is executable by virtue of the fact that the Python interpreter registers the `.pyz` and `.pyzw` file extensions when installed.

Making a Windows executable

On Windows, registration of the `.pyz` extension is optional, and furthermore, there are certain places that don’t recognise registered extensions “transparently” (the simplest example is that `subprocess.run(['myapp'])` won’t find your application - you need to explicitly specify the extension).

On Windows, therefore, it is often preferable to create an executable from the zipapp. This is relatively easy, although it does require a C compiler. The basic approach relies on the fact that zipfiles can have arbitrary data prepended, and Windows exe files can have arbitrary data appended. So by creating a suitable launcher and tacking the `.pyz` file onto the end of it, you end up with a single-file executable that runs your application.

A suitable launcher can be as simple as the following:

```c
#define Py_LIMITED_API 1
#include "Python.h"

#define WIN32_LEAN_AND_MEAN
#include <windows.h>

#ifdef WINDOWS
int WINAPI wWinMain(
    HINSTANCE hInstance,
    /\* handle to current instance */
    HINSTANCE hPrevInstance,
    /\* handle to previous instance */
    LPWSTR lpCmdLine,
    /\* pointer to command line */
    int nCmdShow
    /\* show state of window */
)
#else
int wmain()
#endif
```

(continues on next page)
wchar_t **myargv = __alloca((__argc + 1) * sizeof(wchar_t*));
myargv[0] = __wargv[0];
memcpy(myargv + 1, __wargv, __argc * sizeof(wchar_t *));
return Py_Main(__argc+1, myargv);

If you define the WINDOWS preprocessor symbol, this will generate a GUI executable, and without it, a console executable.

To compile the executable, you can either just use the standard MSVC command line tools, or you can take advantage of the fact that distutils knows how to compile Python source:

```python
>>> from distutils.ccompiler import new_compiler
>>> import distutils.sysconfig
>>> import sys
>>> import os
>>> from pathlib import Path

>>> def compile(src):
...     src = Path(src)
...     cc = new_compiler()
...     exe = src.stem
...     cc.add_include_dir(distutils.sysconfig.get_python_inc())
...     cc.add_library_dir(os.path.join(sys.base_exec_prefix, 'libs'))
...     # First the CLI executable
...     objs = cc.compile([str(src)])
...     cc.link_executable(objs, exe)
...     # Now the GUI executable
...     cc.define_macro('WINDOWS')
...     objs = cc.compile([str(src)])
...     cc.link_executable(objs, exe + 'w')

>>> if __name__ == "__main__":
...     compile("zastub.c")
```

The resulting launcher uses the “Limited ABI”, so it will run unchanged with any version of Python 3.x. All it needs is for Python (python3.dll) to be on the user’s PATH.

For a fully standalone distribution, you can distribute the launcher with your application appended, bundled with the Python “embedded” distribution. This will run on any PC with the appropriate architecture (32 bit or 64 bit).

Caveats

There are some limitations to the process of bundling your application into a single file. In most, if not all, cases they can be addressed without needing major changes to your application.

1. If your application depends on a package that includes a C extension, that package cannot be run from a zip file (this is an OS limitation, as executable code must be present in the filesystem for the OS loader to load it). In this case, you can exclude that dependency from the zip file, and either require your users to have it installed, or ship it alongside your zip file and add code to your __main__.py to include the directory containing the unzipped module in sys.path. In this case, you will need to make sure to ship appropriate binaries for your target architecture(s) (and potentially pick the correct version to add to sys.path at runtime, based on the user’s machine).

2. If you are shipping a Windows executable as described above, you either need to ensure that your users have python3.dll on their PATH (which is not the default behaviour of the installer) or you should bundle your application with the embedded distribution.

3. The suggested launcher above uses the Python embedding API. This means that in your application, sys.executable will be your application, and not a conventional Python interpreter. Your code and its dependencies need to be prepared for this possibility. For example, if your application uses the multipro-
cessing module, it will need to call `multiprocessing.set_executable()` to let the module know where to find the standard Python interpreter.

### 28.4.7 The Python Zip Application Archive Format

Python has been able to execute zip files which contain a `__main__.py` file since version 2.6. In order to be executed by Python, an application archive simply has to be a standard zip file containing a `__main__.py` file which will be run as the entry point for the application. As usual for any Python script, the parent of the script (in this case the zip file) will be placed on `sys.path` and thus further modules can be imported from the zip file.

The zip file format allows arbitrary data to be prepended to a zip file. The zip application format uses this ability to prepend a standard POSIX “shebang” line to the file (`#!/path/to/interpreter`).

Formally, the Python zip application format is therefore:

1. An optional shebang line, containing the characters `b'#!'` followed by an interpreter name, and then a newline (`b'
') character. The interpreter name can be anything acceptable to the OS “shebang” processing, or the Python launcher on Windows. The interpreter should be encoded in UTF-8 on Windows, and in `sys.getfilesystemencoding()` on POSIX.

2. Standard zipfile data, as generated by the `zipfile` module. The zipfile content `must` include a file called `__main__.py` (which must be in the “root” of the zipfile - i.e., it cannot be in a subdirectory). The zipfile data can be compressed or uncompressed.

If an application archive has a shebang line, it may have the executable bit set on POSIX systems, to allow it to be executed directly.

There is no requirement that the tools in this module are used to create application archives - the module is a convenience, but archives in the above format created by any means are acceptable to Python.
The modules described in this chapter provide a wide range of services related to the Python interpreter and its interaction with its environment. Here’s an overview:

### 29.1 sys — System-specific parameters and functions

This module provides access to some variables used or maintained by the interpreter and to functions that interact strongly with the interpreter. It is always available.

**sys.abiflags**

On POSIX systems where Python was built with the standard `configure` script, this contains the ABI flags as specified by PEP 3149.

Changed in version 3.8: Default flags became an empty string (`m` flag for pymalloc has been removed).

New in version 3.2.

**sys.addaudithook**(hook)

Append the callable `hook` to the list of active auditing hooks for the current (sub)interpreter.

When an auditing event is raised through the `sys.audit()` function, each hook will be called in the order it was added with the event name and the tuple of arguments. Native hooks added by `PySys_AddAuditHook()` are called first, followed by hooks added in the current (sub)interpreter. Hooks can then log the event, raise an exception to abort the operation, or terminate the process entirely.

Calling `sys.addaudithook()` will itself raise an auditing event named `sys.addaudithook` with no arguments. If any existing hooks raise an exception derived from `RuntimeError`, the new hook will not be added and the exception suppressed. As a result, callers cannot assume that their hook has been added unless they control all existing hooks.

See the audit events table for all events raised by CPython, and PEP 578 for the original design discussion.

New in version 3.8.

Changed in version 3.8.1: Exceptions derived from `Exception` but not `RuntimeError` are no longer suppressed.

CPython implementation detail: When tracing is enabled (see `settrace()`), Python hooks are only traced if the callable has a `__cantrace__` member that is set to a true value. Otherwise, trace functions will skip the hook.

**sys.argv**

The list of command line arguments passed to a Python script. `argv[0]` is the script name (it is operating system dependent whether this is a full pathname or not). If the command was executed using the `-c` command line option to the interpreter, `argv[0]` is set to the string `-c`. If no script name was passed to the Python interpreter, `argv[0]` is the empty string.

To loop over the standard input, or the list of files given on the command line, see the `fileinput` module.
The Python Library Reference, Release 3.10.4

See also `sys.orig_argv`.

**Note:** On Unix, command line arguments are passed by bytes from OS. Python decodes them with filesystem encoding and “surrogateescape” error handler. When you need original bytes, you can get it by `[os.fsencode(arg) for arg in sys.argv]`.

```python
def sys.audit(event, *args):
    Raise an auditing event and trigger any active auditing hooks. `event` is a string identifying the event, and `args` may contain optional arguments with more information about the event. The number and types of arguments for a given event are considered a public and stable API and should not be modified between releases.

    For example, one auditing event is named `os.chdir`. This event has one argument called `path` that will contain the requested new working directory.

    `sys.audit()` will call the existing auditing hooks, passing the event name and arguments, and will re-raise the first exception from any hook. In general, if an exception is raised, it should not be handled and the process should be terminated as quickly as possible. This allows hook implementations to decide how to respond to particular events: they can merely log the event or abort the operation by raising an exception.

    Hooks are added using the `sys.addaudithook()` or `PySys_AddAuditHook()` functions.

    The native equivalent of this function is `PySys_Audit()`. Using the native function is preferred when possible.

    See the audit events table for all events raised by CPython.

    New in version 3.8.
```

```python
def sys.base_exec_prefix:
    Set during Python startup, before `site.py` is run, to the same value as `exec_prefix`. If not running in a virtual environment, the values will stay the same; if `site.py` finds that a virtual environment is in use, the values of `prefix` and `exec_prefix` will be changed to point to the virtual environment, whereas `base_prefix` and `base_exec_prefix` will remain pointing to the base Python installation (the one which the virtual environment was created from).

    New in version 3.3.
```

```python
def sys.base_prefix:
    Set during Python startup, before `site.py` is run, to the same value as `prefix`. If not running in a virtual environment, the values will stay the same; if `site.py` finds that a virtual environment is in use, the values of `prefix` and `exec_prefix` will be changed to point to the virtual environment, whereas `base_prefix` and `base_exec_prefix` will remain pointing to the base Python installation (the one which the virtual environment was created from).

    New in version 3.3.
```

```python
def sys.byteorder:
    An indicator of the native byte order. This will have the value 'big' on big-endian (most-significant byte first) platforms, and 'little' on little-endian (least-significant byte first) platforms.
```

```python
def sys.builtin_module_names:
    A tuple of strings containing the names of all modules that are compiled into this Python interpreter. (This information is not available in any other way — `modules.keys()` only lists the imported modules.)

    See also the `sys.stdlib_module_names` list.
```

```python
def sys.call_tracing(func, *args):
    Call `func`(*`args`), while tracing is enabled. The tracing state is saved, and restored afterwards. This is intended to be called from a debugger from a checkpoint, to recursively debug some other code.
```

```python
def sys.copyright:
    A string containing the copyright pertaining to the Python interpreter.
```
sys._clear_type_cache()
Clear the internal type cache. The type cache is used to speed up attribute and method lookups. Use the function only to drop unnecessary references during reference leak debugging.

This function should be used for internal and specialized purposes only.

sys._current_frames()
Return a dictionary mapping each thread’s identifier to the topmost stack frame currently active in that thread at the time the function is called. Note that functions in the traceback module can build the call stack given such a frame.

This is most useful for debugging deadlock: this function does not require the deadlocked threads’ cooperation, and such threads’ call stacks are frozen for as long as they remain deadlocked. The frame returned for a non-deadlocked thread may bear no relationship to that thread’s current activity by the time calling code examines the frame.

This function should be used for internal and specialized purposes only.

Raises an auditing event sys._current_frames with no arguments.

sys._current_exceptions()
Return a dictionary mapping each thread’s identifier to the topmost exception currently active in that thread at the time the function is called. If a thread is not currently handling an exception, it is not included in the result dictionary.

This is most useful for statistical profiling.

This function should be used for internal and specialized purposes only.

Raises an auditing event sys._current_exceptions with no arguments.

sys.breakpointhook()
This hook function is called by built-in breakpoint(). By default, it drops you into the pdb debugger, but it can be set to any other function so that you can choose which debugger gets used.

The signature of this function is dependent on what it calls. For example, the default binding (e.g. pdb.set_trace()) expects no arguments, but you might bind it to a function that expects additional arguments (positional and/or keyword). The built-in breakpoint() function passes its *args and **kws straight through. Whatever breakpointhooks() returns is returned from breakpoint().

The default implementation first consults the environment variable PYTHONBREAKPOINT. If that is set to "0" then this function returns immediately; i.e. it is a no-op. If the environment variable is not set, or is set to the empty string, pdb.set_trace() is called. Otherwise this variable should name a function to run, using Python's dotted-import nomenclature, e.g. package.subpackage.module.function. In this case, package.subpackage.module would be imported and the resulting module must have a callable named function(). This is run, passing in *args and **kws, and whatever function() returns, sys.breakpointhook() returns to the built-in breakpoint() function.

Note that if anything goes wrong while importing the callable named by PYTHONBREAKPOINT, a Run-timeWarning is reported and the breakpoint is ignored.

Also note that if sys.breakpointhook() is overridden programmatically, PYTHONBREAKPOINT is not consulted.

New in version 3.7.

sys._debugmallocstats()
Print low-level information to stderr about the state of CPython’s memory allocator.

If Python is built in debug mode <debug-build> (configure --with-pydebug option), it also performs some expensive internal consistency checks.

New in version 3.3.

CPython implementation detail: This function is specific to CPython. The exact output format is not defined here, and may change.
sys.dllhandle

Integer specifying the handle of the Python DLL.

Availability: Windows.

sys.displayhook(value)

If value is not None, this function prints repr(value) to sys.stdout, and saves value in builtins._. If repr(value) is not encodable to sys.stdout.encoding with sys.stdout.errors error handler (which is probably 'strict'), encode it to sys.stdout.encoding with 'backslashreplace' error handler.

sys.displayhook is called on the result of evaluating an expression entered in an interactive Python session. The display of these values can be customized by assigning another one-argument function to sys.displayhook.

Pseudo-code:

```python
def displayhook(value):
    if value is None:
        return
    # Set '_' to None to avoid recursion
    builtins._ = None
    text = repr(value)
    try:
        sys.stdout.write(text)
    except UnicodeEncodeError:
        bytes = text.encode(sys.stdout.encoding, 'backslashreplace')
        if hasattr(sys.stdout, 'buffer'):
            sys.stdout.buffer.write(bytes)
        else:
            text = bytes.decode(sys.stdout.encoding, 'strict')
        sys.stdout.write(text)
    builtins._ = value
```

Changed in version 3.2: Use 'backslashreplace' error handler on UnicodeEncodeError.

sys.dont_write_bytecode

If this is true, Python won’t try to write .pyc files on the import of source modules. This value is initially set to True or False depending on the -B command line option and the PYTHONDONTWRITEBYTECODE environment variable, but you can set it yourself to control bytecode file generation.

sys.pycache_prefix

If this is set (not None), Python will write bytecode-cache .pyc files to (and read them from) a parallel directory tree rooted at this directory, rather than from __pycache__ directories in the source code tree. Any __pycache__ directories in the source code tree will be ignored and new .pyc files written within the pycache prefix. Thus if you use compileall as a pre-build step, you must ensure you run it with the same pycache prefix (if any) that you will use at runtime.

A relative path is interpreted relative to the current working directory.

This value is initially set based on the value of the -X pycache_prefix=PATH command-line option or the PYTHONPYCACHEPREFIX environment variable (command-line takes precedence). If neither are set, it is None.

New in version 3.8.

sys.excepthook(type, value, traceback)

This function prints out a given traceback and exception to sys.stderr.

When an exception is raised and uncaught, the interpreter calls sys.excepthook with three arguments, the exception class, exception instance, and a traceback object. In an interactive session this happens just before control is returned to the prompt; in a Python program this happens just before the program exits. The handling of such top-level exceptions can be customized by assigning another three-argument function to sys.excepthook.
Raise an auditing event `sys.excepthook` with arguments `hook`, `type`, `value`, `traceback` when an uncaught exception occurs. If no hook has been set, `hook` may be `None`. If any hook raises an exception derived from `RuntimeError` the call to the hook will be suppressed. Otherwise, the audit hook exception will be reported as unraisable and `sys.excepthook` will be called.

See also:

The `sys.unraisablehook()` function handles unraisable exceptions and the `threading.excepthook()` function handles exception raised by `threading.Thread.run()`.

### sys.__breakpointhook__

These objects contain the original values of `breakpointhook`, `displayhook`, `excepthook`, and `unraisablehook` at the start of the program. They are saved so that `breakpointhook`, `displayhook`, and `excepthook`, `unraisablehook` can be restored in case they happen to get replaced with broken or alternative objects.

New in version 3.7: `__breakpointhook__`

New in version 3.8: `__unraisablehook__`

### sys.exc_info()

This function returns a tuple of three values that give information about the exception that is currently being handled. The information returned is specific both to the current thread and to the current stack frame. If the current stack frame is not handling an exception, the information is taken from the calling stack frame, or its caller, and so on until a stack frame is found that is handling an exception. Here, “handling an exception” is defined as “executing an except clause.” For any stack frame, only information about the exception being currently handled is accessible.

If no exception is being handled anywhere on the stack, a tuple containing three `None` values is returned. Otherwise, the values returned are `(type, value, traceback)`. Their meaning is:

- `type` gets the type of the exception being handled (a subclass of `BaseException`);
- `value` gets the exception instance (an instance of the exception type);
- `traceback` gets a traceback object which encapsulates the call stack at the point where the exception originally occurred.

### sys.exec_prefix

A string giving the site-specific directory prefix where the platform-dependent Python files are installed; by default, this is also `'/usr/local'`. This can be set at build time with the `--exec-prefix` argument to the `configure` script. Specifically, all configuration files (e.g. the `pyconfig.h` header file) are installed in the directory `exec_prefix/lib/pythonX.Y/config`, and shared library modules are installed in `exec_prefix/lib/pythonX.Y/lib-dynload`, where `X.Y` is the version number of Python, for example 3.2.

### Note:

If a virtual environment is in effect, this value will be changed in `site.py` to point to the virtual environment. The value for the Python installation will still be available, via `base_exec_prefix`.

### sys.executable

A string giving the absolute path of the executable binary for the Python interpreter, on systems where this makes sense. If Python is unable to retrieve the real path to its executable, `sys.executable` will be an empty string or `None`.

### sys.exit([arg])

Raise a `SystemExit` exception, signaling an intention to exit the interpreter.

The optional argument `arg` can be an integer giving the exit status (defaulting to zero), or another type of object. If it is an integer, zero is considered “successful termination” and any nonzero value is considered “abnormal termination” by shells and the like. Most systems require it to be in the range 0–127, and produce undefined results otherwise. Some systems have a convention for assigning specific meanings to specific exit codes, but these are generally underdeveloped; Unix programs generally use 2 for command line syntax errors and 1 for all other kind of errors. If another type of object is passed, `None` is equivalent to passing zero, and any other
object is printed to stderr and results in an exit code of 1. In particular, `sys.exit("some error message")` is a quick way to exit a program when an error occurs.

Since `exit()` ultimately “only” raises an exception, it will only exit the process when called from the main thread, and the exception is not intercepted. Cleanup actions specified by finally clauses of try statements are honored, and it is possible to intercept the exit attempt at an outer level.

Changed in version 3.6: If an error occurs in the cleanup after the Python interpreter has caught `SystemExit` (such as an error flushing buffered data in the standard streams), the exit status is changed to 120.

**sys.flags**

The named tuple `flags` exposes the status of command line flags. The attributes are read only.

<table>
<thead>
<tr>
<th>attribute</th>
<th>flag</th>
</tr>
</thead>
<tbody>
<tr>
<td>debug</td>
<td>-d</td>
</tr>
<tr>
<td>inspect</td>
<td>-i</td>
</tr>
<tr>
<td>interactive</td>
<td>-i</td>
</tr>
<tr>
<td>isolated</td>
<td>-I</td>
</tr>
<tr>
<td>optimize</td>
<td>-O or -OO</td>
</tr>
<tr>
<td><code>dont_write_bytecode</code></td>
<td>-B</td>
</tr>
<tr>
<td>no_user_site</td>
<td>-s</td>
</tr>
<tr>
<td>no_site</td>
<td>-S</td>
</tr>
<tr>
<td>ignore_environment</td>
<td>-E</td>
</tr>
<tr>
<td>verbose</td>
<td>-v</td>
</tr>
<tr>
<td>bytes_warning</td>
<td>-b</td>
</tr>
<tr>
<td>quiet</td>
<td>-q</td>
</tr>
<tr>
<td>hash_randomization</td>
<td>-R</td>
</tr>
<tr>
<td>dev_mode</td>
<td>-X dev (Python Development Mode)</td>
</tr>
<tr>
<td>utf8_mode</td>
<td>-X utf8</td>
</tr>
</tbody>
</table>

Changed in version 3.2: Added `quiet` attribute for the new `-q` flag.

New in version 3.2.3: The `hash_randomization` attribute.

Changed in version 3.3: Removed obsolete `division_warning` attribute.

Changed in version 3.4: Added `isolated` attribute for `-I isolated` flag.

Changed in version 3.7: Added the `dev_mode` attribute for the new `Python Development Mode` and the `utf8_mode` attribute for the new `-X utf8` flag.

**sys.float_info**

A namedtuple holding information about the float type. It contains low level information about the precision and internal representation. The values correspond to the various floating-point constants defined in the standard header file `float.h` for the ‘C’ programming language; see section 5.2.4.2.2 of the 1999 ISO/IEC C standard [C99], ‘Characteristics of floating types’, for details.
The attribute `sys.float_info.dig` needs further explanation. If `s` is any string representing a decimal number with at most `sys.float_info.dig` significant digits, then converting `s` to a float and back again will recover a string representing the same decimal value:

```python
>>> import sys
>>> s = '3.14159265358979'  # decimal string with 15 significant digits
15
>>> format(float(s), '.15g')  # convert to float and back -> same value
'3.14159265358979'
```

But for strings with more than `sys.float_info.dig` significant digits, this isn’t always true:

```python
>>> s = '9876543211234567'  # 16 significant digits is too many!
>>> format(float(s), '.16g')  # conversion changes value
'987643211234568'
```

**sys.float_repr_style**

A string indicating how the `repr()` function behaves for floats. If the string has value 'short' then for a finite float `x`, `repr(x)` aims to produce a short string with the property that `float(repr(x)) == x`. This is the usual behaviour in Python 3.1 and later. Otherwise, `float_repr_style` has value 'legacy' and `repr(x)` behaves in the same way as it did in versions of Python prior to 3.1.

New in version 3.1.

**sys.getallocatedblocks()**

Return the number of memory blocks currently allocated by the interpreter, regardless of their size. This function is mainly useful for tracking and debugging memory leaks. Because of the interpreter’s internal caches, the result can vary from call to call; you may have to call `clear_type_cache()` and `gc.collect()` to get more predictable results.

If a Python build or implementation cannot reasonably compute this information, `getallocatedblocks()` is allowed to return 0 instead.
New in version 3.4.

**sys.getandroidapilevel()**
Return the build time API version of Android as an integer.

*Availability:* Android.

New in version 3.7.

**sys.getdefaultencoding()**
Return the name of the current default string encoding used by the Unicode implementation.

**sys.getdlopenflags()**
Return the current value of the flags that are used for *dlopen()* calls. Symbolic names for the flag values can be found in the *os* module (RTLD_xxx constants, e.g. *os.RTLD_LAZY*).

*Availability:* Unix.

**sys.getfilesystemencoding()**
Get the filesystem encoding: the encoding used with the filesystem error handler to convert between Unicode filenames and bytes filenames. The filesystem error handler is returned from *getfilesystemencoding()*.

For best compatibility, *str* should be used for filenames in all cases, although representing filenames as bytes is also supported. Functions accepting or returning filenames should support either *str* or *bytes* and internally convert to the system’s preferred representation.

*os.fsencode()* and *os.fsdecode()* should be used to ensure that the correct encoding and errors mode are used.

The filesystem encoding and error handler are configured at Python startup by the *PyConfig_Read()* function: see *filesystem_encoding* and *filesystem_errors* members of *PyConfig*.

Changed in version 3.2: *getfilesystemencoding()* result cannot be None anymore.

Changed in version 3.6: Windows is no longer guaranteed to return ‘mbcs’. See PEP 529 and *_enablelegacywindowsfsencoding()* for more information.

Changed in version 3.7: Return ‘utf-8’ if the *Python UTF-8 Mode* is enabled.

**sys.getfilesystemencodeerrors()**
Get the filesystem error handler: the error handler used with the filesystem encoding to convert between Unicode filenames and bytes filenames. The filesystem encoding is returned from *getfilesystemencoding()*.

*os.fsencode()* and *os.fsdecode()* should be used to ensure that the correct encoding and errors mode are used.

The filesystem encoding and error handler are configured at Python startup by the *PyConfig_Read()* function: see *filesystem_encoding* and *filesystem_errors* members of *PyConfig*.

New in version 3.6.

**sys.getrefcount**( *object*)
Return the reference count of the *object*. The count returned is generally one higher than you might expect, because it includes the (temporary) reference as an argument to *getrefcount()*.

**sys.getrecursionlimit()**
Return the current value of the recursion limit, the maximum depth of the Python interpreter stack. This limit prevents infinite recursion from causing an overflow of the C stack and crashing Python. It can be set by *setrecursionlimit()*.

**sys.getsizeof**( *object*, *default*)
Return the size of an object in bytes. The object can be any type of object. All built-in objects will return correct results, but this does not have to hold true for third-party extensions as it is implementation specific.

Only the memory consumption directly attributed to the object is accounted for, not the memory consumption of objects it refers to.
If given, `default` will be returned if the object does not provide means to retrieve the size. Otherwise a `TypeError` will be raised.

`getsizeof()` calls the object’s `__sizeof__` method and adds an additional garbage collector overhead if the object is managed by the garbage collector.

See recursive sizeof recipe for an example of using `getsizeof()` recursively to find the size of containers and all their contents.

```python
sys.getswitchinterval()
```

Return the interpreter’s “thread switch interval”; see `setswitchinterval()`.

New in version 3.2.

```python
sys._getframe([depth])
```

Return a frame object from the call stack. If optional integer `depth` is given, return the frame object that many calls below the top of the stack. If that is deeper than the call stack, `ValueError` is raised. The default for `depth` is zero, returning the frame at the top of the call stack.

Raises an auditing event `sys._getframe` with no arguments.

**CPython implementation detail:** This function should be used for internal and specialized purposes only. It is not guaranteed to exist in all implementations of Python.

```python
sys.getprofile()
```

Get the profiler function as set by `setprofile()`.

```python
sys.gettrace()
```

Get the trace function as set by `settrace()`.

**CPython implementation detail:** The `gettrace()` function is intended only for implementing debuggers, profilers, coverage tools and the like. Its behavior is part of the implementation platform, rather than part of the language definition, and thus may not be available in all Python implementations.

```python
sys.getwindowsversion()
```

Return a named tuple describing the Windows version currently running. The named elements are `major`, `minor`, `build`, `platform`, `service_pack`, `service_pack_minor`, `service_pack_major`, `suite_mask`, `product_type` and `platform_version`. `service_pack` contains a string, `platform_version` a 3-tuple and all other values are integers.

The components can also be accessed by name, so `sys.getwindowsversion()[0]` is equivalent to `sys.getwindowsversion().major`. For compatibility with prior versions, only the first 5 elements are retrievable by indexing.

`platform` will be `2` (VER_PLATFORM_WIN32_NT).

`product_type` may be one of the following values:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 (VER_NT_WORKSTATION)</td>
<td>The system is a workstation.</td>
</tr>
<tr>
<td>2 (VER_NT_DOMAIN_CONTROLLER)</td>
<td>The system is a domain controller.</td>
</tr>
<tr>
<td>3 (VER_NT_SERVER)</td>
<td>The system is a server, but not a domain controller.</td>
</tr>
</tbody>
</table>

This function wraps the Win32 `GetVersionEx()` function; see the Microsoft documentation on `OSVERSIONINFOEX()` for more information about these fields.

`platform_version` returns the major version, minor version and build number of the current operating system, rather than the version that is being emulated for the process. It is intended for use in logging rather than feature detection.

**Note:** `platform_version` derives the version from `kernel32.dll` which can be of a different version than the OS version. Please use `platform` module for achieving accurate OS version.

**Availability:** Windows.
Changed in version 3.2: Changed to a named tuple and added `service_pack_minor`, `service_pack_major`, `suite_mask`, and `product_type`.

Changed in version 3.6: Added `platform_version`

```python
sys.get_asyncgen_hooks()
```
Returns an `asyncgen_hooks` object, which is similar to a named tuple of the form `(firstiter, finalizer)`, where `firstiter` and `finalizer` are expected to be either `None` or functions which take an `asynchronous generator iterator` as an argument, and are used to schedule finalization of an asynchronous generator by an event loop.

New in version 3.6: See PEP 525 for more details.

**Note:** This function has been added on a provisional basis (see PEP 411 for details.)

```python
sys.get_coroutine_origin_tracking_depth()
```
Get the current coroutine origin tracking depth, as set by `set_coroutine_origin_tracking_depth()`.

New in version 3.7.

**Note:** This function has been added on a provisional basis (see PEP 411 for details.) Use it only for debugging purposes.

```python
sys.hash_info
```
A named tuple giving parameters of the numeric hash implementation. For more details about hashing of numeric types, see `Hashing of numeric types`.

<table>
<thead>
<tr>
<th>attribute</th>
<th>explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>width</td>
<td>width in bits used for hash values</td>
</tr>
<tr>
<td>modulus</td>
<td>prime modulus P used for numeric hash scheme</td>
</tr>
<tr>
<td>inf</td>
<td>hash value returned for a positive infinity</td>
</tr>
<tr>
<td>nan</td>
<td>(this attribute is no longer used)</td>
</tr>
<tr>
<td>imag</td>
<td>multiplier used for the imaginary part of a complex number</td>
</tr>
<tr>
<td>algorithm</td>
<td>name of the algorithm for hashing of str, bytes, and memoryview</td>
</tr>
<tr>
<td>hash_bits</td>
<td>internal output size of the hash algorithm</td>
</tr>
<tr>
<td>seed_bits</td>
<td>size of the seed key of the hash algorithm</td>
</tr>
</tbody>
</table>

New in version 3.2.

Changed in version 3.4: Added `algorithm`, `hash_bits` and `seed_bits`.

```python
sys.hexversion
```
The version number encoded as a single integer. This is guaranteed to increase with each version, including proper support for non-production releases. For example, to test that the Python interpreter is at least version 1.5.2, use:

```python
if sys.hexversion >= 0x010502F0:
    # use some advanced feature
    ...
else:
    # use an alternative implementation or warn the user
    ...
```

This is called `hexversion` since it only really looks meaningful when viewed as the result of passing it to the built-in `hex()` function. The named tuple `sys.version_info` may be used for a more human-friendly encoding of the same information.

More details of `hexversion` can be found at `apiabiversion`.
**sys.implementation**

An object containing information about the implementation of the currently running Python interpreter. The following attributes are required to exist in all Python implementations.

- **name** is the implementation's identifier, e.g. 'cpython'. The actual string is defined by the Python implementation, but it is guaranteed to be lower case.

- **version** is a named tuple, in the same format as `sys.version_info`. It represents the version of the Python implementation. This has a distinct meaning from the specific version of the Python language to which the currently running interpreter conforms, which `sys.version_info` represents. For example, for PyPy 1.8 `sys.implementation.version` might be `sys.version_info(1, 8, 0, 'final', 0)`, whereas `sys.version_info` would be `sys.version_info(2, 7, 2, 'final', 0)`. For CPython they are the same value, since it is the reference implementation.

- **hexversion** is the implementation version in hexadecimal format, like `sys.hexversion`.

- **cache_tag** is the tag used by the import machinery in the filenames of cached modules. By convention, it would be a composite of the implementation's name and version, like 'cpython-33'. However, a Python implementation may use some other value if appropriate. If `cache_tag` is set to `None`, it indicates that module caching should be disabled.

`sys.implementation` may contain additional attributes specific to the Python implementation. These non-standard attributes must start with an underscore, and are not described here. Regardless of its contents, `sys.implementation` will not change during a run of the interpreter, nor between implementation versions. (It may change between Python language versions, however.) See PEP 421 for more information.

**Note:** The addition of new required attributes must go through the normal PEP process. See PEP 421 for more information.

**sys.int_info**

A named tuple that holds information about Python’s internal representation of integers. The attributes are read only.

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>bits_per_digit</td>
<td>number of bits held in each digit. Python integers are stored internally in base $2^{\text{int_info.bits_per_digit}}$</td>
</tr>
<tr>
<td>sizeof_digit</td>
<td>size in bytes of the C type used to represent a digit</td>
</tr>
</tbody>
</table>

New in version 3.1.

**sys.__interactivehook__**

When this attribute exists, its value is automatically called (with no arguments) when the interpreter is launched in interactive mode. This is done after the PYTHONSTARTUP file is read, so that you can set this hook there. The `site` module sets this.

Raising an auditing event `cpython.run_interactivehook` with the hook object as the argument when the hook is called on startup.

New in version 3.4.

**sys.intern(string)**

Enter string in the table of “interned” strings and return the interned string – which is string itself or a copy. Interning strings is useful to gain a little performance on dictionary lookup – if the keys in a dictionary are interned, and the lookup key is interned, the key comparisons (after hashing) can be done by a pointer compare instead of a string compare. Normally, the names used in Python programs are automatically interned, and the dictionaries used to hold module, class or instance attributes have interned keys.

Interned strings are not immortal; you must keep a reference to the return value of `intern()` around to benefit from it.
sys.is_finalizing()

Return True if the Python interpreter is shutting down, False otherwise.

New in version 3.5.

sys.last_type
sys.last_value
sys.last_traceback

These three variables are not always defined; they are set when an exception is not handled and the interpreter prints an error message and a stack traceback. Their intended use is to allow an interactive user to import a debugger module and engage in post-mortem debugging without having to re-execute the command that caused the error. (Typical use is import pdb; pdb.pm() to enter the post-mortem debugger; see pdb module for more information.)

The meaning of the variables is the same as that of the return values from exc_info() above.

sys.maxsize

An integer giving the maximum value a variable of type Py_ssize_t can take. It’s usually $2^{31} - 1$ on a 32-bit platform and $2^{63} - 1$ on a 64-bit platform.

sys.maxunicode

An integer giving the value of the largest Unicode code point, i.e. $1114111$ (0x10FFFF in hexadecimal).

Changed in version 3.3: Before PEP 393, sys.maxunicode used to be either 0xFFFF or 0x10FFFF, depending on the configuration option that specified whether Unicode characters were stored as UCS-2 or UCS-4.

sys.meta_path

A list of meta path finder objects that have their find_spec() methods called to see if one of the objects can find the module to be imported. The find_spec() method is called with at least the absolute name of the module being imported. If the module to be imported is contained in a package, then the parent package’s __path__ attribute is passed in as a second argument. The method returns a module spec, or None if the module cannot be found.

See also:

importlib.abc.MetaPathFinder The abstract base class defining the interface of finder objects on meta_path.

importlib.machinery.ModuleSpec The concrete class which find_spec() should return instances of.

Changed in version 3.4: Module specs were introduced in Python 3.4, by PEP 451. Earlier versions of Python looked for a method called find_module(). This is still called as a fallback if a meta_path entry doesn’t have a find_spec() method.

sys.modules

This is a dictionary that maps module names to modules which have already been loaded. This can be manipulated to force reloading of modules and other tricks. However, replacing the dictionary will not necessarily work as expected and deleting essential items from the dictionary may cause Python to fail. If you want to iterate over this global dictionary always use sys.modules.copy() or tuple(sys.modules) to avoid exceptions as its size may change during iteration as a side effect of code or activity in other threads.

sys.orig_argv

The list of the original command line arguments passed to the Python executable.

See also sys.argv.

New in version 3.10.

sys.path

A list of strings that specifies the search path for modules. Initialized from the environment variable PYTHONPATH, plus an installation-dependent default.

As initialized upon program startup, the first item of this list, path[0], is the directory containing the script that was used to invoke the Python interpreter. If the script directory is not available (e.g. if the interpreter is
invoked interactively or if the script is read from standard input), path[0] is the empty string, which directs Python to search modules in the current directory first. Notice that the script directory is inserted before the entries inserted as a result of PYTHONPATH.

A program is free to modify this list for its own purposes. Only strings and bytes should be added to sys.path; all other data types are ignored during import.

See also:
Module site This describes how to use .pth files to extend sys.path.

sys.path_hooks
A list of callables that take a path argument to try to create a finder for the path. If a finder can be created, it is to be returned by the callable, else raise ImportError.

Originally specified in PEP 302.

sys.path_importer_cache
A dictionary acting as a cache for finder objects. The keys are paths that have been passed to sys.path_hooks and the values are the finders that are found. If a path is a valid file system path but no finder is found on sys.path_importer_cache then None is stored.

Originally specified in PEP 302.

Changed in version 3.3: None is stored instead of imp.NullImporter when no finder is found.

sys.platform
This string contains a platform identifier that can be used to append platform-specific components to sys.path, for instance.

For Unix systems, except on Linux and AIX, this is the lowercased OS name as returned by uname -s with the first part of the version as returned by uname -r appended, e.g. 'sunos5' or 'freebsd8', at the time when Python was built. Unless you want to test for a specific system version, it is therefore recommended to use the following idiom:

```python
if sys.platform.startswith('freebsd'):
    # FreeBSD-specific code here...
elif sys.platform.startswith('linux'):
    # Linux-specific code here...
elif sys.platform.startswith('aix'):
    # AIX-specific code here...
```

For other systems, the values are:

<table>
<thead>
<tr>
<th>System</th>
<th>platform value</th>
</tr>
</thead>
<tbody>
<tr>
<td>AIX</td>
<td>'aix'</td>
</tr>
<tr>
<td>Linux</td>
<td>'linux'</td>
</tr>
<tr>
<td>Windows</td>
<td>'win32'</td>
</tr>
<tr>
<td>Windows/Cygwin</td>
<td>'cygwin'</td>
</tr>
<tr>
<td>macOS</td>
<td>'darwin'</td>
</tr>
</tbody>
</table>

Changed in version 3.3: On Linux, sys.platform doesn’t contain the major version anymore. It is always 'linux', instead of 'linux2' or 'linux3'. Since older Python versions include the version number, it is recommended to always use the startswith idiom presented above.

Changed in version 3.8: On AIX, sys.platform doesn’t contain the major version anymore. It is always 'aix', instead of 'aix5' or 'aix7'. Since older Python versions include the version number, it is recommended to always use the startswith idiom presented above.

See also:

os.name has a coarser granularity. os.uname() gives system-dependent version information.

The platform module provides detailed checks for the system’s identity.

---

29.1. sys — System-specific parameters and functions 1665
sys.platlibdir
Name of the platform-specific library directory. It is used to build the path of standard library and the paths of installed extension modules.

It is equal to "lib" on most platforms. On Fedora and SuSE, it is equal to "lib64" on 64-bit platforms which gives the following sys.path paths (where X.Y is the Python major.minor version):

- /usr/lib64/pythonX.Y/: Standard library (like os.py of the os module)
- /usr/lib64/pythonX.Y/lib-dynload/: C extension modules of the standard library (like the errno module, the exact filename is platform specific)
- /usr/lib/pythonX.Y/site-packages/ (always use lib, not sys.platlibdir): Third-party modules
- /usr/lib64/pythonX.Y/site-packages/: C extension modules of third-party packages

New in version 3.9.

sys.prefix
A string giving the site-specific directory prefix where the platform independent Python files are installed; on Unix, the default is '/usr/local'. This can be set at build time with the --prefix argument to the configure script. See Installation paths for derived paths.

Note: If a virtual environment is in effect, this value will be changed in site.py to point to the virtual environment. The value for the Python installation will still be available, via base_prefix.

sys.ps1
sys.ps2
Strings specifying the primary and secondary prompt of the interpreter. These are only defined if the interpreter is in interactive mode. Their initial values in this case are '>>> ' and '... '. If a non-string object is assigned to either variable, its str() is re-evaluated each time the interpreter prepares to read a new interactive command; this can be used to implement a dynamic prompt.

sys.setdlopenflags(n)
Set the flags used by the interpreter for dlopen() calls, such as when the interpreter loads extension modules. Among other things, this will enable a lazy resolving of symbols when importing a module, if called as sys.setdlopenflags(0). To share symbols across extension modules, call as sys.setdlopenflags(os.RTLD_GLOBAL). Symbolic names for the flag values can be found in the os module (RTLD_xxx constants, e.g. os.RTLD_LAZY).

Availability: Unix.

sys.setprofile(profilefunc)
Set the system’s profile function, which allows you to implement a Python source code profiler in Python. See chapter The Python Profilers for more information on the Python profiler. The system’s profile function is called similarly to the system’s trace function (see settrace()), but it is called with different events, for example it isn’t called for each executed line of code (only on call and return, but the return event is reported even when an exception has been set). The function is thread-specific, but there is no way for the profiler to know about context switches between threads, so it does not make sense to use this in the presence of multiple threads. Also, its return value is not used, so it can simply return None. Error in the profile function will cause itself unset.

Profile functions should have three arguments: frame, event, and arg. frame is the current stack frame. event is a string: 'call', 'return', 'c_call', 'c_return', or 'c_exception'. arg depends on the event type.

Raises an auditing event sys.setprofile with no arguments.

The events have the following meaning:

'call' A function is called (or some other code block entered). The profile function is called; arg is None.

'return' A function (or other code block) is about to return. The profile function is called; arg is the value that will be returned, or None if the event is caused by an exception being raised.
'c_call' A C function is about to be called. This may be an extension function or a built-in. arg is the C function object.

'c_return' A C function has returned. arg is the C function object.

'c_exception' A C function has raised an exception. arg is the C function object.

```
sys.setrecursionlimit(limit)
```
Set the maximum depth of the Python interpreter stack to limit. This limit prevents infinite recursion from causing an overflow of the C stack and crashing Python.

The highest possible limit is platform-dependent. A user may need to set the limit higher when they have a program that requires deep recursion and a platform that supports a higher limit. This should be done with care, because a too-high limit can lead to a crash.

If the new limit is too low at the current recursion depth, a `RecursionError` exception is raised.

Changed in version 3.5.1: A `RecursionError` exception is now raised if the new limit is too low at the current recursion depth.

```
sys.setswitchinterval(interval)
```
Set the interpreter's thread switch interval (in seconds). This floating-point value determines the ideal duration of the "timeslices" allocated to concurrently running Python threads. Please note that the actual value can be higher, especially if long-running internal functions or methods are used. Also, which thread becomes scheduled at the end of the interval is the operating system's decision. The interpreter doesn’t have its own scheduler.

New in version 3.2.

```
sys.settrace(tracefunc)
```
Set the system's trace function, which allows you to implement a Python source code debugger in Python. The function is thread-specific; for a debugger to support multiple threads, it must register a trace function using `settrace()` for each thread being debugged or use `threading.settrace()`.

Trace functions should have three arguments: `frame`, `event`, and `arg`. `frame` is the current stack frame. `event` is a string: 'call', 'line', 'return', 'exception' or 'opcode'. `arg` depends on the event type.

The trace function is invoked (with `event` set to 'call') whenever a new local scope is entered; it should return a reference to a local trace function to be used for the new scope, or `None` if the scope shouldn’t be traced.

The local trace function should return a reference to itself (or to another function for further tracing in that scope), or `None` to turn off tracing in that scope.

If there is any error occurred in the trace function, it will be unset, just like `settrace(None)` is called.

The events have the following meaning:

'call' A function is called (or some other code block entered). The global trace function is called; `arg` is `None`; the return value specifies the local trace function.

'line' The interpreter is about to execute a new line of code or re-execute the condition of a loop. The local trace function is called; `arg` is `None`; the return value specifies the new local trace function. See `Objects/intotab_notes.txt` for a detailed explanation of how this works. Per-line events may be disabled for a frame by setting `f_trace_lines` to `False` on that frame.

'return' A function (or other code block) is about to return. The local trace function is called; `arg` is the value that will be returned, or `None` if the event is caused by an exception being raised. The trace function's return value is ignored.

'exception' An exception has occurred. The local trace function is called; `arg` is a tuple (exception, value, traceback); the return value specifies the new local trace function.

'opcode' The interpreter is about to execute a new opcode (see `dis` for opcode details). The local trace function is called; `arg` is `None`; the return value specifies the new local trace function. Per-opcode events are not emitted by default: they must be explicitly requested by setting `f_trace_opcodes` to `True` on the frame.
Note that as an exception is propagated down the chain of callers, an 'exception' event is generated at each level.

For more fine-grained usage, it’s possible to set a trace function by assigning `frame.f_trace = trace_func` explicitly, rather than relying on it being set indirectly via the return value from an already installed trace function. This is also required for activating the trace function on the current frame, which `settrace()` doesn’t do. Note that in order for this to work, a global tracing function must have been installed with `settrace()` in order to enable the runtime tracing machinery, but it doesn’t need to be the same tracing function (e.g. it could be a low overhead tracing function that simply returns `None` to disable itself immediately on each frame).

For more information on code and frame objects, refer to types.

Raises an auditing event `sys.settrace` with no arguments.

**CPython implementation detail:** The `settrace()` function is intended only for implementing debuggers, profilers, coverage tools and the like. Its behavior is part of the implementation platform, rather than part of the language definition, and thus may not be available in all Python implementations.

Changed in version 3.7: 'opcode' event type added; `f_trace_lines` and `f_trace_opcodes` attributes added to frames

```python
sys.set_asyncgen_hooks(firstiter, finalizer)
```

Accepts two optional keyword arguments which are callables that accept an asynchronous generator iterator as an argument. The `firstiter` callable will be called when an asynchronous generator is iterated for the first time. The `finalizer` will be called when an asynchronous generator is about to be garbage collected.

Raises an auditing event `sys.set_asyncgen_hooks_firstiter` with no arguments.

Raises an auditing event `sys.set_asyncgen_hooks_finalizer` with no arguments.

Two auditing events are raised because the underlying API consists of two calls, each of which must raise its own event.

New in version 3.6: See PEP 525 for more details, and for a reference example of a `finalizer` method see the implementation of `asyncio.Loop.shutdown_asyncgens` in `Lib/asyncio/base_events.py`

**Note:** This function has been added on a provisional basis (see PEP 411 for details.)

```python
sys.set_coroutine_origin_tracking_depth(depth)
```

Allows enabling or disabling coroutine origin tracking. When enabled, the `cr_origin` attribute on coroutine objects will contain a tuple of (filename, line number, function name) tuples describing the traceback where the coroutine object was created, with the most recent call first. When disabled, `cr_origin` will be `None`.

To enable, pass a `depth` value greater than zero; this sets the number of frames whose information will be captured. To disable, pass `set depth to zero`.

This setting is thread-specific.

New in version 3.7.

**Note:** This function has been added on a provisional basis (see PEP 411 for details.) Use it only for debugging purposes.

```python
sys._enablelegacywindowsfsencoding()
```

Changes the filesystem encoding and error handler to 'mbcs' and 'replace' respectively, for consistency with versions of Python prior to 3.6.

This is equivalent to defining the `PYTHONLEGACYWINDOWFSENCODING` environment variable before launching Python.

See also `sys.getfilesystemencoding()` and `sys.getfilesystemencodeerrors()`.

**Availability:** Windows.
New in version 3.6: See PEP 529 for more details.

```python
sys.stdin
sys.stdout
sys.stderr
```

**File objects** used by the interpreter for standard input, output and errors:

- `stdin` is used for all interactive input (including calls to `input()`);
- `stdout` is used for the output of `print()` and `expression` statements and for the prompts of `input()`;
- The interpreter’s own prompts and its error messages go to `stderr`.

These streams are regular **text files** like those returned by the `open()` function. Their parameters are chosen as follows:

- The encoding and error handling are is initialized from `PyConfig.stdio_encoding` and `PyConfig.stdio_errors`.

On Windows, UTF-8 is used for the console device. Non-character devices such as disk files and pipes use the system locale encoding (i.e. the ANSI codepage). Non-console character devices such as NUL (i.e. where `isatty()` returns True) use the value of the console input and output codepages at startup, respectively for stdin and stdout/stderr. This defaults to the system **locale encoding** if the process is not initially attached to a console.

The special behaviour of the console can be overridden by setting the environment variable `PYTHON_LEGACYWINDOWSSTDIO` before starting Python. In that case, the console codepages are used as for any other character device.

Under all platforms, you can override the character encoding by setting the `PYTHONIOENCODING` environment variable before starting Python or by using the new `-X utf8` command line option and `PYTHONUTF8` environment variable. However, for the Windows console, this only applies when `PYTHON_LEGACYWINDOWSSTDIO` is also set.

- When interactive, the `stdout` stream is line-buffered. Otherwise, it is block-buffered like regular text files. The `stderr` stream is line-buffered in both cases. You can make both streams unbuffered by passing the `-u` command-line option or setting the `PYTHONUNBUFFERED` environment variable.

**Note:** To write or read binary data from/to the standard streams, use the underlying binary `buffer` object. For example, to write bytes to `stdout`, use `sys.stdout.buffer.write(b'abc')`.

However, if you are writing a library (and do not control in which context its code will be executed), be aware that the standard streams may be replaced with file-like objects like `io.StringIO` which do not support the `buffer` attribute.

```python
sys.__stdin__
sys.__stdout__
sys.__stderr__
```

These objects contain the original values of `stdin`, `stdout` and `stderr` at the start of the program. They are used during finalization, and could be useful to print to the actual standard stream no matter if the `sys.std*` object has been redirected.

It can also be used to restore the actual files to known working file objects in case they have been overwritten with a broken object. However, the preferred way to do this is to explicitly save the previous stream before replacing it, and restore the saved object.

**Note:** Under some conditions `stdin`, `stdout` and `stderr` as well as the original values `__stdin__`, `__stdout__` and `__stderr__` can be `None`. It is usually the case for Windows GUI apps that aren’t connected to a console and Python apps started with `pythonw`. 

---

**29.1. sys — System-specific parameters and functions**

1669
**sys.stdlib_module_names**
A frozenset of strings containing the names of standard library modules.

It is the same on all platforms. Modules which are not available on some platforms and modules disabled at Python build are also listed. All module kinds are listed: pure Python, built-in, frozen and extension modules. Test modules are excluded.

For packages, only the main package is listed: sub-packages and sub-modules are not listed. For example, the `email` package is listed, but the `email.mime` sub-package and the `email.message` sub-module are not listed.

See also the `sys.builtin_module_names` list.

New in version 3.10.

**sys.thread_info**
A named tuple holding information about the thread implementation.

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>Name of the thread implementation:</td>
</tr>
<tr>
<td></td>
<td>• 'nt': Windows threads</td>
</tr>
<tr>
<td></td>
<td>• 'pthread': POSIX threads</td>
</tr>
<tr>
<td></td>
<td>• 'solaris': Solaris threads</td>
</tr>
<tr>
<td>lock</td>
<td>Name of the lock implementation:</td>
</tr>
<tr>
<td></td>
<td>• 'semaphore': a lock uses a semaphore</td>
</tr>
<tr>
<td></td>
<td>• 'mutex+cond': a lock uses a mutex and a condition variable</td>
</tr>
<tr>
<td></td>
<td>• None if this information is unknown</td>
</tr>
<tr>
<td>version</td>
<td>Name and version of the thread library. It is a string, or None if this information is unknown.</td>
</tr>
</tbody>
</table>

New in version 3.3.

**sys.tracebacklimit**
When this variable is set to an integer value, it determines the maximum number of levels of traceback information printed when an unhandled exception occurs. The default is 1000. When set to 0 or less, all traceback information is suppressed and only the exception type and value are printed.

**sys.unraisablehook** *(unraisable, /)*
Handle an unraisable exception.

Called when an exception has occurred but there is no way for Python to handle it. For example, when a destructor raises an exception or during garbage collection (`gc.collect()`).

The `unraisable` argument has the following attributes:

- `exc_type`: Exception type.
- `exc_value`: Exception value, can be `None`.
- `exc_traceback`: Exception traceback, can be `None`.
- `err_msg`: Error message, can be `None`.
- `object`: Object causing the exception, can be `None`.

The default hook formats `err_msg` and `object` as: `f'{err_msg}: {object!r}'`; use “Exception ignored in” error message if `err_msg` is `None`.

`sys.unraisablehook()` can be overridden to control how unraisable exceptions are handled.

Storing `exc_value` using a custom hook can create a reference cycle. It should be cleared explicitly to break the reference cycle when the exception is no longer needed.

Storing `object` using a custom hook can resurrect it if it is set to an object which is being finalized. Avoid storing `object` after the custom hook completes to avoid resurrecting objects.
See also `excepthook()` which handles uncaught exceptions.

Raise an auditing event `sys.unraisablehook` with arguments `hook, unraisable` when an exception that cannot be handled occurs. The `unraisable` object is the same as what will be passed to the hook. If no hook has been set, `hook` may be `None`.

New in version 3.8.

`sys.version`
A string containing the version number of the Python interpreter plus additional information on the build number and compiler used. This string is displayed when the interactive interpreter is started. Do not extract version information out of it, rather, use `version_info` and the functions provided by the `platform` module.

`sys.api_version`
The C API version for this interpreter. Programmers may find this useful when debugging version conflicts between Python and extension modules.

`sys.version_info`
A tuple containing the five components of the version number: `major`, `minor`, `micro`, `releaselevel`, and `serial`. All values except `releaselevel` are integers; the release level is `'alpha'`, `'beta'`, `'candidate'`, or `'final'`. The `version_info` value corresponding to the Python version 2.0 is `(2, 0, 0, 'final', 0)`. The components can also be accessed by name, so `sys.version_info[0]` is equivalent to `sys.version_info.major` and so on.

Changed in version 3.1: Added named component attributes.

`sys.warnoptions`
This is an implementation detail of the warnings framework; do not modify this value. Refer to the `warnings` module for more information on the warnings framework.

`sys.winver`
The version number used to form registry keys on Windows platforms. This is stored as string resource 1000 in the Python DLL. The value is normally the first three characters of `version`. It is provided in the `sys` module for informational purposes; modifying this value has no effect on the registry keys used by Python.

Availability: Windows.

`sys._xoptions`
A dictionary of the various implementation-specific flags passed through the `-X` command-line option. Option names are either mapped to their values, if given explicitly, or to `True`. Example:

```
$ ./python -Xa=b -Xc
Python 3.2a3+ (py3k, Oct 16 2010, 20:14:50)
[GCC 4.4.3] on linux2
Type "help", "copyright", "credits" or "license" for more information.
>>> import sys
>>> sys._xoptions
{'a': 'b', 'c': True}
```

CPython implementation detail: This is a CPython-specific way of accessing options passed through `-X`. Other implementations may export them through other means, or not at all.

New in version 3.2.
29.2 `sysconfig` — Provide access to Python’s configuration information

New in version 3.2.

**Source code:** Lib/sysconfig.py

The `sysconfig` module provides access to Python’s configuration information like the list of installation paths and the configuration variables relevant for the current platform.

### 29.2.1 Configuration variables

A Python distribution contains a `Makefile` and a `pyconfig.h` header file that are necessary to build both the Python binary itself and third-party C extensions compiled using `distutils`.

`sysconfig` puts all variables found in these files in a dictionary that can be accessed using `get_config_vars()` or `get_config_var()`.

Notice that on Windows, it’s a much smaller set.

```python
sysconfig.get_config_vars(*args)
```

With no arguments, return a dictionary of all configuration variables relevant for the current platform.

With arguments, return a list of values that result from looking up each argument in the configuration variable dictionary.

For each argument, if the value is not found, return `None`.

```python
sysconfig.get_config_var(name)
```

Return the value of a single variable `name`. Equivalent to `get_config_vars().get(name)`.

If `name` is not found, return `None`.

Example of usage:

```python
>>> import sysconfig
>>> sysconfig.get_config_var('Py_ENABLE_SHARED')
0
>>> sysconfig.get_config_var('LIBDIR')
'/usr/local/lib'
>>> sysconfig.get_config_var('AR', 'g++')
['ar', 'g++']
```

### 29.2.2 Installation paths

Python uses an installation scheme that differs depending on the platform and on the installation options. These schemes are stored in `sysconfig` under unique identifiers based on the value returned by `os.name`.

Every new component that is installed using `distutils` or a Distutils-based system will follow the same scheme to copy its file in the right places.

Python currently supports six schemes:

- **posix_prefix**: scheme for POSIX platforms like Linux or macOS. This is the default scheme used when Python or a component is installed.

- **posix_home**: scheme for POSIX platforms used when a `home` option is used upon installation. This scheme is used when a component is installed through Distutils with a specific home prefix.
• **posix_user**: scheme for POSIX platforms used when a component is installed through Distutils and the `user` option is used. This scheme defines paths located under the user home directory.

• **nt**: scheme for NT platforms like Windows.

• **nt_user**: scheme for NT platforms, when the `user` option is used.

• **osx_framework_user**: scheme for macOS, when the `user` option is used.

Each scheme is itself composed of a series of paths and each path has a unique identifier. Python currently uses eight paths:

• **stdlib**: directory containing the standard Python library files that are not platform-specific.

• **platstdlib**: directory containing the standard Python library files that are platform-specific.

• **platlib**: directory for site-specific, platform-specific files.

• **purelib**: directory for site-specific, non-platform-specific files.

• **include**: directory for non-platform-specific header files.

• **plaininclude**: directory for platform-specific header files.

• **scripts**: directory for script files.

• **data**: directory for data files.

`sysconfig` provides some functions to determine these paths.

`sysconfig.get_scheme_names()`  
Return a tuple containing all schemes currently supported in `sysconfig`.

`sysconfig.get_default_scheme()`  
Return the default scheme name for the current platform.

Changed in version 3.10: This function was previously named `_get_default_scheme()` and considered an implementation detail.

`sysconfig.get_preferred_scheme(key)`  
Return a preferred scheme name for an installation layout specified by `key`.

`key` must be either "prefix", "home", or "user".

The return value is a scheme name listed in `get_scheme_names()`. It can be passed to `sysconfig` functions that take a `scheme` argument, such as `get_paths()`.

New in version 3.10.

`sysconfig._get_preferred_schemes()`  
Return a dict containing preferred scheme names on the current platform. Python implementers and redistributors may add their preferred schemes to the `INSTALL_SCHEMES` module-level global value, and modify this function to return those scheme names, to e.g. provide different schemes for system and language package managers to use, so packages installed by either do not mix with those by the other.

End users should not use this function, but `get_default_scheme()` and `get_preferred_scheme()` instead.

New in version 3.10.

`sysconfig.get_path_names()`  
Return a tuple containing all path names currently supported in `sysconfig`.

`sysconfig.get_path(name[, scheme[, vars[, expand ]]]])`  
Return an installation path corresponding to the path `name`, from the install scheme named `scheme`.

`name` has to be a value from the list returned by `get_path_names()`.

`sysconfig` stores installation paths corresponding to each path name, for each platform, with variables to be expanded. For instance the `stdlib` path for the `nt` scheme is: `{base}/Lib.
get_path() will use the variables returned by get_config_vars() to expand the path. All variables have default values for each platform so one may call this function and get the default value.

If scheme is provided, it must be a value from the list returned by get_scheme_names(). Otherwise, the default scheme for the current platform is used.

If vars is provided, it must be a dictionary of variables that will update the dictionary return by get_config_vars().

If expand is set to False, the path will not be expanded using the variables.

If name is not found, raise a KeyError.

```python
sysconfig.get_paths([scheme[, vars[, expand ]]])
```

Return a dictionary containing all installation paths corresponding to an installation scheme. See get_path() for more information.

If scheme is not provided, will use the default scheme for the current platform.

If vars is provided, it must be a dictionary of variables that will update the dictionary used to expand the paths.

If expand is set to false, the paths will not be expanded.

If scheme is not an existing scheme, get_paths() will raise a KeyError.

29.2.3 Other functions

```python
sysconfig.get_python_version()
```

Return the MAJOR.MINOR Python version number as a string. Similar to '%d.%d' % sys.version_info[:2].

```python
sysconfig.get_platform()
```

Return a string that identifies the current platform.

This is used mainly to distinguish platform-specific build directories and platform-specific built distributions. Typically includes the OS name and version and the architecture (as supplied by 'os.uname()'), although the exact information included depends on the OS; e.g., on Linux, the kernel version isn’t particularly important.

Examples of returned values:

- linux-i586
- linux-alpha (?)
- solaris-2.6-sun4u

Windows will return one of:

- win-amd64 (64bit Windows on AMD64, aka x86_64, Intel64, and EM64T)
- win32 (all others - specifically, sys.platform is returned)

macOS can return:

- macosx-10.6-ppc
- macosx-10.4-ppc64
- macosx-10.3-i386
- macosx-10.4-fat

For other non-POSIX platforms, currently just returns sys.platform.

```python
sysconfig.is_python_build()
```

Return True if the running Python interpreter was built from source and is being run from its built location, and not from a location resulting from e.g. running make install or installing via a binary installer.
sysconfig.parse_config_h(fp[, vars])
   Parse a config.h-style file.

   fp is a file-like object pointing to the config.h-like file.

   A dictionary containing name/value pairs is returned. If an optional dictionary is passed in as the second argument, it is used instead of a new dictionary, and updated with the values read in the file.

sysconfig.get_config_h_filename()
   Return the path of pyconfig.h.

sysconfig.get_makefile_filename()
   Return the path of Makefile.

### 29.2.4 Using sysconfig as a script

You can use *sysconfig* as a script with Python’s *-m* option:

```
$ python -m sysconfig
Platform: "macosx-10.4-i386"
Python version: "3.2"
Current installation scheme: "posix_prefix"

Paths:
  data = "/usr/local"
  include = "/Users/tarek/Dev/Dev/svn.python.org/py3k/Include"
  platinclude = "."
  platlib = "/usr/local/lib/python3.2/site-packages"
  platstdlib = "/usr/local/lib/python3.2"
  purelib = "/usr/local/lib/python3.2/site-packages"
  scripts = "/usr/local/bin"
  stdlib = "/usr/local/lib/python3.2"

Variables:
  AC_APPLE_UNIVERSAL_BUILD = "0"
  AIX_GENUINE_CPLUSPLUS = "0"
  AR = "ar"
  ARFLAGS = "rc"
  ...
```

This call will print in the standard output the information returned by *get_platform()*, *get_python_version()*, *get_path()* and *get_config_vars()*.

### 29.3 builtins — Built-in objects

This module provides direct access to all ‘built-in’ identifiers of Python; for example, *builtins.open* is the full name for the built-in function *open()* . See *Built-in Functions* and *Built-in Constants* for documentation.

This module is not normally accessed explicitly by most applications, but can be useful in modules that provide objects with the same name as a built-in value, but in which the built-in of that name is also needed. For example, in a module that wants to implement an *open()* function that wraps the built-in *open()* , this module can be used directly:

```python
import builtins

def open(path):
    f = builtins.open(path, 'r')
    return UpperCaser(f)
```

(continues on next page)
class UpperCaser:
    '''Wrapper around a file that converts output to upper-case.''

    def __init__(self, f):
        self._f = f

    def read(self, count=-1):
        return self._f.read(count).upper()

    # ...

As an implementation detail, most modules have the name __builtins__ made available as part of their globals.
The value of __builtins__ is normally either this module or the value of this module’s __dict__ attribute. Since this is
an implementation detail, it may not be used by alternate implementations of Python.

29.4 __main__ — Top-level code environment

In Python, the special name __main__ is used for two important constructs:

1. the name of the top-level environment of the program, which can be checked using the __name__ == '__main__'
   expression; and
2. the __main__.py file in Python packages.

Both of these mechanisms are related to Python modules; how users interact with them and how they interact with
each other. They are explained in detail below. If you’re new to Python modules, see the tutorial section tut-modules
for an introduction.

29.4.1 __name__ == '__main__'

When a Python module or package is imported, __name__ is set to the module’s name. Usually, this is the name
of the Python file itself without the .py extension:

```
>>> import configparser
>>> configparser.__name__
'configparser'
```

If the file is part of a package, __name__ will also include the parent package’s path:

```
>>> from concurrent.futures import process
>>> process.__name__
'concurrent.futures.process'
```

However, if the module is executed in the top-level code environment, its __name__ is set to the string '__main__'.
What is the “top-level code environment”?

__main__ is the name of the environment where top-level code is run. “Top-level code” is the first user-specified Python module that starts running. It’s “top-level” because it imports all other modules that the program needs. Sometimes “top-level code” is called an **entry point** to the application.

The top-level code environment can be:

- the scope of an interactive prompt:
  ```python
  >>> __name__
  '__main__'
  ```

- the Python module passed to the Python interpreter as a file argument:
  ```bash
  $ python3 helloworld.py
  Hello, world!
  ```

- the Python module or package passed to the Python interpreter with the `-m` argument:
  ```bash
  $ python3 -m tarfile
  usage: tarfile.py [-h] [-v] (...) 
  ```

- Python code read by the Python interpreter from standard input:
  ```bash
  $ echo "import this" | python3
  The Zen of Python, by Tim Peters
  Beautiful is better than ugly.
  Explicit is better than implicit.
  ...
  ```

- Python code passed to the Python interpreter with the `-c` argument:
  ```bash
  $ python3 -c "import this"
  The Zen of Python, by Tim Peters
  Beautiful is better than ugly.
  Explicit is better than implicit.
  ...
  ```

In each of these situations, the top-level module’s __name__ is set to '__main__'.

As a result, a module can discover whether or not it is running in the top-level environment by checking its own __name__, which allows a common idiom for conditionally executing code when the module is not initialized from an import statement:

```python
if __name__ == '__main__':
  # Execute when the module is not initialized from an import statement.
  ...
```

See also:

For a more detailed look at how __name__ is set in all situations, see the tutorial section tut-modules.
Idiomatic Usage

Some modules contain code that is intended for script use only, like parsing command-line arguments or fetching data from standard input. If a module like this was imported from a different module, for example to unit test it, the script code would unintentionally execute as well.

This is where using the `if __name__ == '__main__'` code block comes in handy. Code within this block won’t run unless the module is executed in the top-level environment.

Putting as few statements as possible in the block below `if __name__ == '__main__'` can improve code clarity and correctness. Most often, a function named `main` encapsulates the program’s primary behavior:

```
# echo.py
import shlex
import sys

def echo(phrase: str) -> None:
    """A dummy wrapper around print.""
    # for demonstration purposes, you can imagine that there is some
    # valuable and reusable logic inside this function
    print(phrase)

def main() -> int:
    """Echo the input arguments to standard output""
    phrase = shlex.join(sys.argv)
    echo(phrase)
    return 0

if __name__ == '__main__':
    sys.exit(main())  # next section explains the use of sys.exit
```

Note that if the module didn’t encapsulate code inside the `main` function but instead put it directly within the `if __name__ == '__main__'` block, the `phrase` variable would be global to the entire module. This is error-prone as other functions within the module could be unintentionally using the global variable instead of a local name. A `main` function solves this problem.

Using a `main` function has the added benefit of the `echo` function itself being isolated and importable elsewhere. When `echo.py` is imported, the `echo` and `main` functions will be defined, but neither of them will be called, because `__name__ != '__main__'`.

Packaging Considerations

`main` functions are often used to create command-line tools by specifying them as entry points for console scripts. When this is done, `pip` inserts the function call into a template script, where the return value of `main` is passed into `sys.exit()`. For example:

```
sys.exit(main())
```

Since the call to `main` is wrapped in `sys.exit()`, the expectation is that your function will return some value acceptable as an input to `sys.exit()`; typically, an integer or `None` (which is implicitly returned if your function does not have a return statement).

By proactively following this convention ourselves, our module will have the same behavior when run directly (i.e. `python3 echo.py`) as it will have if we later package it as a console script entry-point in a pip-installable package.

In particular, be careful about returning strings from your `main` function. `sys.exit()` will interpret a string argument as a failure message, so your program will have an exit code of 1, indicating failure, and the string will be written to `sys.stderr`. The `echo.py` example from earlier exemplifies using the `sys.exit(main())` convention.

Python Packaging User Guide contains a collection of tutorials and references on how to distribute and install Python packages with modern tools.

### 29.4.2 __main__.py in Python Packages

If you are not familiar with Python packages, see section tut-packages of the tutorial. Most commonly, the __main__.py file is used to provide a command-line interface for a package. Consider the following hypothetical package, “bandclass”:

```bash
bandclass
  ├── __init__.py
  │    ├── __main__.py
  │    └── student.py
  └── student.py
```

__main__.py will be executed when the package itself is invoked directly from the command line using the `-m` flag. For example:

```bash
$ python3 -m bandclass
```

This command will cause __main__.py to run. How you utilize this mechanism will depend on the nature of the package you are writing, but in this hypothetical case, it might make sense to allow the teacher to search for students:

```python
# bandclass/__main__.py
import sys
from .student import search_students

student_name = sys.argv[2] if len(sys.argv) >= 2 else ''
print(f'Found student: {search_students(student_name)}')
```

Note that `from .student import search_students` is an example of a relative import. This import style can be used when referencing modules within a package. For more details, see intra-package-references in the tut-modules section of the tutorial.

#### Idiomatic Usage

The contents of __main__.py typically isn’t fenced with `if __name__ == '__main__'` blocks. Instead, those files are kept short, functions to execute from other modules. Those other modules can then be easily unit-tested and are properly reusable.

If used, an `if __name__ == '__main__'` block will still work as expected for a __main__.py file within a package, because its __name__ attribute will include the package’s path if imported:

```python
>>> import asyncio.__main__
>>> asyncio.__main__.__name__
'asyncio.__main__'
```

This won’t work for __main__.py files in the root directory of a .zip file though. Hence, for consistency, minimal __main__.py like the venv one mentioned below are preferred.

#### See also:

See venv for an example of a package with a minimal __main__.py in the standard library. It doesn’t contain a `if __name__ == '__main__'` block. You can invoke it with `python3 -m venv [directory].`

See runpy for more details on the `-m` flag to the interpreter executable.

See zipapp for how to run applications packaged as .zip files. In this case Python looks for a __main__.py file in the root directory of the archive.
29.4.3 import __main__

Regardless of which module a Python program was started with, other modules running within that same program can import the top-level environment’s scope (namespace) by importing the __main__ module. This doesn’t import a __main__.py file but rather whichever module that received the special name '__main__'.

Here is an example module that consumes the __main__ namespace:

```python
# namely.py
import __main__

def did_user_define_their_name():
    return 'my_name' in dir(__main__)

def print_user_name():
    if not did_user_define_their_name():
        raise ValueError('Define the variable 'my_name'!')
    if '__file__' in dir(__main__):
        print(__main__.my_name, "found in file", __main__.__file__)
    else:
        print(__main__.my_name)
```

Example usage of this module could be as follows:

```python
# start.py
import sys
from namely import print_user_name

# my_name = "Dinsdale"

def main():
    try:
        print_user_name()
    except ValueError as ve:
        return str(ve)

if __name__ == '__main__':
    sys.exit(main())
```

Now, if we started our program, the result would look like this:

```
$ python3 start.py
Define the variable 'my_name'!
```

The exit code of the program would be 1, indicating an error. Uncommenting the line with `my_name = "Dinsdale"` fixes the program and now it exits with status code 0, indicating success:

```
$ python3 start.py
Dinsdale found in file /path/to/start.py
```

Note that importing __main__ doesn’t cause any issues with unintentionally running top-level code meant for script use which is put in the if __name__ == "__main__" block of the start module. Why does this work?

Python inserts an empty __main__ module in `sys.modules` at interpreter startup, and populates it by running top-level code. In our example this is the start module which runs line by line and imports namely. In turn, namely imports __main__ (which is really start). That’s an import cycle! Fortunately, since the partially populated __main__ module is present in `sys.modules`, Python passes that to namely. See Special considerations for __main__ in the import system’s reference for details on how this works.
The Python REPL is another example of a “top-level environment”, so anything defined in the REPL becomes part of the __main__ scope:

```python
>>> import namely
>>> namely.did_user_define_their_name()
False
>>> namely.print_user_name()
Traceback (most recent call last):
... ValueError: Define the variable `my_name`!
>>> my_name = 'Jabberwocky'
>>> namely.did_user_define_their_name()
True
>>> namely.print_user_name()
Jabberwocky
```

Note that in this case the __main__ scope doesn’t contain a __file__ attribute as it’s interactive.

The __main__ scope is used in the implementation of `pdb` and `rlcompleter`.

### 29.5 warnings — Warning control

**Source code:** Lib/warnings.py

Warning messages are typically issued in situations where it is useful to alert the user of some condition in a program, where that condition (normally) doesn’t warrant raising an exception and terminating the program. For example, one might want to issue a warning when a program uses an obsolete module.

Python programmers issue warnings by calling the `warn()` function defined in this module. (C programmers use `PyErr_WarnEx()`; see exception handling for details).

Warning messages are normally written to `sys.stderr`, but their disposition can be changed flexibly, from ignoring all warnings to turning them into exceptions. The disposition of warnings can vary based on the warning category, the text of the warning message, and the source location where it is issued. Repetitions of a particular warning for the same source location are typically suppressed.

There are two stages in warning control: first, each time a warning is issued, a determination is made whether a message should be issued or not; next, if a message is to be issued, it is formatted and printed using a user-settable hook.

The determination whether to issue a warning message is controlled by the warning filter, which is a sequence of matching rules and actions. Rules can be added to the filter by calling `filterwarnings()` and reset to its default state by calling `resetwarnings()`.

The printing of warning messages is done by calling `showwarning()`, which may be overridden; the default implementation of this function formats the message by calling `formatwarning()`, which is also available for use by custom implementations.

**See also:**

`logging.captureWarnings()` allows you to handle all warnings with the standard logging infrastructure.
29.5.1 Warning Categories

There are a number of built-in exceptions that represent warning categories. This categorization is useful to be able to filter out groups of warnings.

While these are technically *built-in exceptions*, they are documented here, because conceptually they belong to the warnings mechanism.

User code can define additional warning categories by subclassing one of the standard warning categories. A warning category must always be a subclass of the `Warning` class.

The following warnings category classes are currently defined:

<table>
<thead>
<tr>
<th>Class</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>Warning</code></td>
<td>This is the base class of all warning category classes. It is a subclass of <code>Exception</code>.</td>
</tr>
<tr>
<td><code>UserWarning</code></td>
<td>The default category for <code>warn()</code>.</td>
</tr>
<tr>
<td><code>DeprecationWarning</code></td>
<td>Base category for warnings about deprecated features when those warnings are intended for other Python developers (ignored by default, unless triggered by code in <code>__main__</code>).</td>
</tr>
<tr>
<td><code>SyntaxWarning</code></td>
<td>Base category for warnings about dubious syntactic features.</td>
</tr>
<tr>
<td><code>RuntimeWarning</code></td>
<td>Base category for warnings about dubious runtime features.</td>
</tr>
<tr>
<td><code>FutureWarning</code></td>
<td>Base category for warnings about deprecated features when those warnings are intended for end users of applications that are written in Python.</td>
</tr>
<tr>
<td><code>PendingDeprecationWarning</code></td>
<td>Base category for warnings about features that will be deprecated in the future (ignored by default).</td>
</tr>
<tr>
<td><code>ImportWarning</code></td>
<td>Base category for warnings triggered during the process of importing a module (ignored by default).</td>
</tr>
<tr>
<td><code>UnicodeWarning</code></td>
<td>Base category for warnings related to Unicode.</td>
</tr>
<tr>
<td><code>BytesWarning</code></td>
<td>Base category for warnings related to <code>bytes</code> and <code>bytearray</code>.</td>
</tr>
<tr>
<td><code>ResourceWarning</code></td>
<td>Base category for warnings related to resource usage (ignored by default).</td>
</tr>
</tbody>
</table>

Changed in version 3.7: Previously `DeprecationWarning` and `FutureWarning` were distinguished based on whether a feature was being removed entirely or changing its behaviour. They are now distinguished based on their intended audience and the way they’re handled by the default warnings filters.

29.5.2 The Warnings Filter

The warnings filter controls whether warnings are ignored, displayed, or turned into errors (raising an exception).

Conceptually, the warnings filter maintains an ordered list of filter specifications; any specific warning is matched against each filter specification in the list in turn until a match is found; the filter determines the disposition of the match. Each entry is a tuple of the form `(action, message, category, module, lineno)`, where:

- `action` is one of the following strings:
The Python Library Reference, Release 3.10.4

<table>
<thead>
<tr>
<th>Value</th>
<th>Disposition</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;default&quot;</td>
<td>print the first occurrence of matching warnings for each location (module + line number) where the warning is issued</td>
</tr>
<tr>
<td>&quot;error&quot;</td>
<td>turn matching warnings into exceptions</td>
</tr>
<tr>
<td>&quot;ignore&quot;</td>
<td>never print matching warnings</td>
</tr>
<tr>
<td>&quot;always&quot;</td>
<td>always print matching warnings</td>
</tr>
<tr>
<td>&quot;module&quot;</td>
<td>print the first occurrence of matching warnings for each module where the warning is issued (regardless of line number)</td>
</tr>
<tr>
<td>&quot;once&quot;</td>
<td>print only the first occurrence of matching warnings, regardless of location</td>
</tr>
</tbody>
</table>

- **message** is a string containing a regular expression that the start of the warning message must match. The expression is compiled to always be case-insensitive.
- **category** is a class (a subclass of `Warning`) of which the warning category must be a subclass in order to match.
- **module** is a string containing a regular expression that the module name must match. The expression is compiled to be case-sensitive.
- **lineno** is an integer that the line number where the warning occurred must match, or 0 to match all line numbers.

Since the `Warning` class is derived from the built-in `Exception` class, to turn a warning into an error we simply raise `category(message)`.

If a warning is reported and doesn’t match any registered filter then the “default” action is applied (hence its name).

### Describing Warning Filters

The warnings filter is initialized by `–W` options passed to the Python interpreter command line and the `PYTHONWARNINGS` environment variable. The interpreter saves the arguments for all supplied entries without interpretation in `sys.warnoptions`; the `warnings` module parses these when it is first imported (invalid options are ignored, after printing a message to `sys.stderr`).

Individual warnings filters are specified as a sequence of fields separated by colons:

```
action:message:category:module:line
```

The meaning of each of these fields is as described in *The Warnings Filter*. When listing multiple filters on a single line (as for `PYTHONWARNINGS`), the individual filters are separated by commas and the filters listed later take precedence over those listed before them (as they’re applied left-to-right, and the most recently applied filters take precedence over earlier ones).

Commonly used warning filters apply to either all warnings, warnings in a particular category, or warnings raised by particular modules or packages. Some examples:

```
default   # Show all warnings (even those ignored by default)
ignore    # Ignore all warnings
error     # Convert all warnings to errors
error::ResourceWarning  # Treat ResourceWarning messages as errors
default::DeprecationWarning  # Show DeprecationWarning messages
ignore, default::mymodule  # Only report warnings triggered by "mymodule"
error::mymodule[.\*]  # Convert warnings to errors in "mymodule"
# and any subpackages of "mymodule"
```
Default Warning Filter

By default, Python installs several warning filters, which can be overridden by the `-W` command-line option, the PYTHONWARNINGS environment variable and calls to `filterwarnings()`.

In regular release builds, the default warning filter has the following entries (in order of precedence):

```
default::DeprecationWarning::__main__
ignore::DeprecationWarning
ignore::PendingDeprecationWarning
ignore::ImportWarning
ignore::ResourceWarning
```

In a debug build, the list of default warning filters is empty.

Changed in version 3.2: `DeprecationWarning` is now ignored by default in addition to `PendingDeprecationWarning`.

Changed in version 3.7: `DeprecationWarning` is once again shown by default when triggered directly by code in `__main__`.

Changed in version 3.7: `BytesWarning` no longer appears in the default filter list and is instead configured via `sys.warnoptions` when `-b` is specified twice.

Overriding the default filter

Developers of applications written in Python may wish to hide all Python level warnings from their users by default, and only display them when running tests or otherwise working on the application. The `sys.warnoptions` attribute used to pass filter configurations to the interpreter can be used as a marker to indicate whether or not warnings should be disabled:

```
import sys
if not sys.warnoptions:
    import warnings
    warnings.simplefilter("ignore")
```

Developers of test runners for Python code are advised to instead ensure that all warnings are displayed by default for the code under test, using code like:

```
import sys
if not sys.warnoptions:
    import os, warnings
    warnings.simplefilter("default")  # Change the filter in this process
    os.environ["PYTHONWARNINGS"] = "default"  # Also affect subprocesses
```

Finally, developers of interactive shells that run user code in a namespace other than `__main__` are advised to ensure that `DeprecationWarning` messages are made visible by default, using code like the following (where `user_ns` is the module used to execute code entered interactively):

```
import warnings
warnings.filterwarnings("default", category=DeprecationWarning,
                      module=user_ns.get("__name__"))
```
29.5.3 Temporarily Suppressing Warnings

If you are using code that you know will raise a warning, such as a deprecated function, but do not want to see the warning (even when warnings have been explicitly configured via the command line), then it is possible to suppress the warning using the `catch_warnings` context manager:

```python
import warnings

def fxn():
    warnings.warn("deprecated", DeprecationWarning)

with warnings.catch_warnings():
    warnings.simplefilter("ignore")
    fxn()
```

While within the context manager all warnings will simply be ignored. This allows you to use known-deprecated code without having to see the warning while not suppressing the warning for other code that might not be aware of its use of deprecated code. Note: this can only be guaranteed in a single-threaded application. If two or more threads use the `catch_warnings` context manager at the same time, the behavior is undefined.

29.5.4 Testing Warnings

To test warnings raised by code, use the `catch_warnings` context manager. With it you can temporarily mutate the warnings filter to facilitate your testing. For instance, do the following to capture all raised warnings to check:

```python
import warnings

def fxn():
    warnings.warn("deprecated", DeprecationWarning)

with warnings.catch_warnings(record=True) as w:
    # Cause all warnings to always be triggered.
    warnings.simplefilter("always")
    # Trigger a warning.
    fxn()
    # Verify some things
    assert len(w) == 1
    assert issubclass(w[-1].category, DeprecationWarning)
    assert "deprecated" in str(w[-1].message)
```

One can also cause all warnings to be exceptions by using `error` instead of `always`. One thing to be aware of is that if a warning has already been raised because of a once/default rule, then no matter what filters are set the warning will not be seen again unless the warnings registry related to the warning has been cleared.

Once the context manager exits, the warnings filter is restored to its state when the context was entered. This prevents tests from changing the warnings filter in unexpected ways between tests and leading to indeterminate test results. The `showwarning()` function in the module is also restored to its original value. Note: this can only be guaranteed in a single-threaded application. If two or more threads use the `catch_warnings` context manager at the same time, the behavior is undefined.

When testing multiple operations that raise the same kind of warning, it is important to test them in a manner that confirms each operation is raising a new warning (e.g. set warnings to be raised as exceptions and check the operations raise exceptions, check that the length of the warning list continues to increase after each operation, or else delete the previous entries from the warnings list before each new operation).
29.5.5 Updating Code For New Versions of Dependencies

Warning categories that are primarily of interest to Python developers (rather than end users of applications written in Python) are ignored by default.

Notably, this “ignored by default” list includes `DeprecationWarning` (for every module except `__main__`), which means developers should make sure to test their code with typically ignored warnings made visible in order to receive timely notifications of future breaking API changes (whether in the standard library or third party packages).

In the ideal case, the code will have a suitable test suite, and the test runner will take care of implicitly enabling all warnings when running tests (the test runner provided by the `unittest` module does this).

In less ideal cases, applications can be checked for use of deprecated interfaces by passing `-Wd` to the Python interpreter (this is shorthand for `-W default`) or setting `PYTHONWARNINGS=default` in the environment. This enables default handling for all warnings, including those that are ignored by default. To change what action is taken for encountered warnings you can change what argument is passed to `-W` (e.g. `-W error`). See the `-W` flag for more details on what is possible.

29.5.6 Available Functions

`warnings.warn(message, category=None, stacklevel=1, source=None)`

Issue a warning, or maybe ignore it or raise an exception. The `category` argument, if given, must be a `warning category class`; it defaults to `UserWarning`. Alternatively, `message` can be a `Warning` instance, in which case `category` will be ignored and `message.__class__` will be used. In this case, the message text will be `str(message)`. This function raises an exception if the particular warning issued is changed into an error by the `warnings filter`. The `stacklevel` argument can be used by wrapper functions written in Python, like this:

```python
def deprecation(message):
    warnings.warn(message, DeprecationWarning, stacklevel=2)
```

This makes the warning refer to `deprecation`’s caller, rather than to the source of `deprecation()` itself (since the latter would defeat the purpose of the warning message).

`source`, if supplied, is the destroyed object which emitted a `ResourceWarning`.

Changed in version 3.6: Added `source` parameter.

`warnings.warn_explicit(message, category, filename, lineno, module=None, registry=None, module_globals=None, source=None)`

This is a low-level interface to the functionality of `warn()`, passing in explicitly the message, category, filename and line number, and optionally the module name and the registry (which should be the `__warningregistry__` dictionary of the module). The module name defaults to the filename with `.py` stripped; if no registry is passed, the warning is never suppressed. `message` must be a string and `category` a subclass of `Warning` or `message` may be a `Warning` instance, in which case `category` will be ignored.

`module_globals`, if supplied, should be the global namespace in use by the code for which the warning is issued. (This argument is used to support displaying source for modules found in zipfiles or other non-filesystem import sources).

`source`, if supplied, is the destroyed object which emitted a `ResourceWarning`.

Changed in version 3.6: Add the `source` parameter.

`warnings.showwarning(message, category, filename, lineno, file=None, line=None)`

Write a warning to a file. The default implementation calls `formatwarning(message, category, filename, lineno, line)` and writes the resulting string to `file`, which defaults to `sys.stderr`. You may replace this function with any callable by assigning to `warnings.showwarning`. `line` is a line of source code to be included in the warning message; if `line` is not supplied, `showwarning()` will try to read the line specified by `filename` and `lineno`.

`warnings.formatwarning(message, category, filename, lineno, line=None)`

Format a warning the standard way. This returns a string which may contain embedded newlines and ends
in a newline.  `line` is a line of source code to be included in the warning message; if `line` is not supplied, `formatwarning()` will try to read the line specified by `filename` and `lineno`.

```python
warnings.filterwarnings (action, message='', category=Warning, module='', lineno=0, append=False)
```

Insert an entry into the list of `warnings filter specifications`. The entry is inserted at the front by default; if `append` is true, it is inserted at the end. This checks the types of the arguments, compiles the `message` and `module` regular expressions, and inserts them as a tuple in the list of warnings filters. Entries closer to the front of the list override entries later in the list, if both match a particular warning. Omitted arguments default to a value that matches everything.

```python
warnings.simplefilter (action, category=Warning, lineno=0, append=False)
```

Insert a simple entry into the list of `warnings filter specifications`. The meaning of the function parameters is as for `filterwarnings()`, but regular expressions are not needed as the filter inserted always matches any message in any module as long as the category and line number match.

```python
warnings.resetwarnings ()
```

Reset the warnings filter. This discards the effect of all previous calls to `filterwarnings()`, including that of the `-W` command line options and calls to `simplefilter()`.

### 29.5.7 Available Context Managers

```python
class warnings.catch_warnings (*, record=False, module=None)
```

A context manager that copies and, upon exit, restores the warnings filter and the `showwarning()` function. If the `record` argument is `False` (the default) the context manager returns `None` on entry. If `record` is `True`, a list is returned that is progressively populated with objects as seen by a custom `showwarning()` function (which also suppresses output to `sys.stdout`). Each object in the list has attributes with the same names as the arguments to `showwarning()`.

The `module` argument takes a module that will be used instead of the module returned when you import `warnings` whose filter will be protected. This argument exists primarily for testing the `warnings` module itself.

**Note:** The `catch_warnings` manager works by replacing and then later restoring the module’s `showwarning()` function and internal list of filter specifications. This means the context manager is modifying global state and therefore is not thread-safe.

### 29.6 dataclasses — Data Classes

Source code: Lib/dataclasses.py

This module provides a decorator and functions for automatically adding generated special methods such as `__init__()` and `__repr__()` to user-defined classes. It was originally described in PEP 557.

The member variables to use in these generated methods are defined using PEP 526 type annotations. For example, this code:

```python
from dataclasses import dataclass

@dataclass
class InventoryItem:
    '''Class for keeping track of an item in inventory.'''
    name: str
    unit_price: float
    quantity_on_hand: int = 0

    def total_cost (self) -> float:
        return self.unit_price * self.quantity_on_hand
```
The Python Library Reference, Release 3.10.4

will add, among other things, a __init__() that looks like:

```python
def __init__(self, name: str, unit_price: float, quantity_on_hand: int = 0):
    self.name = name
    self.unit_price = unit_price
    self.quantity_on_hand = quantity_on_hand
```

Note that this method is automatically added to the class: it is not directly specified in the `InventoryItem` definition shown above.

New in version 3.7.

29.6.1 Module contents

@dataclasses.dataclass(*, init=True, repr=True, eq=True, order=False, unsafe_hash=False, _frozen=False, match_args=True, kw_only=False, slots=False)
This function is a decorator that is used to add generated special methods to classes, as described below.

The `dataclass()` decorator examines the class to find fields. A field is defined as a class variable that has a type annotation. With two exceptions described below, nothing in `dataclass()` examines the type specified in the variable annotation.

The order of the fields in all of the generated methods is the order in which they appear in the class definition.

The `dataclass()` decorator will add various “dunder” methods to the class, described below. If any of the added methods already exist in the class, the behavior depends on the parameter, as documented below. The decorator returns the same class that it is called on; no new class is created.

If `dataclass()` is used just as a simple decorator with no parameters, it acts as if it has the default values documented in this signature. That is, these three uses of `dataclass()` are equivalent:

```python
@dataclass
class C:
    ...

@dataclass()
class C:
    ...

@dataclass(init=True, repr=True, eq=True, order=False, unsafe_hash=False, _frozen=False, match_args=True, kw_only=False, slots=False)
class C:
    ...
```

The parameters to `dataclass()` are:

- **init**: If true (the default), a __init__() method will be generated. If the class already defines __init__(), this parameter is ignored.

- **repr**: If true (the default), a __repr__() method will be generated. The generated repr string will have the class name and the name and repr of each field, in the order they are defined in the class. Fields that are marked as being excluded from the repr are not included. For example: `InventoryItem(name='widget', unit_price=3.0, quantity_on_hand=10).

- **eq**: If true (the default), an __eq__() method will be generated. This method compares the class as if it were a tuple of its fields, in order. Both instances in the comparison must be of the identical type.

- **order**: If true (the default is False), __lt__(), __le__(), __gt__(), and __ge__() methods will be generated. These compare the class as if it were a tuple of its fields, in order. Both instances
in the comparison must be of the identical type. If order is true and eq is false, a `ValueError` is raised.

If the class already defines any of `__lt__()`, `__le__()`, `__gt__()`, or `__ge__()`, then `TypeError` is raised.

- **unsafe_hash**: If False (the default), a `__hash__()` method is generated according to how `eq` and `frozen` are set.

  `__hash__()` is used by built-in `hash()`, and when objects are added to hashed collections such as dictionaries and sets. Having a `__hash__()` implies that instances of the class are immutable. Mutability is a complicated property that depends on the programmer’s intent, the existence and behavior of `__eq__()`, and the values of the `eq` and `frozen` flags in the `dataclass()` decorator.

  By default, `dataclass()` will not implicitly add a `__hash__()` method unless it is safe to do so. Neither will it add or change an existing explicitly defined `__hash__()` method. Setting the class attribute `__hash__ = None` has a specific meaning to Python, as described in the `__hash__()` documentation.

  If `__hash__()` is not explicitly defined, or if it is set to `None`, then `dataclass()` may add an implicit `__hash__()` method. Although not recommended, you can force `dataclass()` to create a `__hash__() method with unsafe_hash=True`. This might be the case if your class is logically immutable but can nonetheless be mutated. This is a specialized use case and should be considered carefully.

Here are the rules governing implicit creation of a `__hash__() method. Note that you cannot both have an explicit `__hash__() method in your dataclass and set unsafe_hash=True; this will result in a `TypeError`.

If `eq` and `frozen` are both true, by default `dataclass()` will generate a `__hash__() method for you. If `eq` is true and `frozen` is false, `__hash__()` will be set to `None`, marking it unhashable (which it is, since it is mutable). If `eq` is false, `__hash__()` will be left untouched meaning the `__hash__()` method of the superclass will be used (if the superclass is `object`, this means it will fall back to id-based hashing).

- **frozen**: If true (the default is False), assigning to fields will generate an exception. This emulates read-only frozen instances. If `__setattr__()` or `__delattr__()` is defined in the class, then `TypeError` is raised. See the discussion below.

- **match_args**: If true (the default is True), the `__match_args__ tuple will be created from the list of parameters to the generated `__init__()` method (even if `__init__()` is not generated, see above). If false, or if `__match_args__` is already defined in the class, then `__match_args__` will not be generated.

  New in version 3.10.

- **kw_only**: If true (the default value is False), then all fields will be marked as keyword-only. If a field is marked as keyword-only, then the only affect is that the `__init__()` parameter generated from a keyword-only field must be specified with a keyword when `__init__()` is called. There is no effect on any other aspect of dataclasses. See the `parameter` glossary entry for details. Also see the `KW_ONLY` section.

  New in version 3.10.

- **slots**: If true (the default is False), `__slots__` attribute will be generated and new class will be returned instead of the original one. If `__slots__` is already defined in the class, then `TypeError` is raised.

  New in version 3.10.

`fields` may optionally specify a default value, using normal Python syntax:

29.6. `dataclasses` — Data Classes

1689
In this example, both `a` and `b` will be included in the added `__init__()` method, which will be defined as:

```python
def __init__(self, a: int, b: int = 0):
```

A `TypeError` will be raised if a field without a default value follows a field with a default value. This is true whether this occurs in a single class, or as a result of class inheritance.

```python
dataclasses.field(*, default=MISSING, default_factory=MISSING, init=True, repr=True, hash=None, compare=True, metadata=None, kw_only=MISSING)
```

For common and simple use cases, no other functionality is required. There are, however, some dataclass features that require additional per-field information. To satisfy this need for additional information, you can replace the default field value with a call to the provided `field()` function. For example:

```python
@dataclass
class C:
    mylist: list[int] = field(default_factory=list)

c = C()
c.mylist += [1, 2, 3]
```

As shown above, the `MISSING` value is a sentinel object used to detect if some parameters are provided by the user. This sentinel is used because `None` is a valid value for some parameters with a distinct meaning. No code should directly use the `MISSING` value.

The parameters to `field()` are:

- **default**: If provided, this will be the default value for this field. This is needed because the `field()` call itself replaces the normal position of the default value.
- **default_factory**: If provided, it must be a zero-argument callable that will be called when a default value is needed for this field. Among other purposes, this can be used to specify fields with mutable default values, as discussed below. It is an error to specify both `default` and `default_factory`.
- **init**: If true (the default), this field is included as a parameter to the generated `__init__()` method.
- **repr**: If true (the default), this field is included in the string returned by the generated `__repr__()` method.
- **hash**: This can be a bool or `None`. If true, this field is included in the generated `__hash__()` method. If `None` (the default), use the value of `compare`: this would normally be the expected behavior. A field should be considered in the hash if it’s used for comparisons. Setting this value to anything other than `None` is discouraged.

One possible reason to set `hash=False` but `compare=True` would be if a field is expensive to compute a hash value for, that field is needed for equality testing, and there are other fields that contribute to the type’s hash value. Even if a field is excluded from the hash, it will still be used for comparisons.

- **compare**: If true (the default), this field is included in the generated equality and comparison methods (`__eq__()`, `__gt__()` etc.).
- **metadata**: This can be a mapping or `None`. None is treated as an empty dict. This value is wrapped in a `MappingProxyType()` to make it read-only, and exposed on the `Field` object. It is not used at all by Data Classes, and is provided as a third-party extension mechanism. Multiple third-parties can each have their own key, to use as a namespace in the metadata.
- **kw_only**: If true, this field will be marked as keyword-only. This is used when the generated `__init__()` method’s parameters are computed.

New in version 3.10.
If the default value of a field is specified by a call to `field()`, then the class attribute for this field will be replaced by the specified default value. If no default is provided, then the class attribute will be deleted. The intent is that after the `dataclass()` decorator runs, the class attributes will all contain the default values for the fields, just as if the default value itself were specified. For example, after:

```python
@dataclass
class C:
    x: int
    y: int = field(repr=False)
    z: int = field(repr=False, default=10)
    t: int = 20
```

The class attribute `C.z` will be 10, the class attribute `C.t` will be 20, and the class attributes `C.x` and `C.y` will not be set.

```python
class dataclasses.Field
Field objects describe each defined field. These objects are created internally, and are returned by the `fields()` module-level method (see below). Users should never instantiate a `Field` object directly. Its documented attributes are:

- `name`: The name of the field.
- `type`: The type of the field.
- `default`, `default_factory`, `init`, `repr`, `hash`, `compare`, `metadata`, and `kw_only` have the identical meaning and values as they do in the `field()` function.

Other attributes may exist, but they are private and must not be inspected or relied on.

```python
dataclasses.fields(class_or_instance)
Returns a tuple of `Field` objects that define the fields for this dataclass. Accepts either a dataclass, or an instance of a dataclass. Raises `TypeError` if not passed a dataclass or instance of one. Does not return pseudo-fields which are `ClassVar` or `InitVar`.

```python
dataclasses.asdict(obj, *, dict_factory=dict)
Converts the dataclass `obj` to a dict (by using the factory function `dict_factory`). Each dataclass is converted to a dict of its fields, as name: value pairs. dataclasses, dicts, lists, and tuples are recursed into. Other objects are copied with `copy.deepcopy()`.

Example of using `asdict()` on nested dataclasses:

```python
@dataclass
class Point:
    x: int
    y: int

@dataclass
class C:
    mylist: list
        Point

p = Point(10, 20)
assert asdict(p) == {'x': 10, 'y': 20}

c = C([Point(0, 0), Point(10, 4)])
assert asdict(c) == {'mylist': [{'x': 0, 'y': 0}, {'x': 10, 'y': 4}]}
converted to a tuple of its field values. dataclasses, dicts, lists, and tuples are recursed into. Other objects are copied with `copy.deepcopy()`.

Continuing from the previous example:

```python
assert astuple(p) == (10, 20)
assert astuple(c) == ((0, 0), (10, 4)),
```

To create a shallow copy, the following workaround may be used:

```python
tuple(getattr(obj, field.name) for field in dataclasses.fields(obj))
```

`astuple()` raises `TypeError` if `obj` is not a dataclass instance.

dataclasses.make_dataclass(  
  cls_name, fields, *bases=(), namespace=None, init=True,  
  repr=field, eq=False, order=field, unsafe_hash=field,  
  frozen=field, match_args=field, kw_only=field, slots=field  
)

Creates a new dataclass with name `cls_name`, fields as defined in `fields`, base classes as given in `bases`, and initialized with a namespace as given in `namespace`. fields is an iterable whose elements are each either name, (name, type), or (name, type, Field). If just name is supplied, `typing.Any` is used for type. The values of `init`, `repr`, `eq`, `order`, `unsafe_hash`, `frozen`, `match_args`, `kw_only`, and `slots` have the same meaning as they do in `dataclass()`.

This function is not strictly required, because any Python mechanism for creating a new class with __annotations__ can then apply the `dataclass()` function to convert that class to a dataclass. This function is provided as a convenience. For example:

```python
C = make_dataclass('C',  
  [('x', int),  
   ('y',),  
   ('z', int, field(default=5))],  
  namespace={'add_one': lambda self: self.x + 1})
```

Is equivalent to:

```python
@dataclass
class C:  
  x: int  
  y: 'typing.Any'  
  z: int = 5
  
  def add_one(self):  
    return self.x + 1
```

dataclasses.replace(obj, **changes)

Creates a new object of the same type as `obj`, replacing fields with values from `changes`. If `obj` is not a DataClass, raises `TypeError`. If values in `changes` do not specify fields, raises `TypeError`.

The newly returned object is created by calling the `__init__()` method of the dataclass. This ensures that `__post_init__()` is called.

Init-only variables without default values, if any exist, must be specified on the call to `replace()` so that they can be passed to `__init__()` and `__post_init__()`.

It is an error for `changes` to contain any fields that are defined as having `init=False`. A `ValueError` will be raised in this case.

Be forewarned about how `init=False` fields work during a call to `replace()`. They are not copied from the source object, but rather are initialized in `__post_init__()`, if they’re initialized at all. It is expected that `init=False` fields will be rarely and judiciously used. If they are used, it might be wise to have alternate class constructors, or perhaps a custom `replace()` (or similarly named) method which handles instance copying.

dataclasses.is_dataclass(obj)

Return True if its parameter is a dataclass or an instance of one, otherwise return False.
If you need to know if a class is an instance of a dataclass (and not a dataclass itself), then add a further check for `not isinstance(obj, type)`:

```python
def is_dataclass_instance(obj):
    return is_dataclass(obj) and not isinstance(obj, type)
```

dataclasses.MISSING

A sentinel value signifying a missing default or default_factory.

dataclasses.KW_ONLY

A sentinel value used as a type annotation. Any fields after a pseudo-field with the type of `KW_ONLY` are marked as keyword-only fields. Note that a pseudo-field of type `KW_ONLY` is otherwise completely ignored. This includes the name of such a field. By convention, a name of `_` is used for a `KW_ONLY` field. Keyword-only fields signify `__init__()` parameters that must be specified as keywords when the class is instantiated.

In this example, the fields `y` and `z` will be marked as keyword-only fields:

```python
@dataclass
class Point:
    x: float
    __: KW_ONLY
    y: float
    z: float

p = Point(0, y=1.5, z=2.0)
```

In a single dataclass, it is an error to specify more than one field whose type is `KW_ONLY`. New in version 3.10.

exception dataclasses.FrozenInstanceError

Raised when an implicitly defined `__setattr__() or __delattr__()` is called on a dataclass which was defined with `frozen=True`. It is a subclass of `AttributeError`.

29.6.2 Post-init processing

The generated `__init__()` code will call a method named `__post_init__()`, if `__post_init__()` is defined on the class. It will normally be called as `self.__post_init__()`(). However, if any InitVar fields are defined, they will also be passed to `__post_init__()` in the order they were defined in the class. If no `__init__()` method is generated, then `__post_init__()` will not automatically be called.

Among other uses, this allows for initializing field values that depend on one or more other fields. For example:

```python
@dataclass
class C:
    a: float
    b: float
    c: float = field(init=False)

    def __post_init__(self):
        self.c = self.a + self.b
```

The `__init__() method generated by `dataclass()` does not call base class `__init__()` methods. If the base class has an `__init__()` method that has to be called, it is common to call this method in a `__post_init__()` method:

```python
@dataclass
class Rectangle:
    height: float
    width: float

@dataclass
```
class Square(Rectangle):
    side: float

    def __post_init__(self):
        super().__init__(self.side, self.side)

Note, however, that in general the dataclass-generated __init__() methods don’t need to be called, since the derived dataclass will take care of initializing all fields of any base class that is a dataclass itself.

See the section below on init-only variables for ways to pass parameters to __post_init__(). Also see the warning about how replace() handles init=False fields.

### 29.6.3 Class variables

One of two places where dataclass() actually inspects the type of a field is to determine if a field is a class variable as defined in PEP 526. It does this by checking if the type of the field is typing.ClassVar. If a field is a ClassVar, it is excluded from consideration as a field and is ignored by the dataclass mechanisms. Such ClassVar pseudo-fields are not returned by the module-level fields() function.

### 29.6.4 Init-only variables

The other place where dataclass() inspects a type annotation is to determine if a field is an init-only variable. It does this by seeing if the type of a field is of type dataclasses.InitVar. If a field is an InitVar, it is considered a pseudo-field called an init-only field. As it is not a true field, it is not returned by the module-level fields() function. Init-only fields are added as parameters to the generated __init__() method, and are passed to the optional __post_init__() method. They are not otherwise used by dataclasses.

For example, suppose a field will be initialized from a database, if a value is not provided when creating the class:

```python
@dataclass
class C:
    i: int
    j: int = None
    database: InitVar[DatabaseType] = None

    def __post_init__(self, database):
        if self.j is None and database is not None:
            self.j = database.lookup('j')

c = C(10, database=my_database)
```

In this case, fields() will return Field objects for i and j, but not for database.

### 29.6.5 Frozen instances

It is not possible to create truly immutable Python objects. However, by passing frozen=True to the dataclass() decorator you can emulate immutability. In that case, dataclasses will add __setattr__() and __delattr__() methods to the class. These methods will raise a FrozenInstanceError when invoked.

There is a tiny performance penalty when using frozen=True: __init__() cannot use simple assignment to initialize fields, and must use object.__setattr__().
29.6.6 Inheritance

When the dataclass is being created by the `dataclass()` decorator, it looks through all of the class’s base classes in reverse MRO (that is, starting at `object`) and, for each dataclass that it finds, adds the fields from that base class to an ordered mapping of fields. After all of the base class fields are added, it adds its own fields to the ordered mapping. All of the generated methods will use this combined, calculated ordered mapping of fields. Because the fields are in insertion order, derived classes override base classes. An example:

```python
@dataclass
class Base:
    x: Any = 15.0
    y: int = 0
@dataclass
class C(Base):
    z: int = 10
    x: int = 15
```

The final list of fields is, in order, `x`, `y`, `z`. The final type of `x` is `int`, as specified in class `C`.

The generated `__init__()` method for `C` will look like:

```python
def __init__(self, x: int = 15, y: int = 0, z: int = 10):
```

29.6.7 Re-ordering of keyword-only parameters in `__init__()`

After the parameters needed for `__init__()` are computed, any keyword-only parameters are moved to come after all regular (non-keyword-only) parameters. This is a requirement of how keyword-only parameters are implemented in Python: they must come after non-keyword-only parameters.

In this example, `Base.y`, `Base.w`, and `D.t` are keyword-only fields, and `Base.x` and `D.z` are regular fields:

```python
@dataclass
class Base:
    x: Any = 15.0
    _: KW_ONLY
    y: int = 0
    w: int = 1
@dataclass
class D(Base):
    z: int = 10
    t: int = field(kw_only=True, default=0)
```

The generated `__init__()` method for `D` will look like:

```python
def __init__(self, x: Any = 15.0, z: int = 10, *, y: int = 0, w: int = 1, t: int = 0):
```

Note that the parameters have been re-ordered from how they appear in the list of fields: parameters derived from regular fields are followed by parameters derived from keyword-only fields.

The relative ordering of keyword-only parameters is maintained in the re-ordered `__init__()` parameter list.
29.6.8 Default factory functions

If a `field()` specifies a `default_factory`, it is called with zero arguments when a default value for the field is needed. For example, to create a new instance of a list, use:

```python
mylist: list = field(default_factory=list)
```

If a field is excluded from `__init__()` (using `init=False`) and the field also specifies `default_factory`, then the default factory function will always be called from the generated `__init__()` function. This happens because there is no other way to give the field an initial value.

29.6.9 Mutable default values

Python stores default member variable values in class attributes. Consider this example, not using dataclasses:

```python
class C:
    x = []
    def add(self, element):
        self.x.append(element)

o1 = C()
o2 = C()
o1.add(1)
o2.add(2)
assert o1.x == [1, 2]
assert o1.x is o2.x
```

Note that the two instances of class `C` share the same class variable `x`, as expected.

Using dataclasses, if this code was valid:

```python
@dataclass
class D:
    x: List = []
    def add(self, element):
        self.x += element
```

it would generate code similar to:

```python
class D:
    x = []
    def __init__(self, x=x):
        self.x = x
    def add(self, element):
        self.x += element

assert D().x is D().x
```

This has the same issue as the original example using class `C`. That is, two instances of class `D` that do not specify a value for `x` when creating a class instance will share the same copy of `x`. Because dataclasses just use normal Python class creation they also share this behavior. There is no general way for Data Classes to detect this condition. Instead, the `dataclass()` decorator will raise a `TypeError` if it detects a default parameter of type `list`, `dict`, or `set`. This is a partial solution, but it does protect against many common errors.

Using default factory functions is a way to create new instances of mutable types as default values for fields:
```python
@dataclass
class D:
    x: list = field(default_factory=list)

assert D().x is not D().x
```

### 29.7 contextlib — Utilities for with-statement contexts

**Source code:** Lib/contextlib.py

This module provides utilities for common tasks involving the with statement. For more information see also [Context Manager Types](#) and context-managers.

#### 29.7.1 Utilities

Functions and classes provided:

**class contextlib.AbstractContextManager**

An abstract base class for classes that implement object.__enter__() and object.__exit__(). A default implementation for object.__enter__() is provided which returns self while object.__exit__() is an abstract method which by default returns None. See also the definition of [Context Manager Types](#).

New in version 3.6.

**class contextlib.AbstractAsyncContextManager**

An abstract base class for classes that implement object.__aenter__() and object.__aexit__(). A default implementation for object.__aenter__() is provided which returns self while object.__aexit__() is an abstract method which by default returns None. See also the definition of [async-context-managers](#).

New in version 3.7.

**@contextlib.contextmanager**

This function is a decorator that can be used to define a factory function for with statement context managers, without needing to create a class or separate __enter__() and __exit__() methods.

While many objects natively support use in with statements, sometimes a resource needs to be managed that isn’t a context manager in its own right, and doesn’t implement a close() method for use with contextlib. closing

An abstract example would be the following to ensure correct resource management:

```python
from contextlib import contextmanager

@contextmanager
def managed_resource(*args, **kwds):
    # Code to acquire resource, e.g.:
    resource = acquire_resource(*args, **kwds)
    try:
        yield resource
    finally:
        # Code to release resource, e.g.:
        release_resource(resource)

>>> with managed_resource(timeout=3600) as resource:
    ...
    # Resource is released at the end of this block,
    ...
    # even if code in the block raises an exception
```
The function being decorated must return a **generator**-iterator when called. This iterator must yield exactly one value, which will be bound to the targets in the `with` statement’s `as` clause, if any.

At the point where the generator yields, the block nested in the `with` statement is executed. The generator is then resumed after the block is exited. If an unhandled exception occurs in the block, it is reraised inside the generator at the point where the yield occurred. Thus, you can use a `try...except...finally` statement to trap the error (if any), or ensure that some cleanup takes place. If an exception is trapped merely in order to log it or to perform some action (rather than to suppress it entirely), the generator must reraise that exception. Otherwise the generator context manager will indicate to the `with` statement that the exception has been handled, and execution will resume with the statement immediately following the `with` statement.

`contextmanager()` uses `ContextDecorator` so the context managers it creates can be used as decorators as well as in `with` statements. When used as a decorator, a new generator instance is implicitly created on each function call (this allows the otherwise “one-shot” context managers created by `contextmanager()` to meet the requirement that context managers support multiple invocations in order to be used as decorators).

Changed in version 3.2: Use of `ContextDecorator`.

```python
@contextlib.asynccontextmanager
async def get_connection():
    conn = await acquire_db_connection()
    try:
        yield conn
    finally:
        await release_db_connection(conn)

async def get_all_users():
    async with get_connection() as conn:
        return conn.execute('SELECT ...')
```

New in version 3.7.

Context managers defined with `asynccontextmanager()` can be used either as decorators or with `async with` statements:

```python
from time import monotonic
from contextlib import asynccontextmanager

@asynccontextmanager
async def timeit():
    now = monotonic()
    try:
        yield
    finally:
        print(f'it took {monotonic() - now}s to run')

@timeit()
async def main():
    # ... async code ...
```

When used as a decorator, a new generator instance is implicitly created on each function call. This allows the otherwise “one-shot” context managers created by `asynccontextmanager()` to
meet the requirement that context managers support multiple invocations in order to be used as decorators.

Changed in version 3.10: Async context managers created with `asynccontextmanager()` can be used as decorators.

**contextlib.closing(thing)**

Return a context manager that closes `thing` upon completion of the block. This is basically equivalent to:

```python
from contextlib import contextmanager

@contextmanager
def closing(thing):
    try:
        yield thing
    finally:
        thing.close()
```

And lets you write code like this:

```python
from contextlib import closing
from urllib.request import urlopen

with closing(urlopen('https://www.python.org')) as page:
    for line in page:
        print(line)
```

without needing to explicitly close `page`. Even if an error occurs, `page.close()` will be called when the `with` block is exited.

**class contextlib.aclosing(thing)**

Return an async context manager that calls the `aclose()` method of `thing` upon completion of the block. This is basically equivalent to:

```python
from contextlib import asynccontextmanager

@asynccontextmanager
async def aclosing(thing):
    try:
        yield thing
    finally:
        await thing.aclose()
```

Significantly, `aclosing()` supports deterministic cleanup of async generators when they happen to exit early by `break` or an exception. For example:

```python
from contextlib import aclosing

async with aclosing(my_generator()) as values:
    async for value in values:
        if value == 42:
            break
```

This pattern ensures that the generator’s async exit code is executed in the same context as its iterations (so that exceptions and context variables work as expected, and the exit code isn’t run after the lifetime of some task it depends on).

New in version 3.10.

**contextlib.nullcontext(enter_result=None)**

Return a context manager that returns `enter_result` from `__enter__`, but otherwise does nothing. It is intended to be used as a stand-in for an optional context manager, for example:
```python
def myfunction(arg, ignore_exceptions=False):
    if ignore_exceptions:
        # Use suppress to ignore all exceptions.
        cm = contextlib.suppress(Exception)
    else:
        # Do not ignore any exceptions, cm has no effect.
        cm = contextlib.nullcontext()
    with cm:
        # Do something
```

An example using `enter_result`:

```python
def process_file(file_or_path):
    if isinstance(file_or_path, str):
        # If string, open file
        cm = open(file_or_path)
    else:
        # Caller is responsible for closing file
        cm = nullcontext(file_or_path)
    with cm as file:
        # Perform processing on the file
```

It can also be used as a stand-in for asynchronous context managers:

```python
async def send_http(session=None):
    if not session:
        # If no http session, create it with aiohttp
        cm = aiohttp.ClientSession()
    else:
        # Caller is responsible for closing the session
        cm = nullcontext(session)
    async with cm as session:
        # Send http requests with session
```

New in version 3.7.
Changed in version 3.10: `asynchronous context manager` support was added.

`contextlib.suppress(*exceptions)`
Return a context manager that suppresses any of the specified exceptions if they occur in the body of a `with` statement and then resumes execution with the first statement following the end of the `with` statement.

As with any other mechanism that completely suppresses exceptions, this context manager should be used only to cover very specific errors where silently continuing with program execution is known to be the right thing to do.

For example:

```python
from contextlib import suppress

with suppress(FileNotFoundError):
    os.remove('somefile.tmp')

with suppress(FileNotFoundError):
    os.remove('someotherfile.tmp')
```

This code is equivalent to:

```python
try:
    os.remove('somefile.tmp')
except FileNotFoundError:
```

(continues on next page)
pass
try:
    os.remove('someotherfile.tmp')
except FileNotFoundError:
    pass

This context manager is reentrant.

New in version 3.4.

collectors.redirect_stdout(new_target)
Context manager for temporarily redirecting sys.stdout to another file or file-like object.

This tool adds flexibility to existing functions or classes whose output is hardwired to stdout.

For example, the output of help() normally is sent to sys.stdout. You can capture that output in a string by redirecting the output to an io.StringIO object. The replacement stream is returned from the __enter__ method and so is available as the target of the with statement:

```python
with redirect_stdout(io.StringIO()) as f:
    help(pow)
s = f.getvalue()
```

To send the output of help() to a file on disk, redirect the output to a regular file:

```python
with open('help.txt', 'w') as f:
    with redirect_stdout(f):
        help(pow)
```

To send the output of help() to sys.stderr:

```python
with redirect_stdout(sys.stderr):
    help(pow)
```

Note that the global side effect on sys.stdout means that this context manager is not suitable for use in library code and most threaded applications. It also has no effect on the output of subprocesses. However, it is still a useful approach for many utility scripts.

This context manager is reentrant.

New in version 3.4.

collectors.redirect_stderr(new_target)
 Similar to redirect_stdout() but redirecting sys.stderr to another file or file-like object.

This context manager is reentrant.

New in version 3.5.

class Collectors.ContextDecorator
A base class that enables a context manager to also be used as a decorator.

Context managers inheriting from ContextDecorator have to implement __enter__ and __exit__ as normal. __exit__ retains its optional exception handling even when used as a decorator.

ContextDecorator is used by contextmanager(), so you get this functionality automatically.

Example of ContextDecorator:

```python
from collectors import ContextDecorator

class mycontext(ContextDecorator):
    def __enter__(self):
        print('Starting')
```

(continues on next page)
return self

def __exit__(self, *exc):
    print('Finishing')
    return False

>>> @mycontext()
... def function():
...     print('The bit in the middle')
...
>>> function()
Starting
The bit in the middle
Finishing

>>> with mycontext():
...     print('The bit in the middle')
...
Starting
The bit in the middle
Finishing

This change is just syntactic sugar for any construct of the following form:

def f():
    with cm():
        # Do stuff

ContextDecorator lets you instead write:

@cm()
def f():
    # Do stuff

It makes it clear that the cm applies to the whole function, rather than just a piece of it (and saving an indentation level is nice, too).

Existing context managers that already have a base class can be extended by using ContextDecorator as a mixin class:

```python
from contextlib import ContextDecorator

class mycontext(ContextBaseClass, ContextDecorator):
    def __enter__(self):
        return self

    def __exit__(self, *exc):
        return False
```

Note: As the decorated function must be able to be called multiple times, the underlying context manager must support use in multiple with statements. If this is not the case, then the original construct with the explicit with statement inside the function should be used.

New in version 3.2.

class contextlib.AsyncContextDecorator
    Similar to ContextDecorator but only for asynchronous functions.

Example of AsyncContextDecorator:
from asyncio import run
from contextlib import AsyncContextDecorator

class mycontext(AsyncContextDecorator):
    async def __aenter__(self):
        print('Starting')
        return self

    async def __aexit__(self, *exc):
        print('Finishing')
        return False

>>> @mycontext()
... async def function():
...     print('The bit in the middle')
...
>>> run(function())
Starting
The bit in the middle
Finishing

>>> async def function():
...     async with mycontext():
...         print('The bit in the middle')
...
>>> run(function())
Starting
The bit in the middle
Finishing

New in version 3.10.

class contextlib.ExitStack
A context manager that is designed to make it easy to programmatically combine other context managers and cleanup functions, especially those that are optional or otherwise driven by input data.

For example, a set of files may easily be handled in a single with statement as follows:

```python
with ExitStack() as stack:
    files = [stack.enter_context(open(fname)) for fname in filenames]
    # All opened files will automatically be closed at the end of
    # the with statement, even if attempts to open files later
    # in the list raise an exception
```

Each instance maintains a stack of registered callbacks that are called in reverse order when the instance is closed (either explicitly or implicitly at the end of a with statement). Note that callbacks are not invoked implicitly when the context stack instance is garbage collected.

This stack model is used so that context managers that acquire their resources in their __init__ method (such as file objects) can be handled correctly.

Since registered callbacks are invoked in the reverse order of registration, this ends up behaving as if multiple nested with statements had been used with the registered set of callbacks. This even extends to exception handling - if an inner callback suppresses or replaces an exception, then outer callbacks will be passed arguments based on that updated state.

This is a relatively low level API that takes care of the details of correctly unwinding the stack of exit callbacks. It provides a suitable foundation for higher level context managers that manipulate the exit stack in application specific ways.

New in version 3.3.

```python
enter_context(cm)
```
Enters a new context manager and adds its __exit__() method to the callback stack. The return value
is the result of the context manager's own \_\_enter\_\_() method.

These context managers may suppress exceptions just as they normally would if used directly as part of a with statement.

**push** *(exit)*

Adds a context manager's \_\_exit\_\_() method to the callback stack.

As \_\_enter\_\_ is *not* invoked, this method can be used to cover part of a \_\_enter\_\_() implementation with a context manager's own \_\_exit\_\_() method.

If passed an object that is not a context manager, this method assumes it is a callback with the same signature as a context manager's \_\_exit\_\_() method and adds it directly to the callback stack.

By returning true values, these callbacks can suppress exceptions the same way context manager \_\_exit\_\_() methods can.

The passed in object is returned from the function, allowing this method to be used as a function decorator.

**callback** *(callback, /, *args, **kwds)*

Accepts an arbitrary callback function and arguments and adds it to the callback stack.

Unlike the other methods, callbacks added this way cannot suppress exceptions (as they are never passed the exception details).

The passed in callback is returned from the function, allowing this method to be used as a function decorator.

**pop_all()**

Transfers the callback stack to a fresh ExitStack instance and returns it. No callbacks are invoked by this operation - instead, they will now be invoked when the new stack is closed (either explicitly or implicitly at the end of a with statement).

For example, a group of files can be opened as an “all or nothing” operation as follows:

```python
with ExitStack() as stack:
    files = [stack.enter_context(open(fname)) for fname in filenames]
    # Hold onto the close method, but don't call it yet.
    close_files = stack.pop_all().close
    # If opening any file fails, all previously opened files will be
    # closed automatically. If all files are opened successfully,
    # they will remain open even after the with statement ends.
    # close_files() can then be invoked explicitly to close them all.
```

**close()**

Immediately unwinds the callback stack, invoking callbacks in the reverse order of registration. For any context managers and exit callbacks registered, the arguments passed in will indicate that no exception occurred.

**class** contextlib.AsyncExitStack

An asynchronous context manager, similar to ExitStack, that supports combining both synchronous and asynchronous context managers, as well as having coroutines for cleanup logic.

The close() method is not implemented, aclose() must be used instead.

**coroutine enter_async_context** *(cm)*

Similar to enter_context() but expects an asynchronous context manager.

**push_async_exit** *(exit)*

Similar to push() but expects either an asynchronous context manager or a coroutine function.

**push_async_callback** *(callback, /, *args, **kwds)*

Similar to callback() but expects a coroutine function.

**coroutine aclose()**

Similar to close() but properly handles awaitables.

Continuing the example for `asynccontextmanager()`:
async with AsyncExitStack() as stack:
    connections = [await stack.enter_async_context(get_connection())
        for i in range(5)]
    # All opened connections will automatically be released at the end of
    # the async with statement, even if attempts to open a connection
    # later in the list raise an exception.

New in version 3.7.

29.7.2 Examples and Recipes

This section describes some examples and recipes for making effective use of the tools provided by contextlib.

Supporting a variable number of context managers

The primary use case for ExitStack is the one given in the class documentation: supporting a variable number of context managers and other cleanup operations in a single with statement. The variability may come from the number of context managers needed being driven by user input (such as opening a user specified collection of files), or from some of the context managers being optional:

```python
with ExitStack() as stack:
    for resource in resources:
        stack.enter_context(resource)
    if need_special_resource():
        special = acquire_special_resource()
        stack.callback(release_special_resource, special)
    # Perform operations that use the acquired resources
```

As shown, ExitStack also makes it quite easy to use with statements to manage arbitrary resources that don’t natively support the context management protocol.

Catching exceptions from __enter__ methods

It is occasionally desirable to catch exceptions from an __enter__ method implementation, without inadvertently catching exceptions from the with statement body or the context manager’s __exit__ method. By using ExitStack the steps in the context management protocol can be separated slightly in order to allow this:

```python
stack = ExitStack()
try:
    x = stack.enter_context(cm)
except Exception:
    # handle __enter__ exception
else:
    with stack:
        # Handle normal case
```

Actually needing to do this is likely to indicate that the underlying API should be providing a direct resource management interface for use with try/except/finally statements, but not all APIs are well designed in that regard. When a context manager is the only resource management API provided, then ExitStack can make it easier to handle various situations that can’t be handled directly in a with statement.
Cleaning up in an __enter__ implementation

As noted in the documentation of `ExitStack.push()`, this method can be useful in cleaning up an already allocated resource if later steps in the __enter__() implementation fail.

Here’s an example of doing this for a context manager that accepts resource acquisition and release functions, along with an optional validation function, and maps them to the context management protocol:

```python
from contextlib import contextmanager, AbstractContextManager, ExitStack

class ResourceManager(AbstractContextManager):
    def __init__(self, acquire_resource, release_resource, check_resource_ok=None):
        self.acquire_resource = acquire_resource
        self.release_resource = release_resource
        if check_resource_ok is None:
            def check_resource_ok(resource):
                return True
            self.check_resource_ok = check_resource_ok

    @contextmanager
    def __cleanup_on_error(self):
        with ExitStack() as stack:
            yield
            # The validation check passed and didn’t raise an exception
            # Accordingly, we want to keep the resource, and pass it
            # back to our caller
            stack.pop_all()

    def __enter__(self):
        resource = self.acquire_resource()
        with self.__cleanup_on_error():
            if not self.check_resource_ok(resource):
                msg = "Failed validation for {!r}"
                raise RuntimeError(msg.format(resource))
        return resource

    def __exit__(self, *exc_details):
        # We don’t need to duplicate any of our resource release logic
        self.release_resource()
```

Replacing any use of try–finally and flag variables

A pattern you will sometimes see is a try–finally statement with a flag variable to indicate whether or not the body of the finally clause should be executed. In its simplest form (that can’t already be handled just by using an except clause instead), it looks something like this:

```python
cleanup_needed = True
try:
    result = perform_operation()
    if result:
        cleanup_needed = False
finally:
    if cleanup_needed:
        cleanup_resources()
```

As with any try statement based code, this can cause problems for development and review, because the setup code and the cleanup code can end up being separated by arbitrarily long sections of code.

`ExitStack` makes it possible to instead register a callback for execution at the end of a with statement, and then later decide to skip executing that callback:
from contextlib import ExitStack

with ExitStack() as stack:
    stack.callback(cleanup_resources)
    result = perform_operation()
    if result:
        stack.pop_all()

This allows the intended cleanup up behaviour to be made explicit up front, rather than requiring a separate flag variable.

If a particular application uses this pattern a lot, it can be simplified even further by means of a small helper class:

class Callback(ExitStack):
    def __init__(self, callback, /, *args, **kwargs):
        super().__init__()
        self.callback(callback, *args, **kwargs)

        def cancel(self):
            self.pop_all()

with Callback(cleanup_resources) as cb:
    result = perform_operation()
    if result:
        cb.cancel()

If the resource cleanup isn’t already neatly bundled into a standalone function, then it is still possible to use the decorator form of `ExitStack.callback()` to declare the resource cleanup in advance:

from contextlib import ExitStack

with ExitStack() as stack:
    @stack.callback
    def cleanup_resources():
        ...
        result = perform_operation()
        if result:
            stack.pop_all()

Due to the way the decorator protocol works, a callback function declared this way cannot take any parameters. Instead, any resources to be released must be accessed as closure variables.

**Using a context manager as a function decorator**

`ContextDecorator` makes it possible to use a context manager in both an ordinary `with` statement and also as a function decorator.

For example, it is sometimes useful to wrap functions or groups of statements with a logger that can track the time of entry and time of exit. Rather than writing both a function decorator and a context manager for the task, inheriting from `ContextDecorator` provides both capabilities in a single definition:

from contextlib import ContextDecorator
import logging

logging.basicConfig(level=logging.INFO)

class track_entry_and_exit(ContextDecorator):
    def __init__(self, name):
        self.name = name
def __enter__(self):
    logging.info('Entering: %s', self.name)

    def __exit__(self, exc_type, exc, exc_tb):
        logging.info('Exiting: %s', self.name)

Instances of this class can be used as both a context manager:

    with track_entry_and_exit('widget loader'):
        print('Some time consuming activity goes here')
        load_widget()

And also as a function decorator:

    @track_entry_and_exit('widget loader')
    def activity():
        print('Some time consuming activity goes here')
        load_widget()

Note that there is one additional limitation when using context managers as function decorators: there's no way to access the return value of __enter__(). If that value is needed, then it is still necessary to use an explicit with statement.

See also:

**PEP 343 - The “with” statement** The specification, background, and examples for the Python with statement.

### 29.7.3 Single use, reusable and reentrant context managers

Most context managers are written in a way that means they can only be used effectively in a with statement once. These single use context managers must be created afresh each time they’re used - attempting to use them a second time will trigger an exception or otherwise not work correctly.

This common limitation means that it is generally advisable to create context managers directly in the header of the with statement where they are used (as shown in all of the usage examples above).

Files are an example of effectively single use context managers, since the first with statement will close the file, preventing any further IO operations using that file object.

Context managers created using contextmanager() are also single use context managers, and will complain about the underlying generator failing to yield if an attempt is made to use them a second time:

```python
>>> from contextlib import contextmanager
>>> @contextmanager
    ... def singleuse():
    ...     print("Before")
    ...     yield
    ...     print("After")
    ...
>>> cm = singleuse()
>>> with cm:
    ...     pass
... Before
After
>>> with cm:
    ...     pass
... Traceback (most recent call last):
```
Reentrant context managers

More sophisticated context managers may be “reentrant”. These context managers can not only be used in multiple with statements, but may also be used inside a with statement that is already using the same context manager.

`threading.RLock` is an example of a reentrant context manager, as are `suppress()` and `redirect_stdout()`. Here’s a very simple example of reentrant use:

```python
>>> from contextlib import redirect_stdout
>>> from io import StringIO
>>> stream = StringIO()
>>> write_to_stream = redirect_stdout(stream)
>>> with write_to_stream:
...     print("This is written to the stream rather than stdout")
...     with write_to_stream:
...         print("This is also written to the stream")
...
>>> print("This is written directly to stdout")
This is written directly to stdout
>>> print(stream.getvalue())
This is written to the stream rather than stdout
This is also written to the stream
```

Real world examples of reentrancy are more likely to involve multiple functions calling each other and hence be far more complicated than this example.

Note also that being reentrant is not the same thing as being thread safe. `redirect_stdout()`, for example, is definitely not thread safe, as it makes a global modification to the system state by binding `sys.stdout` to a different stream.

Reusable context managers

Distinct from both single use and reentrant context managers are “reusable” context managers (or, to be completely explicit, “reusable, but not reentrant” context managers, since reentrant context managers are also reusable). These context managers support being used multiple times, but will fail (or otherwise not work correctly) if the specific context manager instance has already been used in a containing with statement.

`threading.Lock` is an example of a reusable, but not reentrant, context manager (for a reentrant lock, it is necessary to use `threading.RLock` instead).

Another example of a reusable, but not reentrant, context manager is `ExitStack`, as it invokes all currently registered callbacks when leaving any with statement, regardless of where those callbacks were added:

```python
>>> from contextlib import ExitStack
>>> stack = ExitStack()
>>> with stack:
...     stack.callback(print, "Callback: from first context")
...     print("Leaving first context")
...
Callback: from first context
Leaving first context
>>> with stack:
...     stack.callback(print, "Callback: from second context")
...     print("Leaving second context")
...
(continues on next page)
```
As the output from the example shows, reusing a single stack object across multiple with statements works correctly, but attempting to nest them will cause the stack to be cleared at the end of the innermost with statement, which is unlikely to be desirable behaviour.

Using separate `ExitStack` instances instead of reusing a single instance avoids that problem:

```
>>> from contextlib import ExitStack
>>> with ExitStack() as outer_stack:
...    outer_stack.callback(print, "Callback: from outer context")
...    with ExitStack() as inner_stack:
...        inner_stack.callback(print, "Callback: from inner context")
...        print("Leaving inner context")
...        print("Leaving outer context")
...        print("Leaving inner context")
...        print("Leaving outer context")
Leaving inner context
Callback: from inner context
Leaving outer context
```

# 29.8 abc — Abstract Base Classes

This module provides the infrastructure for defining *abstract base classes* (ABCs) in Python, as outlined in PEP 3119; see the PEP for why this was added to Python. (See also PEP 3141 and the `numbers` module regarding a type hierarchy for numbers based on ABCs.)

The `collections` module has some concrete classes that derive from ABCs; these can, of course, be further derived. In addition, the `collections.abc` submodule has some ABCs that can be used to test whether a class or instance provides a particular interface, for example, if it is hashable or if it is a mapping.

This module provides the metaclass `ABCMeta` for defining ABCs and a helper class `ABC` to alternatively define ABCs through inheritance:

```python
class abc.ABC
    A helper class that has `ABCMeta` as its metaclass. With this class, an abstract base class can be created by simply deriving from `ABC` avoiding sometimes confusing metaclass usage, for example:
    
    ```python
    from abc import ABC
    class MyABC(ABC):
        pass
    ```

    Note that the type of `ABC` is still `ABCMeta`, therefore inheriting from `ABC` requires the usual precautions regarding metaclass usage, as multiple inheritance may lead to metaclass conflicts. One may also define an abstract base class by passing the metaclass keyword and using `ABCMeta` directly, for example:
```
```
from abc import ABCMeta

class MyABC(metaclass=ABCMeta):
    pass

New in version 3.4.

class abc.ABCMeta

Metaclass for defining Abstract Base Classes (ABCs).

Use this metaclass to create an ABC. An ABC can be subclassed directly, and then acts as a mix-in class. You
can also register unrelated concrete classes (even built-in classes) and unrelated ABCs as “virtual subclasses” –
these and their descendants will be considered subclasses of the registering ABC by the built-in issubclass()
function, but the registering ABC won’t show up in their MRO (Method Resolution Order) nor will method
implementations defined by the registering ABC be callable (not even via super()).¹

Classes created with a metaclass of ABCMeta have the following method:

register (subclass)

Register subclass as a “virtual subclass” of this ABC. For example:

```python
from abc import ABC

class MyABC(ABC):
    pass
MyABC.register(tuple)
assert issubclass(tuple, MyABC)
assert isinstance((), MyABC)
```

Changed in version 3.3: Returns the registered subclass, to allow usage as a class decorator.

Changed in version 3.4: To detect calls to register(), you can use the get_cache_token() function.

You can also override this method in an abstract base class:

__subclasshook__ (subclass)

(Must be defined as a class method.)

Check whether subclass is considered a subclass of this ABC. This means that you can customize the
behavior of issubclass further without the need to call register() on every class you want
to consider a subclass of the ABC. (This class method is called from the __subclasscheck__() method of the ABC.)

This method should return True, False or NotImplemented. If it returns True, the subclass is
considered a subclass of this ABC. If it returns False, the subclass is not considered a subclass of this
ABC, even if it would normally be one. If it returns NotImplemented, the subclass check is continued
with the usual mechanism.

For a demonstration of these concepts, look at this example ABC definition:

```python
class Foo:
    def __getitem__(self, index):
        ...
    def __len__(self):
        ...
    def get_iterator(self):
        return iter(self)
class MyIterable(ABC):
```

¹ C++ programmers should note that Python’s virtual base class concept is not the same as C++’s.
The ABC `MyIterable` defines the standard iterable method, `__iter__()`, as an abstract method. The implementation given here can still be called from subclasses. The `get_iterator()` method is also part of the `MyIterable` abstract base class, but it does not have to be overridden in non-abstract derived classes.

The `__subclasshook__()` class method defined here says that any class that has an `__iter__()` method in its `__dict__` (or in that of one of its base classes, accessed via the `__mro__` list) is considered a `MyIterable` too.

Finally, the last line makes `Foo` a virtual subclass of `MyIterable`, even though it does not define an `__iter__()` method (it uses the old-style iterable protocol, defined in terms of `__len__()` and `__getitem__()`). Note that this will not make `get_iterator` available as a method of `Foo`, so it is provided separately.

The `abc` module also provides the following decorator:

```python
@abc.abstractmethod
A decorator indicating abstract methods.
```

Using this decorator requires that the class’s metaclass is `ABCMeta` or is derived from it. A class that has a metaclass derived from `ABCMeta` cannot be instantiated unless all of its abstract methods and properties are overridden. The abstract methods can be called using any of the normal `super` call mechanisms. `abstractmethod()` may be used to declare abstract methods for properties and descriptors.

Dynamically adding abstract methods to a class, or attempting to modify the abstraction status of a method or class once it is created, are only supported using the `update_abstractmethods()` function. The `abstractmethod()` only affects subclasses derived using regular inheritance; “virtual subclasses” registered with the ABC’s `register()` method are not affected.

When `abstractmethod()` is applied in combination with other method descriptors, it should be applied as the innermost decorator, as shown in the following usage examples:

```python
class C(ABC):
    @abstractmethod
    def my_abstract_method(self, arg1):
        ...
    @classmethod
    @abstractmethod
    def my_abstract_classmethod(cls, arg2):
        ...
    @staticmethod
    @abstractmethod
    def my_abstract_staticmethod(arg3):
        ...
```

(continues on next page)
In order to correctly interoperate with the abstract base class machinery, the descriptor must identify itself as abstract using \_isabstractmethod\_. In general, this attribute should be True if any of the methods used to compose the descriptor are abstract. For example, Python’s built-in `property` does the equivalent of:

```python
@abstractmethod
def __isabstractmethod__(self):
    return any(getattr(f, '__isabstractmethod__', False) for f in (self._fget, self._fset, self._fdel))
```

**Note:** Unlike Java abstract methods, these abstract methods may have an implementation. This implementation can be called via the `super()` mechanism from the class that overrides it. This could be useful as an end-point for a super-call in a framework that uses cooperative multiple-inheritance.

The `abc` module also supports the following legacy decorators:

@abc.abstractclassmethod

New in version 3.2. Deprecated since version 3.3: It is now possible to use `classmethod` with `abstractmethod()`, making this decorator redundant.

A subclass of the built-in `classmethod()`, indicating an abstract classmethod. Otherwise it is similar to `abstractmethod()`.

This special case is deprecated, as the `classmethod()` decorator is now correctly identified as abstract when applied to an abstract method:

```python
class C(ABC):
    @classmethod
    @abstractmethod
    def my_abstract_classmethod(cls, arg):
        ...
```

@abc.abstractstaticmethod

New in version 3.2. Deprecated since version 3.3: It is now possible to use `staticmethod` with `abstractmethod()`, making this decorator redundant.

A subclass of the built-in `staticmethod()`, indicating an abstract staticmethod. Otherwise it is similar to `abstractmethod()`.
This special case is deprecated, as the `staticmethod()` decorator is now correctly identified as abstract when applied to an abstract method:

```python
class C(ABC):
    @staticmethod
    @abstractmethod
    def my_abstract_staticmethod(arg):
        ...
```

@abc.abstractproperty

Deprecated since version 3.3: It is now possible to use `property`, `property.getter()`, `property.setter()` and `property.deleter()` with `abstractmethod()`, making this decorator redundant.

A subclass of the built-in `property()`, indicating an abstract property.

This special case is deprecated, as the `property()` decorator is now correctly identified as abstract when applied to an abstract method:

```python
class C(ABC):
    @property
    @abstractmethod
    def my_abstract_property(self):
        ...
```

The above example defines a read-only property; you can also define a read-write abstract property by appropriately marking one or more of the underlying methods as abstract:

```python
class C(ABC):
    @property
    def x(self):
        ...

    @x.setter
    @abstractmethod
    def x(self, val):
        ...
```

If only some components are abstract, only those components need to be updated to create a concrete property in a subclass:

```python
class D(C):
    @C.x.setter
    def x(self, val):
        ...
```

The `abc` module also provides the following functions:

`abc.get_cache_token()`

Returns the current abstract base class cache token.

The token is an opaque object (that supports equality testing) identifying the current version of the abstract base class cache for virtual subclasses. The token changes with every call to `ABCMeta.register()` on any ABC.

New in version 3.4.

`abc.update_abstractmethods(clb)`

A function to recalculate an abstract class’s abstraction status. This function should be called if a class’s abstract methods have been implemented or changed after it was created. Usually, this function should be called from within a class decorator.

Returns `clb`, to allow usage as a class decorator.

If `clb` is not an instance of `ABCMeta`, does nothing.
Note: This function assumes that cls's superclasses are already updated. It does not update any subclasses.

New in version 3.10.

29.9 atexit — Exit handlers

The `atexit` module defines functions to register and unregister cleanup functions. Functions thus registered are automatically executed upon normal interpreter termination. `atexit` runs these functions in the reverse order in which they were registered; if you register A, B, and C, at interpreter termination time they will be run in the order C, B, A.

Note: The functions registered via this module are not called when the program is killed by a signal not handled by Python, when a Python fatal internal error is detected, or when `os._exit()` is called.

Changed in version 3.7: When used with C-API subinterpreters, registered functions are local to the interpreter they were registered in.

```python
atexit.register(func, *args, **kwargs)
```

Register `func` as a function to be executed at termination. Any optional arguments that are to be passed to `func` must be passed as arguments to `register()`. It is possible to register the same function and arguments more than once.

At normal program termination (for instance, if `sys.exit()` is called or the main module's execution completes), all functions registered are called in last in, first out order. The assumption is that lower level modules will normally be imported before higher level modules and thus must be cleaned up later.

If an exception is raised during execution of the exit handlers, a traceback is printed (unless `SystemExit` is raised) and the exception information is saved. After all exit handlers have had a chance to run, the last exception to be raised is re-raised.

This function returns `func`, which makes it possible to use it as a decorator.

```python
atexit.unregister(func)
```

Remove `func` from the list of functions to be run at interpreter shutdown. `unregister()` silently does nothing if `func` was not previously registered. If `func` has been registered more than once, every occurrence of that function in the `atexit` call stack will be removed. Equality comparisons (==) are used internally during unregistration, so function references do not need to have matching identities.

See also:

Module `readline` Useful example of `atexit` to read and write `readline` history files.

29.9.1 atexit Example

The following simple example demonstrates how a module can initialize a counter from a file when it is imported and save the counter's updated value automatically when the program terminates without relying on the application making an explicit call into this module at termination.

```python
try:
    with open('counterfile') as infile:
        _count = int(infile.read())
except FileNotFoundError:
    _count = 0

def incrcounter(n):
    global _count
    _count = _count + n
```

(continues on next page)
def savecounter():
    with open('counterfile', 'w') as outfile:
        outfile.write('%d
' % _count)

import atexit
atexit.register(savecounter)

Positional and keyword arguments may also be passed to `register()` to be passed along to the registered function when it is called:

def goodbye(name, adjective):
    print('Goodbye %s, it was %s to meet you.' % (name, adjective))

import atexit
atexit.register(goodbye, 'Donny', 'nice')
# or:
atexit.register(goodbye, adjective='nice', name='Donny')

Usage as a decorator:

import atexit

@atexit.register
def goodbye():
    print('You are now leaving the Python sector.')

This only works with functions that can be called without arguments.

### 29.10 traceback — Print or retrieve a stack traceback

**Source code:** Lib/traceback.py

This module provides a standard interface to extract, format and print stack traces of Python programs. It exactly mimics the behavior of the Python interpreter when it prints a stack trace. This is useful when you want to print stack traces under program control, such as in a "wrapper" around the interpreter. The module uses traceback objects — this is the object type that is stored in the `sys.last_traceback` variable and returned as the third item from `sys.exc_info()`.

The module defines the following functions:

- `traceback.print_tb(tb, limit=None, file=None)`
  - Print up to `limit` stack trace entries from traceback object `tb` (starting from the caller’s frame) if `limit` is positive. Otherwise, print the last `abs(limit)` entries. If `limit` is omitted or `None`, all entries are printed. If `file` is omitted or `None`, the output goes to `sys.stderr`; otherwise it should be an open file or file-like object to receive the output.
  - Changed in version 3.5: Added negative `limit` support.

- `traceback.print_exception(exc, /, value, tb, limit=None, file=None, chain=True)`
  - Print exception information and stack trace entries from traceback object `tb` to `file`. This differs from `print_tb()` in the following ways:
    - if `tb` is not `None`, it prints a header `Traceback (most recent call last):`
    - it prints the exception type and `value` after the stack trace
• if `type(value)` is `SyntaxError` and `value` has the appropriate format, it prints the line where the syntax error occurred with a caret indicating the approximate position of the error.

Since Python 3.10, instead of passing `value` and `tb`, an exception object can be passed as the first argument. If `value` and `tb` are provided, the first argument is ignored in order to provide backwards compatibility.

The optional `limit` argument has the same meaning as for `print_tb()`. If `chain` is true (the default), then chained exceptions (the `__cause__` or `__context__` attributes of the exception) will be printed as well, like the interpreter itself does when printing an unhandled exception.

Changed in version 3.5: The `etype` argument is ignored and inferred from the type of `value`.

Changed in version 3.10: The `etype` parameter has been renamed to `exc` and is now positional-only.

```python
traceback.print_exc(limit=None, file=None, chain=True)
```

This is a shorthand for `print_exception(*sys.exc_info()`, `limit`, `file`, `chain`).

```python
traceback.print_last(limit=None, file=None, chain=True)
```

This is a shorthand for `print_exception(sys.last_type, sys.last_value, sys.last_traceback, limit, file, chain)`. In general it will work only after an exception has reached an interactive prompt (see `sys.last_type`).

```python
traceback.print_stack(f=None, limit=None, file=None)
```

Print up to `limit` stack trace entries (starting from the invocation point) if `limit` is positive. Otherwise, print the last `abs(limit)` entries. If `limit` is omitted or `None`, all entries are printed. The optional `f` argument can be used to specify an alternate stack frame to start. The optional `file` argument has the same meaning as for `print_tb()`.

Changed in version 3.5: Added negative `limit` support.

```python
traceback.extract_tb(tb, limit=None)
```

Return a `StackSummary` object representing a list of “pre-processed” stack trace entries extracted from the traceback object `tb`. It is useful for alternate formatting of stack traces. The optional `limit` argument has the same meaning as for `print_tb()`. A “pre-processed” stack trace entry is a `FrameSummary` object containing attributes `filename`, `lineno`, `name`, and `line` representing the information that is usually printed for a stack trace. The `line` is a string with leading and trailing whitespace stripped; if the source is not available it is `None`.

```python
traceback.extract_stack(f=None, limit=None)
```

Extract the raw traceback from the current stack frame. The return value has the same format as for `extract_tb()`. The optional `f` and `limit` arguments have the same meaning as for `print_stack()`.

```python
traceback.format_list(extracted_list)
```

Given a list of tuples or `FrameSummary` objects as returned by `extract_tb()` or `extract_stack()`, return a list of strings ready for printing. Each string in the resulting list corresponds to the item with the same index in the argument list. Each string ends in a newline; the strings may contain internal newlines as well, for those items whose source text line is not `None`.

```python
traceback.format_exception_only(exc, [value])
```

Format the exception part of a traceback using an exception value such as given by `sys.last_value`. The return value is a list of strings, each ending in a newline. Normally, the list contains a single string; however, for `SyntaxError` exceptions, it contains several lines that (when printed) display detailed information about where the syntax error occurred. The message indicating which exception occurred is the always last string in the list.

Since Python 3.10, instead of passing `value`, an exception object can be passed as the first argument. If `value` is provided, the first argument is ignored in order to provide backwards compatibility.

Changed in version 3.10: The `etype` parameter has been renamed to `exc` and is now positional-only.

```python
traceback.format_exception(exc, [value, tb], limit=None, chain=True)
```

Format a stack trace and the exception information. The arguments have the same meaning as the corresponding arguments to `print_exception()`. The return value is a list of strings, each ending in a newline and some containing internal newlines. When these lines are concatenated and printed, exactly the same text is printed as does `print_exception()`.
Changed in version 3.5: The \texttt{etype} argument is ignored and inferred from the type of \texttt{value}.

Changed in version 3.10: This function's behavior and signature were modified to match \texttt{print\_exception()}.

\verb|traceback.format_exc(limit=None, chain=True)|

This is like \texttt{print\_exc(limit)} but returns a string instead of printing to a file.

\verb|traceback.format_tb(tb, limit=None)|

A shorthand for \texttt{format\_list(extract\_tb(tb, limit))}.

\verb|traceback.format_stack(f=None, limit=None)|

A shorthand for \texttt{format\_list(extract\_stack(f, limit))}.

\verb|traceback.clear_frames(tb)|

Clears the local variables of all the stack frames in a traceback \texttt{tb} by calling the \texttt{clear()} method of each frame object.

New in version 3.4.

\verb|traceback.walk_stack(f)|

Walk a stack following \texttt{f.f\_back} from the given frame, yielding the frame and line number for each frame. If \texttt{f} is \texttt{None}, the current stack is used. This helper is used with \texttt{StackSummary.extract()}.

New in version 3.5.

\verb|traceback.walk_tb(tb)|

Walk a traceback following \texttt{tb\_next} yielding the frame and line number for each frame. This helper is used with \texttt{StackSummary.extract()}.

New in version 3.5.

The module also defines the following classes:

\subsection*{29.10.1 TracebackException Objects}

New in version 3.5.

\texttt{TracebackException} objects are created from actual exceptions to capture data for later printing in a lightweight fashion.

\begin{verbatim}
class traceback.TracebackException(exc_type, exc_value, exc_traceback, *, limit=None, lookup_lines=True, capture_locals=False, compact=False):
    
    Capture an exception for later rendering. \texttt{limit}, \texttt{lookup\_lines} and \texttt{capture\_locals} are as for the \texttt{StackSummary} class.

    If \texttt{compact} is true, only data that is required by \texttt{TracebackException}'s \texttt{format} method is saved in the class attributes. In particular, the \texttt{__context__} field is calculated only if \texttt{__cause__} is \texttt{None} and \texttt{__suppress\_context__} is false.

    Note that when locals are captured, they are also shown in the traceback.

    \texttt{__cause__}
    
    A \texttt{TracebackException} of the original \texttt{__cause__}.

    \texttt{__context__}
    
    A \texttt{TracebackException} of the original \texttt{__context__}.

    \texttt{__suppress_context__}
    
    The \texttt{__suppress\_context__} value from the original exception.

    \texttt{stack}
    
    A \texttt{StackSummary} representing the traceback.

    \texttt{exc\_type}
    
    The class of the original traceback.
\end{verbatim}
filename
   For syntax errors - the file name where the error occurred.
lineno
   For syntax errors - the line number where the error occurred.
text
   For syntax errors - the text where the error occurred.
offset
   For syntax errors - the offset into the text where the error occurred.
msg
   For syntax errors - the compiler error message.

classmethod from_exception(exc, *, limit=None, lookup_lines=True, capture_locals=False)
   Capture an exception for later rendering. limit, lookup_lines and capture_locals are as for the Stack-
   Summary class.

   Note that when locals are captured, they are also shown in the traceback.

format(*, chain=True)
   Format the exception.

   If chain is not True, __cause__ and __context__ will not be formatted.

   The return value is a generator of strings, each ending in a newline and some containing internal newlines.
   print_exception() is a wrapper around this method which just prints the lines to a file.

   The message indicating which exception occurred is always the last string in the output.

format_exception_only()
   Format the exception part of the traceback.

   The return value is a generator of strings, each ending in a newline.

   Normally, the generator emits a single string; however, for SyntaxError exceptions, it emits several
   lines that (when printed) display detailed information about where the syntax error occurred.

   The message indicating which exception occurred is always the last string in the output.

   Changed in version 3.10: Added the compact parameter.

29.10.2 StackSummary Objects

New in version 3.5.

StackSummary objects represent a call stack ready for formatting.

class traceback.StackSummary

classmethod extract(frame_gen, *, limit=None, lookup_lines=True, capture_locals=False)
   Construct a StackSummary object from a frame generator (such as is returned by walk_stack() or walk_tb()).

   If limit is supplied, only this many frames are taken from frame_gen. If lookup_lines is False, the
   returned FrameSummary objects will not have read their lines in yet, making the cost of creating the
   StackSummary cheaper (which may be valuable if it may not actually get formatted). If capture_locals
   is True the local variables in each FrameSummary are captured as object representations.

classmethod from_list(a_list)
   Construct a StackSummary object from a supplied list of FrameSummary objects or old-style list
   of tuples. Each tuple should be a 4-tuple with filename, lineno, name, line as the elements.

format()
   Returns a list of strings ready for printing. Each string in the resulting list corresponds to a single frame
from the stack. Each string ends in a newline; the strings may contain internal newlines as well, for those items with source text lines.

For long sequences of the same frame and line, the first few repetitions are shown, followed by a summary line stating the exact number of further repetitions.

Changed in version 3.6: Long sequences of repeated frames are now abbreviated.

### 29.10.3 FrameSummary Objects

New in version 3.5.

*FrameSummary* objects represent a single frame in a traceback.

```python
class traceback.FrameSummary (filename, lineno, name, lookup_line=True, line=None, locals=None)
```

Represent a single frame in the traceback or stack that is being formatted or printed. It may optionally have a stringified version of the frames locals included in it. If *lookup_line* is False, the source code is not looked up until the *FrameSummary* has the *line* attribute accessed (which also happens when casting it to a tuple).

*line* may be directly provided, and will prevent line lookups happening at all. *locals* is an optional local variable dictionary, and if supplied the variable representations are stored in the summary for later display.

### 29.10.4 Traceback Examples

This simple example implements a basic read-eval-print loop, similar to (but less useful than) the standard Python interactive interpreter loop. For a more complete implementation of the interpreter loop, refer to the *code* module.

```python
import sys, traceback

def run_user_code(envdir):
    source = input(">>> ")
    try:
        exec(source, envdir)
    except Exception:
        print("Exception in user code:")
        print("-
"*60)
        traceback.print_exc(file=sys.stdout)
        print("-
"*60)
    envdir = {}
    while True:
        run_user_code(envdir)
```

The following example demonstrates the different ways to print and format the exception and traceback:

```python
import sys, traceback

def lumberjack():
    bright_side_of_death()

def bright_side_of_death():
    return tuple()[0]

try:
    lumberjack()
except IndexError:
    exc_type, exc_value, exc_traceback = sys.exc_info()
    print("*** print_tb:")
    traceback.print_tb(exc_traceback, limit=1, file=sys.stdout)
    print("*** print_exception:")
    # exc_type below is ignored on 3.5 and later
```

(continues on next page)
The output for the example would look similar to this:

```python
>>> print_tb:
  File "<doctest...>", line 10, in <module>
    lumberjack()

*** print_exception:
  File "<doctest...>", line 10, in <module>
    lumberjack()
  File "<doctest...>", line 4, in lumberjack
    bright_side_of_death()
  IndexError: tuple index out of range

*** print_exc:
  File "<doctest...>", line 10, in <module>
    lumberjack()
  File "<doctest...>", line 4, in lumberjack
    bright_side_of_death()
  IndexError: tuple index out of range

*** format_exc, first and last line:
'IndexError: tuple index out of range'

*** format_exception:
['Traceback (most recent call last):
  File "<doctest...>", line 10, in <module>
    lumberjack()
  File "<doctest...>", line 4, in lumberjack
    bright_side_of_death()
  File "<doctest...>", line 7, in bright_side_of_death
    return tuple()[0]
', 'IndexError: tuple index out of range\n']

*** extract_tb:
[<FrameSummary file <doctest...>, line 10 in <module>],
[<FrameSummary file <doctest...>, line 4 in lumberjack>,
[<FrameSummary file <doctest...>, line 7 in bright_side_of_death>]

*** format_tb:
['File "<doctest...>", line 10, in <module>
  lumberjack()
', 'File "<doctest...>", line 4, in lumberjack
  bright_side_of_death()
', 'File "<doctest...>", line 7, in bright_side_of_death
  return tuple()[0]
']

*** tb_lineno: 10
```

The following example shows the different ways to print and format the stack:

```python
>>> import traceback
>>> def another_function():
    ... lumberjack()
```

(continues on next page)
... def lumberstack():
...
    traceback.print_stack()
...
    print(repr(traceback.extract_stack()))
...
    print(repr(traceback.format_stack()))
...

>>> another_function()
<<< File "<doctest>", line 10, in <module>
 another_function()
File "<doctest>", line 3, in another_function
 lumberstack()
File "<doctest>", line 6, in lumberstack
    traceback.print_stack()
[('doctest', 10, '<module>', 'another_function'),
 ('doctest', 3, 'another_function', 'lumberstack'),
 ('doctest', 7, 'lumberstack', 'print(repr(traceback.extract_stack()))')]
[ ' File "<doctest>", line 10, in <module>
 another_function()
',
 ' File "<doctest>", line 3, in another_function
 lumberstack()
',
 ' File "<doctest>", line 8, in lumberstack
 print(repr(traceback.format_stack()))']

This last example demonstrates the final few formatting functions:

>>> import traceback

>>> traceback.format_list([('spam.py', 3, '<module>', 'spam.eggs'),
... ('eggs.py', 42, 'eggs', 'return "bacon"')])
[['File "spam.py", line 3, in <module>
 spam.eggs()
',
 'File "eggs.py", line 42, in eggs
 return "bacon"
']

>>> an_error = IndexError('tuple index out of range')

>>> traceback.format_exception_only(type(an_error), an_error)
['IndexError: tuple index out of range
']

29.11 __future__ — Future statement definitions

Source code: Lib/__future__.py

__future__ is a real module, and serves three purposes:

- To avoid confusing existing tools that analyze import statements and expect to find the modules they're importing.
- To ensure that future statements run under releases prior to 2.1 at least yield runtime exceptions (the import of __future__ will fail, because there was no module of that name prior to 2.1).
- To document when incompatible changes were introduced, and when they will be — or were — made mandatory. This is a form of executable documentation, and can be inspected programatically via importing __future__ and examining its contents.

Each statement in __future__.py is of the form:

FeatureName = _Feature(OptionalRelease, MandatoryRelease, CompilerFlag)

where, normally, OptionalRelease is less than MandatoryRelease, and both are 5-tuples of the same form as sys.version_info:
OptionalRelease records the first release in which the feature was accepted.

In the case of a MandatoryRelease that has not yet occurred, MandatoryRelease predicts the release in which the feature will become part of the language.

Else MandatoryRelease records when the feature became part of the language; in releases at or after that, modules no longer need a future statement to use the feature in question, but may continue to use such imports.

MandatoryRelease may also be None, meaning that a planned feature got dropped.

Instances of class _Feature have two corresponding methods, getOptionalRelease() and getMandatoryRelease().

CompilerFlag is the (bitfield) flag that should be passed in the fourth argument to the built-in function compile() to enable the feature in dynamically compiled code. This flag is stored in the compiler_flag attribute on _Feature instances.

No feature description will ever be deleted from __future__. Since its introduction in Python 2.1 the following features have found their way into the language using this mechanism:

<table>
<thead>
<tr>
<th>feature</th>
<th>optional in</th>
<th>mandatory in</th>
<th>effect</th>
</tr>
</thead>
<tbody>
<tr>
<td>nested_scopes</td>

future How the compiler treats future imports.

29.12 gc — Garbage Collector interface

This module provides an interface to the optional garbage collector. It provides the ability to disable the collector, tune the collection frequency, and set debugging options. It also provides access to unreachable objects that the collector found but cannot free. Since the collector supplements the reference counting already used in Python, you can disable the collector if you are sure your program does not create reference cycles. Automatic collection can be disabled by calling gc.disable(). To debug a leaking program call gc.set_debug(gc.DEBUG_LEAK). Notice that this includes gc.DEBUG_SAVEALL, causing garbage-collected objects to be saved in gc.garbage for inspection.

The gc module provides the following functions:
The Python Library Reference, Release 3.10.4

The gc module provides several functions for controlling the automatic garbage collection:

- **gc.enable()**
  Enable automatic garbage collection.

- **gc.disable()**
  Disable automatic garbage collection.

- **gc.isenabled()**
  Return True if automatic collection is enabled.

- **gc.collect(generation=2)**
  With no arguments, run a full collection. The optional argument generation may be an integer specifying which generation to collect (from 0 to 2). A ValueError is raised if the generation number is invalid. The number of unreachable objects found is returned.

  The free lists maintained for a number of built-in types are cleared whenever a full collection or collection of the highest generation (2) is run. Not all items in some free lists may be freed due to the particular implementation, in particular float.

- **gc.set_debug(flags)**
  Set the garbage collection debugging flags. Debugging information will be written to sys.stderr. See below for a list of debugging flags which can be combined using bit operations to control debugging.

- **gc.get_debug()**
  Return the debugging flags currently set.

- **gc.get_objects(generation=None)**
  Returns a list of all objects tracked by the collector, excluding the list returned. If generation is not None, return only the objects tracked by the collector that are in that generation.

  Changed in version 3.8: New generation parameter.

  Raises an auditing event gc.get_objects with argument generation.

- **gc.get_stats()**
  Return a list of three per-generation dictionaries containing collection statistics since interpreter start. The number of keys may change in the future, but currently each dictionary will contain the following items:

  - **collections** is the number of times this generation was collected;
  - **collected** is the total number of objects collected inside this generation;
  - **uncollectable** is the total number of objects which were found to be uncollectable (and were therefore moved to the garbage list) inside this generation.

  New in version 3.4.

- **gc.set_threshold(threshold0, threshold1, threshold2)**
  Set the garbage collection thresholds (the collection frequency). Setting threshold0 to zero disables collection.

  The GC classifies objects into three generations depending on how many collection sweeps they have survived. New objects are placed in the youngest generation (generation 0). If an object survives a collection it is moved into the next older generation. Since generation 2 is the oldest generation, objects in that generation remain there after a collection. In order to decide when to run, the collector keeps track of the number object allocations and deallocations since the last collection. When the number of allocations minus the number of deallocations exceeds threshold0, collection starts. Initially only generation 0 is examined. If generation 0 has been examined more than threshold1 times since generation 1 has been examined, then generation 1 is examined as well. With the third generation, things are a bit more complicated, see Collecting the oldest generation for more information.

- **gc.get_count()**
  Return the current collection counts as a tuple of (count0, count1, count2).

- **gc.get_threshold()**
  Return the current collection thresholds as a tuple of (threshold0, threshold1, threshold2).

- **gc.get_referrers(*objs)**
  Return the list of objects that directly refer to any of objs. This function will only locate those containers
which support garbage collection; extension types which do refer to other objects but do not support garbage collection will not be found.

Note that objects which have already been dereferenced, but which live in cycles and have not yet been collected by the garbage collector can be listed among the resulting referrers. To get only currently live objects, call `collect()` before calling `get_referrers()`.

**Warning:** Care must be taken when using objects returned by `get_referrers()` because some of them could still be under construction and hence in a temporarily invalid state. Avoid using `get_referrers()` for any purpose other than debugging.

Raises an auditing event `gc.get_referrers` with argument `objs`.

```python
gc.get_referents(*objs)
```

Return a list of objects directly referred to by any of the arguments. The referents returned are those objects visited by the arguments’ C-level `tp_traverse` methods (if any), and may not be all objects actually directly reachable. `tp_traverse` methods are supported only by objects that support garbage collection, and are only required to visit objects that may be involved in a cycle. So, for example, if an integer is directly reachable from an argument, that integer object may or may not appear in the result list.

Raises an auditing event `gc.get_referents` with argument `objs`.

```python
gc.is_tracked(obj)
```

Returns `True` if the object is currently tracked by the garbage collector, `False` otherwise. As a general rule, instances of atomic types aren’t tracked and instances of non-atomic types (containers, user-defined objects...) are. However, some type-specific optimizations can be present in order to suppress the garbage collector footprint of simple instances (e.g. dicts containing only atomic keys and values):

```python
>>> gc.is_tracked(0)
False
>>> gc.is_tracked("a")
False
>>> gc.is_tracked([])
True
>>> gc.is_tracked({})
False
>>> gc.is_tracked({"a": 1})
False
>>> gc.is_tracked({"a": []})
True
```

New in version 3.1.

```python
gc.is_finalized(obj)
```

Returns `True` if the given object has been finalized by the garbage collector, `False` otherwise.

```python
>>> x = None
>>> class Lazarus:
...     def __del__(self):
...         global x
...         x = self
... >>> lazarus = Lazarus()
>>> gc.is_finalized(lazarus)
False
>>> del lazarus
>>> gc.is_finalized(x)
True
```

New in version 3.9.
**gc.freeze()**
Freeze all the objects tracked by gc - move them to a permanent generation and ignore all the future collections. This can be used before a POSIX fork() call to make the gc copy-on-write friendly or to speed up collection. Also collection before a POSIX fork() call may free pages for future allocation which can cause copy-on-write too so it’s advised to disable gc in parent process and freeze before fork and enable gc in child process.

New in version 3.7.

**gc.unfreeze()**
Unfreeze the objects in the permanent generation, put them back into the oldest generation.

New in version 3.7.

**gc.get_freeze_count ()**
Return the number of objects in the permanent generation.

New in version 3.7.

The following variables are provided for read-only access (you can mutate the values but should not rebind them):

**gc.garbage**
A list of objects which the collector found to be unreachable but could not be freed (uncollectable objects). Starting with Python 3.4, this list should be empty most of the time, except when using instances of C extension types with a non-NULL tp_del slot.

If `DEBUG_SAVEALL` is set, then all unreachable objects will be added to this list rather than freed.

Changed in version 3.2: If this list is non-empty at `interpreter shutdown`, a `ResourceWarning` is emitted, which is silent by default. If `DEBUG_UNCOLLECTABLE` is set, in addition all uncollectable objects are printed.

Changed in version 3.4: Following [PEP 442](https://www.python.org/dev/peps/pep-0442/), objects with a `__del__()` method don’t end up in `gc.garbage` anymore.

**gc.callbacks**
A list of callbacks that will be invoked by the garbage collector before and after collection. The callbacks will be called with two arguments, `phase` and `info`.

`phase` can be one of two values:

"start": The garbage collection is about to start.

"stop": The garbage collection has finished.

`info` is a dict providing more information for the callback. The following keys are currently defined:

"generation": The oldest generation being collected.

"collected": When `phase` is "stop", the number of objects successfully collected.

"uncollectable": When `phase` is "stop", the number of objects that could not be collected and were put in `garbage`.

Applications can add their own callbacks to this list. The primary use cases are:

Gathering statistics about garbage collection, such as how often various generations are collected, and how long the collection takes.

Allowing applications to identify and clear their own uncollectable types when they appear in `garbage`.

New in version 3.3.

The following constants are provided for use with `set_debug()`:

**gc.DEBUG_STATS**
Print statistics during collection. This information can be useful when tuning the collection frequency.

**gc.DEBUG_COLLECTABLE**
Print information on collectable objects found.
gc.DEBUG_UNCOLLECTABLE
Print information of uncollectable objects found (objects which are not reachable but cannot be freed by the collector). These objects will be added to the garbage list.

Changed in version 3.2: Also print the contents of the garbage list at interpreter shutdown, if it isn’t empty.

gc.DEBUG_SAVEALL
When set, all unreachable objects found will be appended to garbage rather than being freed. This can be useful for debugging a leaking program.

gc.DEBUG_LEAK
The debugging flags necessary for the collector to print information about a leaking program (equal to DEBUG_COLLECTABLE | DEBUG_UNCOLLECTABLE | DEBUG_SAVEALL).

29.13 inspect — Inspect live objects

Source code: Lib/inspect.py

The inspect module provides several useful functions to help get information about live objects such as modules, classes, methods, functions, tracebacks, frame objects, and code objects. For example, it can help you examine the contents of a class, retrieve the source code of a method, extract and format the argument list for a function, or get all the information you need to display a detailed traceback.

There are four main kinds of services provided by this module: type checking, getting source code, inspecting classes and functions, and examining the interpreter stack.

29.13.1 Types and members

The getmembers() function retrieves the members of an object such as a class or module. The functions whose names begin with “is” are mainly provided as convenient choices for the second argument to getmembers(). They also help you determine when you can expect to find the following special attributes:

<table>
<thead>
<tr>
<th>Type</th>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>module</td>
<td><strong>doc</strong></td>
<td>documentation string</td>
</tr>
<tr>
<td></td>
<td><strong>file</strong></td>
<td>filename (missing for built-in modules)</td>
</tr>
<tr>
<td>class</td>
<td><strong>doc</strong></td>
<td>documentation string</td>
</tr>
<tr>
<td></td>
<td><strong>name</strong></td>
<td>name with which this class was defined</td>
</tr>
<tr>
<td></td>
<td><strong>qualname</strong></td>
<td>qualified name</td>
</tr>
<tr>
<td></td>
<td><strong>module</strong></td>
<td>name of module in which this class was defined</td>
</tr>
<tr>
<td>method</td>
<td><strong>doc</strong></td>
<td>documentation string</td>

<td>cr_origin</td>
<td>where coroutine was created, or None. See <code>sys.set_coroutine_origin_tracking_depth()</code></td>
</tr>
<tr>
<td>builtin</td>
<td><strong>doc</strong></td>
<td>documentation string</td>
</tr>
<tr>
<td></td>
<td><strong>name</strong></td>
<td>original name of this function or method</td>
</tr>
<tr>
<td></td>
<td><strong>qualname</strong></td>
<td>qualified name</td>
</tr>
<tr>
<td></td>
<td><strong>self</strong></td>
<td>instance to which a method is bound, or None</td>
</tr>
</tbody>
</table>

Changed in version 3.5: Add `__qualname__` and `gi_yieldfrom` attributes to generators.

The `__name__` attribute of generators is now set from the function name, instead of the code name, and it can now be modified.

Changed in version 3.7: Add `cr_origin` attribute to coroutines.

Changed in version 3.10: Add `__builtins__` attribute to functions.
inspect.getmembers(object[, predicate])
Return all the members of an object in a list of (name, value) pairs sorted by name. If the optional predicate argument—which will be called with the value object of each member—is supplied, only members for which the predicate returns a true value are included.

**Note:** `getmembers()` will only return class attributes defined in the metaclass when the argument is a class and those attributes have been listed in the metaclass’ custom `__dir__()`.

inspect.getmodulename(path)
Return the name of the module named by the file path, without including the names of enclosing packages. The file extension is checked against all of the entries in `importlib.machinery.all_suffixes()`. If it matches, the final path component is returned with the extension removed. Otherwise, None is returned.

Note that this function only returns a meaningful name for actual Python modules - paths that potentially refer to Python packages will still return None.

Changed in version 3.3: The function is based directly on `importlib`.

inspect.ismodule(object)
Return True if the object is a module.

inspect.isclass(object)
Return True if the object is a class, whether built-in or created in Python code.

inspect.ismethod(object)
Return True if the object is a bound method written in Python.

inspect.isfunction(object)
Return True if the object is a Python function, which includes functions created by a `lambda` expression.

inspect.isgeneratorfunction(object)
Return True if the object is a Python generator function.

Changed in version 3.8: Functions wrapped in `functools.partial()` now return True if the wrapped function is a Python generator function.

inspect.isgenerator(object)
Return True if the object is a generator.

inspect.iscoroutinefunction(object)
Return True if the object is a coroutine function (a function defined with an `async def` syntax).

New in version 3.5.

Changed in version 3.8: Functions wrapped in `functools.partial()` now return True if the wrapped function is a coroutine function.

inspect.iscoroutine(object)
Return True if the object is a coroutine created by an `async def` function.

New in version 3.5.

inspect.isawaitable(object)
Return True if the object can be used in `await` expression.

Can also be used to distinguish generator-based coroutines from regular generators:

```python
def gen():
    yield
@types.coroutine
def gen_coro():
    yield

assert not isawaitable(gen())
assert isawaitable(gen_coro())
```
New in version 3.5.

```
>>> async def agen():
    ...
    yield 1
    ...
>>> inspect.isasyncgenfunction(agen)
True
```

New in version 3.6.

Changed in version 3.8: Functions wrapped in `functools.partial()` now return `True` if the wrapped function is an *asynchronous generator* function.

```
>>> inspect.isasyncgenfunction(agen)
True
```

New in version 3.6.

```
>>> inspect.isasyncgen(agen)
True
```

New in version 3.6.

```
>>> inspect.istraceback(agen)
True
```

New in version 3.6.

```
>>> inspect.isframe(agen)
True
```

New in version 3.6.

```
>>> inspect.iscode(agen)
True
```

New in version 3.6.

```
>>> inspect.isbuiltin(agen)
True
```

New in version 3.6.

```
>>> inspect.isroutine(agen)
True
```

New in version 3.6.

```
>>> inspect.isabstract(agen)
True
```

New in version 3.6.

```
>>> inspect.isdatadescriptor(agen)
True
```

New in version 3.6.

```
>>> inspect.isgetsetdescriptor(agen)
True
```

New in version 3.6.

```
>>> inspect.ismemberdescriptor(agen)
True
```

1730 Chapter 29. Python Runtime Services
CPython implementation detail: Member descriptors are attributes defined in extension modules via `PyMemberDef` structures. For Python implementations without such types, this method will always return `False`.

### 29.13.2 Retrieving source code

`inspect.getdoc(object)`

Get the documentation string for an object, cleaned up with `cleandoc()`. If the documentation string for an object is not provided and the object is a class, a method, a property or a descriptor, retrieve the documentation string from the inheritance hierarchy.

Changed in version 3.5: Documentation strings are now inherited if not overridden.

`inspect.getcomments(object)`

Return in a single string any lines of comments immediately preceding the object’s source code (for a class, function, or method), or at the top of the Python source file (if the object is a module). If the object’s source code is unavailable, return `None`. This could happen if the object has been defined in C or the interactive shell.

`inspect.getfile(object)`

Return the name of the (text or binary) file in which an object was defined. This will fail with a `TypeError` if the object is a built-in module, class, or function.

`inspect.getmodule(object)`

Try to guess which module an object was defined in.

`inspect.getsourcefile(object)`

Return the name of the Python source file in which an object was defined. This will fail with a `TypeError` if the object is a built-in module, class, or function.

`inspect.getsourcelines(object)`

Return a list of source lines and starting line number for an object. The argument may be a module, class, method, function, traceback, frame, or code object. The source code is returned as a list of the lines corresponding to the object and the line number indicates where in the original source file the first line of code was found. An `OSError` is raised if the source code cannot be retrieved.

Changed in version 3.3: `OSError` is raised instead of `IOError`, now an alias of the former.

`inspect.getsource(object)`

Return the text of the source code for an object. The argument may be a module, class, method, function, traceback, frame, or code object. The source code is returned as a single string. An `OSError` is raised if the source code cannot be retrieved.

Changed in version 3.3: `OSError` is raised instead of `IOError`, now an alias of the former.

`inspect.cleandoc(doc)`

Clean up indentation from docstrings that are indented to line up with blocks of code.

All leading whitespace is removed from the first line. Any leading whitespace that can be uniformly removed from the second line onwards is removed. Empty lines at the beginning and end are subsequently removed. Also, all tabs are expanded to spaces.

### 29.13.3 Introspecting callables with the Signature object

New in version 3.3.

The Signature object represents the call signature of a callable object and its return annotation. To retrieve a Signature object, use the `signature()` function.

`inspect.signature(callable, *, follow_wrapped=True, globals=None, locals=None, eval_str=False)`

Return a `Signature` object for the given `callable`:

---

**29.13. inspect — Inspect live objects** 1731
>>> from inspect import signature
>>> def foo(a, *, b:int, **kwargs):
...     pass

>>> sig = signature(foo)

>>> str(sig)
'(a, *, b:int, **kwargs)'

>>> str(sig.parameters['b'])
'b:int'

>>> sig.parameters['b'].annotation
<class 'int'>

Accepts a wide range of Python callables, from plain functions and classes to `functools.partial()` objects.

For objects defined in modules using stringized annotations (from `__future__` import annotations), `signature()` will attempt to automatically un-stringize the annotations using `inspect.get_annotations()`. The global, locals, and `eval_str` parameters are passed into `inspect.get_annotations()` when resolving the annotations; see the documentation for `inspect.get_annotations()` for instructions on how to use these parameters.

Raises `ValueError` if no signature can be provided, and `TypeError` if that type of object is not supported. Also, if the annotations are stringized, and `eval_str` is not false, the `eval()` call(s) to un-stringize the annotations could potentially raise any kind of exception.

A slash(/) in the signature of a function denotes that the parameters prior to it are positional-only. For more info, see the FAQ entry on positional-only parameters.

New in version 3.5: `follow_wrapped` parameter. Pass `False` to get a signature of callable specifically (callable.__wrapped__ will not be used to unwrap decorated callables.)

New in version 3.10: `globals`, `locals`, and `eval_str` parameters.

Note: Some callables may not be introspectable in certain implementations of Python. For example, in CPython, some built-in functions defined in C provide no metadata about their arguments.

**class** inspect.Signature(parameters=None, *, return_annotation=Signature.empty)

A Signature object represents the call signature of a function and its return annotation. For each parameter accepted by the function it stores a `Parameter` object in its `parameters` collection.

The optional `parameters` argument is a sequence of `Parameter` objects, which is validated to check that there are no parameters with duplicate names, and that the parameters are in the right order, i.e. positional-only first, then positional-or-keyword, and that parameters with defaults follow parameters without defaults.

The optional `return_annotation` argument, can be an arbitrary Python object, is the “return” annotation of the callable.

Signature objects are immutable. Use `Signature.replace()` to make a modified copy.

Changed in version 3.5: Signature objects are picklable and hashable.

**empty**

A special class-level marker to specify absence of a return annotation.

**parameters**

An ordered mapping of parameters’ names to the corresponding `Parameter` objects. Parameters appear in strict definition order, including keyword-only parameters.

Changed in version 3.7: Python only explicitly guaranteed that it preserved the declaration order of keyword-only parameters as of version 3.7, although in practice this order had always been preserved in Python 3.
The “return” annotation for the callable. If the callable has no “return” annotation, this attribute is set to `Signature.empty`.

`bind(*args, **kwargs)`
Create a mapping from positional and keyword arguments to parameters. Returns `BoundArguments` if *args and **kwargs match the signature, or raises a `TypeError`.

`bind_partial(*args, **kwargs)`
Works the same way as `Signature.bind()`, but allows the omission of some required arguments (mimics `functools.partial()` behavior.) Returns `BoundArguments`, or raises a `TypeError` if the passed arguments do not match the signature.

`replace(*, parameters=[], return_annotation=)`
Create a new Signature instance based on the instance replace was invoked on. It is possible to pass different parameters and/or return_annotation to override the corresponding properties of the base signature. To remove return_annotation from the copied Signature, pass in `Signature.empty`.

```python
def test(a, b):
    ...
pass
>>> sig = signature(test)
>>> new_sig = sig.replace(return_annotation="new return anno")
>>> str(new_sig)
"(a, b) -> 'new return anno'"
```

`classmethod from_callable(obj, *, follow_wrapped=True, globalns=None, localns=None)`
Return a `Signature` (or its subclass) object for a given callable obj. Pass follow_wrapped=False to get a signature of obj without unwrapping its __wrapped__ chain. globalns and localns will be used as the namespaces when resolving annotations.

This method simplifies subclassing of `Signature`:

```python
class MySignature(Signature):
    pass
sig = MySignature.from_callable(min)
assert isinstance(sig, MySignature)
```

New in version 3.5.
New in version 3.10: globalns and localns parameters.

`class inspect.Parameter(name, kind, *, default=Parameter.empty, annotation=Parameter.empty)`
Parameter objects are immutable. Instead of modifying a Parameter object, you can use Parameter.replace() to create a modified copy.

Changed in version 3.5: Parameter objects are picklable and hashable.

`empty`
A special class-level marker to specify absence of default values and annotations.

`name`
The name of the parameter as a string. The name must be a valid Python identifier.

`CPython implementation detail`: CPython generates implicit parameter names of the form .0 on the code objects used to implement comprehensions and generator expressions.

Changed in version 3.6: These parameter names are exposed by this module as names like implicit0.

`default`
The default value for the parameter. If the parameter has no default value, this attribute is set to `Parameter.empty`.

`annotation`
The annotation for the parameter. If the parameter has no annotation, this attribute is set to `Parameter.empty`.

29.13. inspect — Inspect live objects
**kind**

Describes how argument values are bound to the parameter. Possible values (accessible via `Parameter`, like `Parameter.KEYWORD_ONLY`):

<table>
<thead>
<tr>
<th>Name</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>POSITIONAL_ONLY</td>
<td>Value must be supplied as a positional argument. Positional only parameters are those which appear before a / entry (if present) in a Python function definition.</td>
</tr>
<tr>
<td>POSITIONAL_OR_KEYWORD</td>
<td>Value may be supplied as either a keyword or positional argument (this is the standard binding behaviour for functions implemented in Python.)</td>
</tr>
<tr>
<td>VAR_POSITIONAL</td>
<td>A tuple of positional arguments that aren’t bound to any other parameter. This corresponds to a *args parameter in a Python function definition.</td>
</tr>
<tr>
<td>KEYWORD_ONLY</td>
<td>Value must be supplied as a keyword argument. Keyword only parameters are those which appear after a * or *args entry in a Python function definition.</td>
</tr>
<tr>
<td>VAR_KEYWORD</td>
<td>A dict of keyword arguments that aren’t bound to any other parameter. This corresponds to a **kwargs parameter in a Python function definition.</td>
</tr>
</tbody>
</table>

Example: print all keyword-only arguments without default values:

```python
>>> def foo(a, b, *, c, d=10):
...     pass

>>> sig = signature(foo)
>>> for param in sig.parameters.values():
...     if (param.kind == param.KEYWORD_ONLY and
...         param.default is param.empty):
...         print('Parameter: ', param)
Parameter: c
```

**kind.description**

Describes a enum value of Parameter.kind.

New in version 3.8.

Example: print all descriptions of arguments:

```python
>>> def foo(a, b, *, c, d=10):
...     pass

>>> sig = signature(foo)
>>> for param in sig.parameters.values():
...     print(param.kind.description)
positional or keyword
positional or keyword
keyword-only
keyword-only
```

**replace**(*name, kind, default, annotation*)

Create a new Parameter instance based on the instance replaced was invoked on. To override a Parameter attribute, pass the corresponding argument. To remove a default value or/and an annotation from a Parameter, pass `Parameter.empty`.

```python
>>> from inspect import Parameter
>>> param = Parameter('foo', Parameter.KEYWORD_ONLY, default=42)
>>> str(param)
'foo=42'
```

(continues on next page)
>>> str(param.replace())  # Will create a shallow copy of 'param'
'foo=42'

>>> str(param.replace(default=Parameter.empty, annotation='spam'))
"foo:'spam'"

Changed in version 3.4: In Python 3.3 Parameter objects were allowed to have name set to None if their kind was set to POSITIONAL_ONLY. This is no longer permitted.

class inspect.BoundArguments
Result of a Signature.bind() or Signature.bind_partial() call. Holds the mapping of arguments to the function's parameters.

arguments
A mutable mapping of parameters' names to arguments' values. Contains only explicitly bound arguments. Changes in arguments will reflect in args and kwargs.

Should be used in conjunction with Signature.parameters for any argument processing purposes.

Note: Arguments for which Signature.bind() or Signature.bind_partial() relied on a default value are skipped. However, if needed, use BoundArguments.apply_defaults() to add them.

Changed in version 3.9: arguments is now of type dict. Formerly, it was of type collections.OrderedDict.

args
A tuple of positional arguments values. Dynamically computed from the arguments attribute.

kwargs
A dict of keyword arguments values. Dynamically computed from the arguments attribute.

signature
A reference to the parent Signature object.

apply_defaults()
Set default values for missing arguments.

For variable-positional arguments (*args) the default is an empty tuple.

For variable-keyword arguments (**kwargs) the default is an empty dict.

```python
>>> def foo(a, b='ham', *args): pass
>>> ba = inspect.signature(foo).bind('spam')
>>> ba.apply_defaults()
>>> ba.arguments
{'a': 'spam', 'b': 'ham', 'args': ()}
```

New in version 3.5.

The args and kwargs properties can be used to invoke functions:

```python
def test(a, *, b):
    ...
sig = signature(test)
ba = sig.bind(10, b=20)
test(*ba.args, **ba.kwargs)
```

See also:

PEP 362 - Function Signature Object. The detailed specification, implementation details and examples.
29.13.4 Classes and functions

inspect.getclasstree(classes, unique=False)

Arrange the given list of classes into a hierarchy of nested lists. Where a nested list appears, it contains classes
derived from the class whose entry immediately precedes the list. Each entry is a 2-tuple containing a class and
a tuple of its base classes. If the unique argument is true, exactly one entry appears in the returned structure
for each class in the given list. Otherwise, classes using multiple inheritance and their descendants will appear
multiple times.

inspect.getargspec(func)

Get the names and default values of a Python function’s parameters. A named tuple ArgSpec(args, varargs, keywords, defaults) is returned. args is a list of the parameter names. varargs and
keywords are the names of the * and ** parameters or None. defaults is a tuple of default argument values
or None if there are no default arguments; if this tuple has n elements, they correspond to the last n elements
listed in args.

Deprecated since version 3.0: Use getfullargspec() for an updated API that is usually a drop-in re-
placement, but also correctly handles function annotations and keyword-only parameters.

Alternatively, use signature() and Signature Object, which provide a more structured introspection API
for callables.

inspect.getfullargspec(func)

Get the names and default values of a Python function’s parameters. A named tuple is returned:
FullArgSpec(args, varargs, varkw, defaults, kwonlyargs, kwonlydefaults, annotations)

args is a list of the positional parameter names. varargs is the name of the * parameter or None if arbitrary
positional arguments are not accepted. varkw is the name of the ** parameter or None if arbitrary keyword
arguments are not accepted. defaults is an n-tuple of default argument values corresponding to the last n
positional parameters, or None if there are no such defaults defined. kwonlyargs is a list of keyword-only pa-
rameter names in declaration order. kwonlydefaults is a dictionary mapping parameter names from kwonlyargs
to the default values used if no argument is supplied. annotations is a dictionary mapping parameter names to
annotations. The special key "return" is used to report the function return value annotation (if any).

Note that signature() and Signature Object provide the recommended API for callable introspection, and
support additional behaviours (like positional-only arguments) that are sometimes encountered in extension
module APIs. This function is retained primarily for use in code that needs to maintain compatibility with the
Python 2 inspect module API.

Changed in version 3.4: This function is now based on signature(), but still ignores __wrapped__
attributes and includes the already bound first parameter in the signature output for bound methods.

Changed in version 3.6: This method was previously documented as deprecated in favour of signature() in
Python 3.5, but that decision has been reversed in order to restore a clearly supported standard interface for
single-source Python 2/3 code migrating away from the legacy getargspec() API.

Changed in version 3.7: Python only explicitly guaranteed that it preserved the declaration order of keyword-
only parameters as of version 3.7, although in practice this order had always been preserved in Python 3.

inspect.getargvalues(frame)

Get information about arguments passed into a particular frame. A named tuple ArgInfo(args, varargs, keywords, locals) is returned. args is a list of the argument names. varargs and keywords
are the names of the * and ** arguments or None. locals is the locals dictionary of the given frame.

Note: This function was inadvertently marked as deprecated in Python 3.5.

inspect.formatargspec(args[, varargs, varkw, defaults, kwonlyargs, kwonlydefaults, annotations[, formatarg, formatvarargs, formatvarkw, formatvalue, formatreturns, formatannotations]])

Format a pretty argument spec from the values returned by getfullargspec().

1736 Chapter 29. Python Runtime Services
The first seven arguments are (args, varargs, varkw, defaults, kwonlyargs, kwonlydefaults, annotations).

The other six arguments are functions that are called to turn argument names, * argument name, ** argument name, default values, return annotation and individual annotations into strings, respectively.

For example:

```python
>>> from inspect import formatargspec, getfullargspec
>>> def f(a: int, b: float):
...     pass
... >>> formatargspec(*getfullargspec(f))
'(a: int, b: float)'
```  

Deprecated since version 3.5: Use signature() and Signature Object, which provide a better introspecting API for callables.

```
inspect.formatargvalues(args[, varargs, varkw, locals, formatarg, formatvarargs, formatvarkw, formatvalue])
```

Format a pretty argumentspec from the four values returned by getargvalues(). The format* arguments are the corresponding optional formatting functions that are called to turn names and values into strings.

**Note:** This function was inadvertently marked as deprecated in Python 3.5.

```
inspect.getmro(cls)
```

Return a tuple of class cls’s base classes, including cls, in method resolution order. No class appears more than once in this tuple. Note that the method resolution order depends on cls’s type. Unless a very peculiar user-defined metatype is in use, cls will be the first element of the tuple.

```
inspect.getcallargs(func, /, *args, **kwds)
```

Bind the args and kwds to the argument names of the Python function or method func, as if it was called with them. For bound methods, bind also the first argument (typically named self) to the associated instance. A dict is returned, mapping the argument names (including the names of the * and ** arguments, if any) to their values from args and kwds. In case of invoking func incorrectly, i.e. whenever func(*args, **kwds) would raise an exception because of incompatible signature, an exception of the same type and the same or similar message is raised. For example:

```python
>>> from inspect import getcallargs
>>> def f(a, b=1, *pos, **named):
...     pass
... >>> getcallargs(f, 1, 2, 3) == {'a': 1, 'named': {}, 'b': 2, 'pos': (3,)}
True
>>> getcallargs(f, a=2, x=4) == {'a': 2, 'named': {'x': 4}, 'b': 1, 'pos': ()}
True
>>> getcallargs(f)
Traceback (most recent call last):
  ...
TypeError: f() missing 1 required positional argument: 'a'
```

New in version 3.2.

Deprecated since version 3.5: Use Signature.bind() and Signature.bind_partial() instead.

```
inspect.getclosurevars(func)
```

Get the mapping of external name references in a Python function or method func to their current values. A namedtuple ClosureVars(nonlocals, globals, builtins, unbound) is returned. nonlocals maps referenced names to lexical closure variables, globals to the function’s module globals and builtins to the builtins visible from the function body. unbound is the set of names referenced in the function that could not be resolved at all given the current module globals and builtins.

TypeError is raised if func is not a Python function or method.
New in version 3.3.

```
inspect.unwrap(func, *, stop=None)
```

Get the object wrapped by `func`. It follows the chain of `__wrapped__` attributes returning the last object in the chain.

`stop` is an optional callback accepting an object in the wrapper chain as its sole argument that allows the unwrapping to be terminated early if the callback returns a true value. If the callback never returns a true value, the last object in the chain is returned as usual. For example, `signature()` uses this to stop unwrapping if any object in the chain has a `__signature__` attribute defined. `ValueError` is raised if a cycle is encountered.

New in version 3.4.

```
inspect.get_annotations(obj, *, globals=None, locals=None, eval_str=False)
```

Compute the annotations dict for an object.

`obj` may be a callable, class, or module. Passing in an object of any other type raises `TypeError`. Returns a dict. `get_annotations()` returns a new dict every time it’s called; calling it twice on the same object will return two different but equivalent dicts.

This function handles several details for you:

- If `eval_str` is true, values of type `str` will be un-stringized using `eval()`. This is intended for use with stringized annotations (from `__future__ import annotations`).
- If `obj` doesn’t have an annotations dict, returns an empty dict. (Functions and methods always have an annotations dict; classes, modules, and other types of callables may not.)
- Ignores inherited annotations on classes. If a class doesn’t have its own annotations dict, returns an empty dict.
- All accesses to object members and dict values are done using `getattr()` and `dict.get()` for safety.
- Always, always, always returns a freshly-created dict.

`eval_str` controls whether or not values of type `str` are replaced with the result of calling `eval()` on those values:

- If `eval_str` is true, `eval()` is called on values of type `str`. (Note that `get_annotations` doesn’t catch exceptions; if `eval()` raises an exception, it will unwind the stack past the `get_annotations` call.)
- If `eval_str` is false (the default), values of type `str` are unchanged.

`globals` and `locals` are passed in to `eval()`; see the documentation for `eval()` for more information. If `globals` or `locals` is `None`, this function may replace that value with a context-specific default, contingent on `type(obj)`:

- If `obj` is a module, `globals` defaults to `obj.__dict__`.
- If `obj` is a class, `globals` defaults to `sys.modules[obj.__module__].__dict__` and `locals` defaults to the `obj` class namespace.
- If `obj` is a callable, `globals` defaults to `obj.__globals__`, although if `obj` is a wrapped function (using `functools.update_wrapper()`) it is first unwrapped.

Calling `get_annotations` is best practice for accessing the annotations dict of any object. See annotations-howto for more information on annotations best practices.

New in version 3.10.
29.13.5 The interpreter stack

When the following functions return “frame records,” each record is a named tuple `FrameInfo(frame, filename, lineno, function, code_context, index)`. The tuple contains the frame object, the filename, the line number of the current line, the function name, a list of lines of context from the source code, and the index of the current line within that list.

Changed in version 3.5: Return a named tuple instead of a tuple.

Note: Keeping references to frame objects, as found in the first element of the frame records these functions return, can cause your program to create reference cycles. Once a reference cycle has been created, the lifespan of all objects which can be accessed from the objects which form the cycle can become much longer even if Python’s optional cycle detector is enabled. If such cycles must be created, it is important to ensure they are explicitly broken to avoid the delayed destruction of objects and increased memory consumption which occurs.

Though the cycle detector will catch these, destruction of the frames (and local variables) can be made deterministic by removing the cycle in a finally clause. This is also important if the cycle detector was disabled when Python was compiled or using `gc.disable()`. For example:

```python
def handle_stackframe_without_leak():
    frame = inspect.currentframe()
    try:
        # do something with the frame
    finally:
        del frame
```

If you want to keep the frame around (for example to print a traceback later), you can also break reference cycles by using the `frame.clear()` method.

The optional `context` argument supported by most of these functions specifies the number of lines of context to return, which are centered around the current line.

```python
inspect.getframeinfo(frame, context=1)
Get information about a frame or traceback object. A named tuple `Traceback(filename, lineno, function, code_context, index)` is returned.
```

```python
inspect.getouterframes(frame, context=1)
Get a list of frame records for a frame and all outer frames. These frames represent the calls that lead to the creation of `frame`. The first entry in the returned list represents `frame`; the last entry represents the outermost call on `frame`'s stack.

Changed in version 3.5: A list of named tuples `FrameInfo(frame, filename, lineno, function, code_context, index)` is returned.
```

```python
inspect.getinnerframes(traceback, context=1)
Get a list of frame records for a traceback's frame and all inner frames. These frames represent calls made as a consequence of `frame`. The first entry in the list represents `traceback`; the last entry represents where the exception was raised.

Changed in version 3.5: A list of named tuples `FrameInfo(frame, filename, lineno, function, code_context, index)` is returned.
```

```python
inspect.currentframe()
Return the frame object for the caller's stack frame.
```

CPython implementation detail: This function relies on Python stack frame support in the interpreter, which isn’t guaranteed to exist in all implementations of Python. If running in an implementation without Python stack frame support this function returns `None`.

```python
inspect.stack(context=1)
Return a list of frame records for the caller’s stack. The first entry in the returned list represents the caller; the last entry represents the outermost call on the stack.
```
Changed in version 3.5: A list of `named tuples` FrameInfo(frame, filename, lineno, function, code_context, index) is returned.

```python
inspect.trace(context=1)
```

Return a list of frame records for the stack between the current frame and the frame in which an exception currently being handled was raised in. The first entry in the list represents the caller; the last entry represents where the exception was raised.

Changed in version 3.5: A list of `named tuples` FrameInfo(frame, filename, lineno, function, code_context, index) is returned.

### 29.13.6 Fetching attributes statically

Both `getattr()` and `hasattr()` can trigger code execution when fetching or checking for the existence of attributes. Descriptors, like properties, will be invoked and `__getattr__()` and `__getattribute__()` may be called.

For cases where you want passive introspection, like documentation tools, this can be inconvenient. `getattr_static()` has the same signature as `getattr()` but avoids executing code when it fetches attributes.

```python
inspect.getattr_static(obj, attr, default=None)
```

Retrieve attributes without triggering dynamic lookup via the descriptor protocol, `__getattr__()` or `__getattribute__()`. Note: this function may not be able to retrieve all attributes that `getattr` can fetch (like dynamically created attributes) and may find attributes that `getattr` can’t (like descriptors that raise AttributeError). It can also return descriptors objects instead of instance members.

If the instance `__dict__` is shadowed by another member (for example a property) then this function will be unable to find instance members.

New in version 3.2.

`getattr_static()` does not resolve descriptors, for example slot descriptors or getset descriptors on objects implemented in C. The descriptor object is returned instead of the underlying attribute.

You can handle these with code like the following. Note that for arbitrary getset descriptors invoking these may trigger code execution:

```python
# example code for resolving the builtin descriptor types
class _foo:
    __slots__ = ['foo']

slot_descriptor = type(_foo.foo)
getset_descriptor = type(open(__file__).name)
wrapper_descriptor = type(str.__dict__['__add__'])
descriptor_types = (slot_descriptor, getset_descriptor, wrapper_descriptor)

result = getattr_static(some_object, 'foo')
if type(result) in descriptor_types:
    try:
        result = result.__get__()
    except AttributeError:
        # descriptors can raise AttributeError to
        # indicate there is no underlying value
        # in which case the descriptor itself will
        # have to do
        pass
```
29.13.7 Current State of Generators and Coroutines

When implementing coroutine schedulers and for other advanced uses of generators, it is useful to determine whether a generator is currently executing, is waiting to start or resume or execution, or has already terminated. `getgeneratorstate()` allows the current state of a generator to be determined easily.

```python
inspect.getgeneratorstate(generator)
```
Get current state of a generator-iterator.

**Possible states are:**
- **GEN_CREATED**: Waiting to start execution.
- **GEN_RUNNING**: Currently being executed by the interpreter.
- **GEN_SUSPENDED**: Currently suspended at a yield expression.
- **GEN_CLOSED**: Execution has completed.

New in version 3.2.

```python
inspect.getcoroutinestate(coroutine)
```
Get current state of a coroutine object. The function is intended to be used with coroutine objects created by `async def` functions, but will accept any coroutine-like object that has `cr_running` and `cr_frame` attributes.

**Possible states are:**
- **CORO_CREATED**: Waiting to start execution.
- **CORO_RUNNING**: Currently being executed by the interpreter.
- **CORO_SUSPENDED**: Currently suspended at an await expression.
- **CORO_CLOSED**: Execution has completed.

New in version 3.5.

The current internal state of the generator can also be queried. This is mostly useful for testing purposes, to ensure that internal state is being updated as expected:

```python
inspect.getgeneratorlocals(generator)
```
Get the mapping of live local variables in `generator` to their current values. A dictionary is returned that maps from variable names to values. This is the equivalent of calling `locals()` in the body of the generator, and all the same caveats apply.

If `generator` is a `generator` with no currently associated frame, then an empty dictionary is returned. `TypeError` is raised if `generator` is not a Python generator object.

**CPython implementation detail:** This function relies on the generator exposing a Python stack frame for introspection, which isn’t guaranteed to be the case in all implementations of Python. In such cases, this function will always return an empty dictionary.

New in version 3.3.

```python
inspect.getcoroutinelocals(coroutine)
```
This function is analogous to `getgeneratorlocals()`, but works for coroutine objects created by `async def` functions.

New in version 3.5.
29.13.8 Code Objects Bit Flags

Python code objects have a `co_flags` attribute, which is a bitmap of the following flags:

- `inspect.CO_OPTIMIZED`
  - The code object is optimized, using fast locals.
- `inspect.CO_NEWLOCALS`
  - If set, a new dict will be created for the frame’s `f_locals` when the code object is executed.
- `inspect.CO_VARARGS`
  - The code object has a variable positional parameter (like `*args`).
- `inspect.CO_VARKEYWORDS`
  - The code object has a variable keyword parameter (like `**kwargs`).
- `inspect.CO_NESTED`
  - The flag is set when the code object is a nested function.
- `inspect.CO_GENERATOR`
  - The flag is set when the code object is a generator function, i.e. a generator object is returned when the code object is executed.
- `inspect.CO_NOFREE`
  - The flag is set if there are no free or cell variables.
- `inspect.CO_COROUTINE`
  - The flag is set when the code object is a coroutine function. When the code object is executed it returns a coroutine object. See PEP 492 for more details.
  - New in version 3.5.
- `inspect.CO_ITERABLE_COROUTINE`
  - The flag is used to transform generators into generator-based coroutines. Generator objects with this flag can be used in `await` expression, and can `yield from` coroutine objects. See PEP 492 for more details.
  - New in version 3.5.
- `inspect.CO_ASYNC_GENERATOR`
  - The flag is set when the code object is an asynchronous generator function. When the code object is executed it returns an asynchronous generator object. See PEP 525 for more details.
  - New in version 3.6.

**Note:** The flags are specific to CPython, and may not be defined in other Python implementations. Furthermore, the flags are an implementation detail, and can be removed or deprecated in future Python releases. It’s recommended to use public APIs from the `inspect` module for any introspection needs.

29.13.9 Command Line Interface

The `inspect` module also provides a basic introspection capability from the command line.

By default, accepts the name of a module and prints the source of that module. A class or function within the module can be printed instead by appended a colon and the qualified name of the target object.

```
--details
```

Print information about the specified object rather than the source code.
29.14 site — Site-specific configuration hook

Source code: Lib/site.py

This module is automatically imported during initialization. The automatic import can be suppressed using the interpreter’s `-S` option.

Importing this module will append site-specific paths to the module search path and add a few builtins, unless `-S` was used. In that case, this module can be safely imported with no automatic modifications to the module search path or additions to the builtins. To explicitly trigger the usual site-specific additions, call the `site.main()` function.

Changed in version 3.3: Importing the module used to trigger paths manipulation even when using `-S`.

It starts by constructing up to four directories from a head and a tail part. For the head part, it uses `sys.prefix` and `sys.exec_prefix`; empty heads are skipped. For the tail part, it uses the empty string and then `lib/site-packages` (on Windows) or `lib/pythonX.Y/site-packages` (on Unix and macOS). For each of the distinct head-tail combinations, it sees if it refers to an existing directory, and if so, adds it to `sys.path` and also inspects the newly added path for configuration files.

Changed in version 3.5: Support for the “site-python” directory has been removed.

If a file named “pyvenv.cfg” exists one directory above `sys.executable`, `sys.prefix` and `sys.exec_prefix` are set to that directory and it is also checked for site-packages (`sys.base_prefix` and `sys.base_exec_prefix` will always be the “real” prefixes of the Python installation). If “pyvenv.cfg” (a bootstrap configuration file) contains the key “include-system-site-packages” set to anything other than “true” (case-insensitive), the system-level prefixes will not be searched for site-packages; otherwise they will.

A path configuration file is a file whose name has the form `name.pth` and exists in one of the four directories mentioned above; its contents are additional items (one per line) to be added to `sys.path`. Non-existing items are never added to `sys.path`, and no check is made that the item refers to a directory rather than a file. No item is added to `sys.path` more than once. Blank lines and lines beginning with `#` are skipped. Lines starting with `import` (followed by space or tab) are executed.

Note: An executable line in a `.pth` file is run at every Python startup, regardless of whether a particular module is actually going to be used. Its impact should thus be kept to a minimum. The primary intended purpose of executable lines is to make the corresponding module(s) importable (load 3rd-party import hooks, adjust `PATH` etc). Any other initialization is supposed to be done upon a module’s actual import, if and when it happens. Limiting a code chunk to a single line is a deliberate measure to discourage putting anything more complex here.

For example, suppose `sys.prefix` and `sys.exec_prefix` are set to `/usr/local`. The Python X.Y library is then installed in `/usr/local/lib/pythonX.Y`. Suppose this has a subdirectory `/usr/local/lib/pythonX.Y/site-packages` with three subdirectories, `foo`, `bar` and `spam`, and two path configuration files, `foo.pth` and `bar.pth`. Assume `foo.pth` contains the following:

```python
# foo package configuration
foo
bar
bletch
```

and `bar.pth` contains:

```python
# bar package configuration
bar
```

Then the following version-specific directories are added to `sys.path`, in this order:
Note that bletch is omitted because it doesn’t exist; the bar directory precedes the foo directory because bar. pth comes alphabetically before foo.pth; and spam is omitted because it is not mentioned in either path configuration file.

After these path manipulations, an attempt is made to import a module named sitecustomize, which can perform arbitrary site-specific customizations. It is typically created by a system administrator in the site-packages directory. If this import fails with an ImportError or its subclass exception, and the exception’s name attribute equals to 'sitecustomize', it is silently ignored. If Python is started without output streams available, as with pythonw.exe on Windows (which is used by default to start IDLE), attempted output from sitecustomize is ignored. Any other exception causes a silent and perhaps mysterious failure of the process.

After this, an attempt is made to import a module named usercustomize, which can perform arbitrary user-specific customizations, if ENABLE_USER_SITE is true. This file is intended to be created in the user site-packages directory (see below), which is part of sys.path unless disabled by -s. If this import fails with an ImportError or its subclass exception, and the exception’s name attribute equals to 'usercustomize', it is silently ignored.

Note that for some non-Unix systems, sys.prefix and sys.exec_prefix are empty, and the path manipulations are skipped; however the import of sitecustomize and usercustomize is still attempted.

29.14.1 Readline configuration

On systems that support readline, this module will also import and configure the rlcompleter module, if Python is started in interactive mode and without the -S option. The default behavior is enable tab-completion and to use ~/.python_history as the history save file. To disable it, delete (or override) the sys.__interactivehook__ attribute in your sitecustomize or usercustomize module or your PYTHONSTARTUP file.

Changed in version 3.4: Activation of rlcompleter and history was made automatic.

29.14.2 Module contents

site.PREFIXES
A list of prefixes for site-packages directories.

site.ENABLE_USER_SITE
Flag showing the status of the user site-packages directory. True means that it is enabled and was added to sys.path. False means that it was disabled by user request (with -s or PYTHONNOUSERSITE). None means it was disabled for security reasons (mismatch between user or group id and effective id) or by an administrator.

site.USER_SITE
Path to the user site-packages for the running Python. Can be None if getUsersitepackages() hasn’t been called yet. Default value is ~/.local/lib/pythonX.Y/site-packages for UNIX and non-framework macOS builds, ~/Library/Python/X.Y/lib/python/site-packages for macOS framework builds, and %APPDATA%\Python\PythonXY\site-packages on Windows. This directory is a site directory, which means that .pth files in it will be processed.

site.USER_BASE
Path to the base directory for the user site-packages. Can be None if getuserbase() hasn’t been called yet. Default value is ~/.local for UNIX and macOS non-framework builds, ~/Library/Python/X.Y for macOS framework builds, and %APPDATA%\Python for Windows. This value is used by Distutils to compute the installation directories for scripts, data files, Python modules, etc. for the user installation scheme. See also PYTHONUSERBASE.

site.main()
Adds all the standard site-specific directories to the module search path. This function is called automatically when this module is imported, unless the Python interpreter was started with the -S flag.
Changed in version 3.3: This function used to be called unconditionally.

```python
site.addsitedir(sitedir, known_paths=None)
```

Add a directory to sys.path and process its .pth files. Typically used in sitecustomize or usercustomize (see above).

```python
site.getsitepackages()
```

Return a list containing all global site-packages directories.

New in version 3.2.

```python
site.getuserbase()
```

Return the path of the user base directory, USER_BASE. If it is not initialized yet, this function will also set it, respecting PYTHONUSERBASE.

New in version 3.2.

```python
site.getusersitepackages()
```

Return the path of the user-specific site-packages directory, USER_SITE. If it is not initialized yet, this function will also set it, respecting USER_BASE. To determine if the user-specific site-packages was added to sys.path ENABLE_USER_SITE should be used.

New in version 3.2.

### 29.14.3 Command Line Interface

The `site` module also provides a way to get the user directories from the command line:

```
$ python3 -m site --user-site
/home/user/.local/lib/python3.3/site-packages
```

If it is called without arguments, it will print the contents of sys.path on the standard output, followed by the value of USER_BASE and whether the directory exists, then the same thing for USER_SITE, and finally the value of ENABLE_USER_SITE.

```
--user-base
    Print the path to the user base directory.

--user-site
    Print the path to the user site-packages directory.
```

If both options are given, user base and user site will be printed (always in this order), separated by os.pathsep.

If any option is given, the script will exit with one of these values: 0 if the user site-packages directory is enabled, 1 if it was disabled by the user, 2 if it is disabled for security reasons or by an administrator, and a value greater than 2 if there is an error.

**See also:**

PEP 370 – Per user site-packages directory
The modules described in this chapter allow writing interfaces similar to Python’s interactive interpreter. If you want a Python interpreter that supports some special feature in addition to the Python language, you should look at the code module. (The codeop module is lower-level, used to support compiling a possibly-incomplete chunk of Python code.)

The full list of modules described in this chapter is:

### 30.1 code — Interpreter base classes

The code module provides facilities to implement read-eval-print loops in Python. Two classes and convenience functions are included which can be used to build applications which provide an interactive interpreter prompt.

**class code.InteractiveInterpreter (locals=None)**

This class deals with parsing and interpreter state (the user’s namespace); it does not deal with input buffering or prompting or input file naming (the filename is always passed in explicitly). The optional locals argument specifies the dictionary in which code will be executed; it defaults to a newly created dictionary with key '__name__' set to '__console__' and key '__doc__' set to None.

**class code.InteractiveConsole (locals=None, filename='<console>')**

Closely emulate the behavior of the interactive Python interpreter. This class builds on InteractiveInterpreter and adds prompting using the familiar sys.ps1 and sys.ps2, and input buffering.

**code.interact (banner=None, readfunc=None, local=None, exitmsg=None)**

Convenience function to run a read-eval-print loop. This creates a new instance of InteractiveConsole and sets readfunc to be used as the InteractiveConsole.raw_input() method, if provided. If local is provided, it is passed to the InteractiveConsole constructor for use as the default namespace for the interpreter loop. The interact() method of the instance is then run with banner and exitmsg passed as the banner and exit message to use, if provided. The console object is discarded after use.

Changed in version 3.6: Added exitmsg parameter.

**code.compile_command (source, filename='<input>', symbol='single')**

This function is useful for programs that want to emulate Python’s interpreter main loop (a.k.a. the read-eval-print loop). The tricky part is to determine when the user has entered an incomplete command that can be completed by entering more text (as opposed to a complete command or a syntax error). This function almost always makes the same decision as the real interpreter main loop.

source is the source string; filename is the optional filename from which source was read, defaulting to '<input>'; and symbol is the optional grammar start symbol, which should be 'single' (the default), 'eval' or 'exec'.

Returns a code object (the same as compile(source, filename, symbol)) if the command is complete and valid; None if the command is incomplete; raises SyntaxError if the command is complete and contains a syntax error, or raises OverflowError or ValueError if the command contains an invalid literal.
30.1.1 Interactive Interpreter Objects

InteractiveInterpreter\_runsource(order, filename='<input>', symbol='single')

Compile and run source in the interpreter. Arguments are the same as for compile\_command(); the default for filename is '<input>', and for symbol is 'single'. One of several things can happen:

- The input is incorrect; compile\_command() raised an exception (SyntaxError or OverflowError). A syntax traceback will be printed by calling the showsyntaxerror() method. run\_source() returns False.
- The input is incomplete, and more input is required; compile\_command() returned None. run\_source() returns True.
- The input is complete; compile\_command() returned a code object. The code is executed by calling the runcode() (which also handles run-time exceptions, except for SystemExit). runsource() returns False.

The return value can be used to decide whether to use sys.ps1 or sys.ps2 to prompt the next line.

InteractiveInterpreter\_runcode(code)

Execute a code object. When an exception occurs, showtraceback() is called to display a traceback. All exceptions are caught except SystemExit, which is allowed to propagate.

A note about Keyboardinterrupt: this exception may occur elsewhere in this code, and may not always be caught. The caller should be prepared to deal with it.

InteractiveInterpreter\_showsyntaxerror(filename=None)

Display the syntax error that just occurred. This does not display a stack trace because there isn't one for syntax errors. If filename is given, it is stuffed into the exception instead of the default filename provided by Python's parser, because it always uses '<string>' when reading from a string. The output is written by the write() method.

InteractiveInterpreter\_showtraceback()

Display the exception that just occurred. We remove the first stack item because it is within the interpreter object implementation. The output is written by the write() method.

Changed in version 3.5: The full chained traceback is displayed instead of just the primary traceback.

InteractiveInterpreter\_write(data)

Write a string to the standard error stream (sys.stderr). Derived classes should override this to provide the appropriate output handling as needed.

30.1.2 Interactive Console Objects

The InteractiveConsole class is a subclass of InteractiveInterpreter, and so offers all the methods of the interpreter objects as well as the following additions.

InteractiveConsole\_interact(banner=None, exitmsg=None)

Closely emulate the interactive Python console. The optional banner argument specifies the banner to print before the first interaction; by default it prints a banner similar to the one printed by the standard Python interpreter, followed by the class name of the console object in parentheses (so as not to confuse this with the real interpreter – since it’s so close!).

The optional exitmsg argument specifies an exit message printed when exiting. Pass the empty string to suppress the exit message. If exitmsg is not given or None, a default message is printed.

Changed in version 3.4: To suppress printing any banner, pass an empty string.

Changed in version 3.6: Print an exit message when exiting.

InteractiveConsole\_push(line)

Push a line of source text to the interpreter. The line should not have a trailing newline; it may have internal newlines. The line is appended to a buffer and the interpreter’s runsource() method is called with the concatenated contents of the buffer as source. If this indicates that the command was executed or invalid, the buffer is reset; otherwise, the command is incomplete, and the buffer is left as it was after the line was
appended. The return value is True if more input is required, False if the line was dealt with in some way (this is the same as `runsource()`).

**InteractiveConsole.resetbuffer()**
Remove any unhandled source text from the input buffer.

**InteractiveConsole.raw_input**(prompt=)
Write a prompt and read a line. The returned line does not include the trailing newline. When the user enters the EOF key sequence, `EOFError` is raised. The base implementation reads from `sys.stdin`; a subclass may replace this with a different implementation.

### 30.2 codeop — Compile Python code

**Source code:** `Lib/codeop.py`

The `codeop` module provides utilities upon which the Python read-eval-print loop can be emulated, as is done in the `code` module. As a result, you probably don’t want to use the module directly; if you want to include such a loop in your program you probably want to use the `code` module instead.

There are two parts to this job:

1. Being able to tell if a line of input completes a Python statement: in short, telling whether to print `>>>` or `...` next.
2. Remembering which future statements the user has entered, so subsequent input can be compiled with these in effect.

The `codeop` module provides a way of doing each of these things, and a way of doing them both.

To do just the former:

```python
codeop.compile_command(source, filename='<input>', symbol='single')
```

Tries to compile `source`, which should be a string of Python code and return a code object if `source` is valid Python code. In that case, the filename attribute of the code object will be `filename`, which defaults to '<input>'. Returns None if `source` is not valid Python code, but is a prefix of valid Python code.

If there is a problem with `source`, an exception will be raised. `SyntaxError` is raised if there is invalid Python syntax, and `OverflowError` or `ValueError` if there is an invalid literal.

The `symbol` argument determines whether `source` is compiled as a statement (`'single'`, the default), as a sequence of statements (`'exec'`) or as an expression (`'eval'`). Any other value will cause `ValueError` to be raised.

**Note:** It is possible (but not likely) that the parser stops parsing with a successful outcome before reaching the end of the source; in this case, trailing symbols may be ignored instead of causing an error. For example, a backslash followed by two newlines may be followed by arbitrary garbage. This will be fixed once the API for the parser is better.

```python
class codeop.Compile
Instances of this class have _call__() methods identical in signature to the built-in function compile(), but with the difference that if the instance compiles program text containing a __future__ statement, the instance ‘remembers’ and compiles all subsequent program texts with the statement in force.
```

```python
class codeop.CommandCompiler
Instances of this class have _call__() methods identical in signature to compile_command(); the difference is that if the instance compiles program text containing a __future__ statement, the instance ‘remembers’ and compiles all subsequent program texts with the statement in force.
```
The modules described in this chapter provide new ways to import other Python modules and hooks for customizing the import process.

The full list of modules described in this chapter is:

### 31.1 zipimport — Import modules from Zip archives

**Source code:** Lib/zipimport.py

This module adds the ability to import Python modules (*.py, *.pyc) and packages from ZIP-format archives. It is usually not needed to use the `zipimport` module explicitly; it is automatically used by the built-in import mechanism for `sys.path` items that are paths to ZIP archives.

Typically, `sys.path` is a list of directory names as strings. This module also allows an item of `sys.path` to be a string naming a ZIP file archive. The ZIP archive can contain a subdirectory structure to support package imports, and a path within the archive can be specified to only import from a subdirectory. For example, the path `example.zip/lib/` would only import from the `lib/` subdirectory within the archive.

Any files may be present in the ZIP archive, but importers are only invoked for `.py` and `.pyc` files. ZIP import of dynamic modules (`.pyd`, `.so`) is disallowed. Note that if an archive only contains `.py` files, Python will not attempt to modify the archive by adding the corresponding `.pyc` file, meaning that if a ZIP archive doesn’t contain `.pyc` files, importing may be rather slow.

Changed in version 3.8: Previously, ZIP archives with an archive comment were not supported.

**See also:**

- **PKZIP Application Note**  Documentation on the ZIP file format by Phil Katz, the creator of the format and algorithms used.

- **PEP 273 - Import Modules from Zip Archives**  Written by James C. Ahlstrom, who also provided an implementation. Python 2.3 follows the specification in PEP 273, but uses an implementation written by Just van Rossum that uses the import hooks described in PEP 302.

- **importlib - The implementation of the import machinery**  Package providing the relevant protocols for all importers to implement.

This module defines an exception:

- **exception** `zipimport.ZipImportError`  Exception raised by zipimporter objects. It’s a subclass of `ImportError`, so it can be caught as `ImportError`, too.
31.1.1 zipimporter Objects

`zipimporter` is the class for importing ZIP files.

```python
class zipimport.zipimporter(archivepath)
```
Create a new zipimporter instance. `archivepath` must be a path to a ZIP file, or to a specific path within a ZIP file. For example, an `archivepath` of `foo/bar.zip/lib` will look for modules in the `lib` directory inside the ZIP file `foo/bar.zip` (provided that it exists).

`ZipImportError` is raised if `archivepath` doesn’t point to a valid ZIP archive.

```python
def create_module(spec)
    Implementation of `importlib.abc.Loader.create_module()` that returns `None` to explicitly request the default semantics.
    New in version 3.10.

def exec_module(module)
    Implementation of `importlib.abc.Loader.exec_module()`.
    New in version 3.10.

def find_loader(fullname, path=None)
    An implementation of `importlib.abc.PathEntryFinder.find_loader()`.
    Deprecated since version 3.10: Use `find_spec()` instead.

def find_module(fullname, path=None)
    Search for a module specified by `fullname`. `fullname` must be the fully qualified (dotted) module name. It returns the zipimporter instance itself if the module was found, or `None` if it wasn’t. The optional `path` argument is ignored—it’s there for compatibility with the importer protocol.
    Deprecated since version 3.10: Use `find_spec()` instead.

def find_spec(fullname, target=None)
    An implementation of `importlib.abc.PathEntryFinder.find_spec()`.
    New in version 3.10.

def get_code(fullname)
    Return the code object for the specified module. Raise `ZipImportError` if the module couldn’t be import.

def get_data(pathname)
    Return the data associated with `pathname`. Raise `OSError` if the file wasn’t found.
    Changed in version 3.3: `IOError` used to be raised instead of `OSError`.

def get_filename(fullname)
    Return the value `__file__` would be set to if the specified module was imported. Raise `ZipImportError` if the module couldn’t be imported.
    New in version 3.1.

def get_source(fullname)
    Return the source code for the specified module. Raise `ZipImportError` if the module couldn’t be found, return `None` if the archive does contain the module, but has no source for it.

def is_package(fullname)
    Return `True` if the module specified by `fullname` is a package. Raise `ZipImportError` if the module couldn’t be found.

def load_module(fullname)
    Load the module specified by `fullname`. `fullname` must be the fully qualified (dotted) module name. Returns the imported module on success, raises `ZipImportError` on failure.
    Deprecated since version 3.10: Use `exec_module()` instead.
```
invalidate_caches()

Clear out the internal cache of information about files found within the ZIP archive.

New in version 3.10.

archive

The file name of the importer's associated ZIP file, without a possible subpath.

prefix

The subpath within the ZIP file where modules are searched. This is the empty string for zipfile objects which point to the root of the ZIP file.

The archive and prefix attributes, when combined with a slash, equal the original archivepath argument given to the zipfile constructor.

31.1.2 Examples

Here is an example that imports a module from a ZIP archive - note that the zipfile module is not explicitly used.

```
$ unzip -l example.zip
Archive: example.zip
 Length Date Time Name
-------- ---- ---- ----
8467 11-26-02 22:30 jwzthreading.py
-------- -------
8467 1 file
$ ./python
Python 2.3 (#1, Aug 1 2003, 19:54:32)
>>> import sys
>>> sys.path.insert(0, 'example.zip')  # Add .zip file to front of path
>>> import jwzthreading
>>> jwzthreading.__file__
'example.zip/jwzthreading.py'
```

31.2 pkgutil — Package extension utility

Source code: Lib/pkgutil.py

This module provides utilities for the import system, in particular package support.

class pkgutil.ModuleInfo (module_finder, name, ispkg)

A namedtuple that holds a brief summary of a module's info.

New in version 3.6.

pkgutil.extend_path (path, name)

Extend the search path for the modules which comprise a package. Intended use is to place the following code in a package's __init__.py:

```
from pkgutil import extend_path
__path__ = extend_path(__path__, __name__)
```

This will add to the package's __path__ all subdirectories of directories on sys.path named after the package. This is useful if one wants to distribute different parts of a single logical package as multiple directories.

It also looks for *.pkg files beginning where * matches the name argument. This feature is similar to *.pth files (see the site module for more information), except that it doesn't special-case lines starting with
import. A *.pkg file is trusted at face value: apart from checking for duplicates, all entries found in a
*.pkg file are added to the path, regardless of whether they exist on the filesystem. (This is a feature.)

If the input path is not a list (as is the case for frozen packages) it is returned unchanged. The input path is not
modified; an extended copy is returned. Items are only appended to the copy at the end.

It is assumed that sys.path is a sequence. Items of sys.path that are not strings referring to existing
directories are ignored. Unicode items on sys.path that cause errors when used as filenames may cause this
function to raise an exception (in line with os.path.isdir() behavior).

class pkgutil.ImpImporter (dirname=None)

PEP 302 Finder that wraps Python’s “classic” import algorithm.

If dirname is a string, a PEP 302 finder is created that searches that directory. If dirname is None, a PEP
302 finder is created that searches the current sys.path, plus any modules that are frozen or built-in.

Note that ImpImporter does not currently support being used by placement on sys.meta_path.

Deprecated since version 3.3: This emulation is no longer needed, as the standard import mechanism is now
fully PEP 302 compliant and available in importlib.

class pkgutil.ImpLoader (fullname, file, filename, etc)

Loader that wraps Python’s “classic” import algorithm.

Deprecated since version 3.3: This emulation is no longer needed, as the standard import mechanism is now
fully PEP 302 compliant and available in importlib.

pkgutil.find_loader (fullname)

Retrieve a module loader for the given fullname.

This is a backwards compatibility wrapper around importlib.util.find_spec() that converts most
failures to ImportError and only returns the loader rather than the full ModuleSpec.

Changed in version 3.3: Updated to be based directly on importlib rather than relying on the package
internal PEP 302 import emulation.

Changed in version 3.4: Updated to be based on PEP 451

pkgutil.get_importer (path_item)

Retrieve a finder for the given path_item.

The returned finder is cached in sys.path_importer_cache if it was newly created by a path hook.

The cache (or part of it) can be cleared manually if a rescan of sys.path_hooks is necessary.

Changed in version 3.3: Updated to be based directly on importlib rather than relying on the package
internal PEP 302 import emulation.

pkgutil.get_loader (module_or_name)

Get a loader object for module_or_name.

If the module or package is accessible via the normal import mechanism, a wrapper around the relevant part of
that machinery is returned. Returns None if the module cannot be found or imported. If the named module is
not already imported, its containing package (if any) is imported, in order to establish the package __path__.

Changed in version 3.3: Updated to be based directly on importlib rather than relying on the package
internal PEP 302 import emulation.

Changed in version 3.4: Updated to be based on PEP 451

pkgutil.iter_importers (fullname=““)

Yield finder objects for the given module name.

If fullname contains a ‘.’, the finders will be for the package containing fullname, otherwise they will be all
registered top level finders (i.e. those on both sys.meta_path and sys.path_hooks).

If the named module is in a package, that package is imported as a side effect of invoking this function.

If no module name is specified, all top level finders are produced.
Changed in version 3.3: Updated to be based directly on *importlib* rather than relying on the package internal *PEP 302* import emulation.

```
pkgutil.iter_modules(path=None, prefix="")
```

Yields *ModuleInfo* for all submodules on *path*, or, if *path* is None, all top-level modules on *sys.path*. *path* should be either None or a list of paths to look for modules in.

*prefix* is a string to output on the front of every module name on output.

**Note:** Only works for a *finder* which defines an *iter_modules()* method. This interface is non-standard, so the module also provides implementations for *importlib.machinery.FileFinder* and *zipimport.zipimporter*.

---

Changed in version 3.3: Updated to be based directly on *importlib* rather than relying on the package internal *PEP 302* import emulation.

```
pkgutil.walk_packages(path=None, prefix='', onerror=None)
```

Yields *ModuleInfo* for all modules recursively on *path*, or, if *path* is None, all accessible modules.

*path* should be either None or a list of paths to look for modules in.

*prefix* is a string to output on the front of every module name on output.

*onerror* is a function which gets called with one argument (the name of the package which was being imported) if any exception occurs while trying to import a package. If no *onerror* function is supplied, *ImportErrors* are caught and ignored, while all other exceptions are propagated, terminating the search.

Examples:

```
# list all modules python can access
walk_packages()

# list all submodules of ctypes
walk_packages(ctypes.__path__, ctypes.__name__ + '.')
```

**Note:** Only works for a *finder* which defines an *iter_modules()* method. This interface is non-standard, so the module also provides implementations for *importlib.machinery.FileFinder* and *zipimport.zipimporter*.

---

Changed in version 3.3: Updated to be based directly on *importlib* rather than relying on the package internal *PEP 302* import emulation.

```
pkgutil.get_data(package, resource)
```

Get a resource from a package.

This is a wrapper for the *loader* *get_data* API. The *package* argument should be the name of a package, in standard module format (*foo.bar*). The *resource* argument should be in the form of a relative filename, using / as the path separator. The parent directory name .. is not allowed, and nor is a rooted name (starting with a /).

The function returns a binary string that is the contents of the specified resource.

For packages located in the filesystem, which have already been imported, this is the rough equivalent of:

```
d = os.path.dirname(sys.modules[package].__file__)
data = open(os.path.join(d, resource), 'rb').read()
```

If the package cannot be located or loaded, or it uses a *loader* which does not support *get_data*, then *None* is returned. In particular, the *loader* for *namespace packages* does not support *get_data*.
pkgutil.resolve_name(name)
Resolve a name to an object.

This functionality is used in numerous places in the standard library (see bpo-12915) - and equivalent functionality is also in widely used third-party packages such as setuptools, Django and Pyramid.

It is expected that name will be a string in one of the following formats, where W is shorthand for a valid Python identifier and dot stands for a literal period in these pseudo-regexes:

- W(.W)*
- W(.W)*: (W(.W) *)?

The first form is intended for backward compatibility only. It assumes that some part of the dotted name is a package, and the rest is an object somewhere within that package, possibly nested inside other objects. Because the place where the package stops and the object hierarchy starts can’t be inferred by inspection, repeated attempts to import must be done with this form.

In the second form, the caller makes the division point clear through the provision of a single colon: the dotted name to the left of the colon is a package to be imported, and the dotted name to the right is the object hierarchy within that package. Only one import is needed in this form. If it ends with the colon, then a module object is returned.

The function will return an object (which might be a module), or raise one of the following exceptions:

- **ValueError** – if name isn’t in a recognised format.
- **ImportError** – if an import failed when it shouldn’t have.
- **(AttributeError** – If a failure occurred when traversing the object hierarchy within the imported package to get to the desired object.

New in version 3.9.

### 31.3 modulefinder — Find modules used by a script

**Source code:** Lib/modulefinder.py

This module provides a `ModuleFinder` class that can be used to determine the set of modules imported by a script. `modulefinder.py` can also be run as a script, giving the filename of a Python script as its argument, after which a report of the imported modules will be printed.

`modulefinder.AddPackagePath(pkg_name, path)`
Record that the package named `pkg_name` can be found in the specified `path`.

`modulefinder.ReplacePackage(oldname, newname)`
Allows specifying that the module named `oldname` is in fact the package named `newname`.

```python
class modulefinder.ModuleFinder(path=None, debug=0, excludes=[], replace_paths=[])```
This class provides `run_script()` and `report()` methods to determine the set of modules imported by a script. `path` can be a list of directories to search for modules; if not specified, `sys.path` is used. `debug` sets the debugging level; higher values make the class print debugging messages about what it’s doing. `excludes` is a list of module names to exclude from the analysis. `replace_paths` is a list of `(oldpath, newpath)` tuples that will be replaced in module paths.

```python
report()
```
Print a report to standard output that lists the modules imported by the script and their paths, as well as modules that are missing or seem to be missing.

```python
run_script(pathname)
```
Analyze the contents of the `pathname` file, which must contain Python code.

`modules`
A dictionary mapping module names to modules. See Example usage of ModuleFinder.
### 31.3.1 Example usage of ModuleFinder

The script that is going to get analyzed later on (bacon.py):

```python
import re, itertools
try:
    import baconhameggs
except ImportError:
    pass

try:
    import guido.python.ham
except ImportError:
    pass
```

The script that will output the report of bacon.py:

```python
from modulefinder import ModuleFinder
finder = ModuleFinder()
finder.run_script('bacon.py')
print('Loaded modules:')
for name, mod in finder.modules.items():
    print('%s: %s' % (name, end=''))
    print(','.join(list(mod.globalnames.keys()))[:3])
print('Modules not imported:')
print('
'.join(finder.badmodules.keys()))
```

Sample output (may vary depending on the architecture):

```
Loaded modules:
_types: _types:
 copyreg: _inverted_registry, _slotnames, __all__
 sre_compile: isstring, _sre, _optimize_unicode
 __sre: _sre:
 sre_constants: REPEAT_ONE, makedict, AT_END_LINE
 sys:
 re: __module__, finditer, __expand
 itertools: __main__: re, itertools, baconhameggs
 sre_parse: _PATTERNENDERS, SRE_FLAG_UNICODE
 array:
 types: __module__, IntType, TypeType

Modules not imported:
 guido.python.ham
 baconhameggs
```
31.4 runpy — Locating and executing Python modules

Source code: Lib/runpy.py

The runpy module is used to locate and run Python modules without importing them first. Its main use is to implement the \(-m\) command line switch that allows scripts to be located using the Python module namespace rather than the filesystem.

Note that this is not a sandbox module - all code is executed in the current process, and any side effects (such as cached imports of other modules) will remain in place after the functions have returned.

Furthermore, any functions and classes defined by the executed code are not guaranteed to work correctly after a runpy function has returned. If that limitation is not acceptable for a given use case, importlib is likely to be a more suitable choice than this module.

The runpy module provides two functions:

runpy.run_module(mod_name, init_globals=None, run_name=None, alter_sys=False)

Execute the code of the specified module and return the resulting module globals dictionary. The module’s code is first located using the standard import mechanism (refer to PEP 302 for details) and then executed in a fresh module namespace.

The mod_name argument should be an absolute module name. If the module name refers to a package rather than a normal module, then that package is imported and the __main__ submodule within that package is then executed and the resulting module globals dictionary returned.

The optional dictionary argument init_globals may be used to pre-populate the module’s globals dictionary before the code is executed. The supplied dictionary will not be modified. If any of the special global variables below are defined in the supplied dictionary, those definitions are overridden by run_module().

The special global variables __name__, __spec__, __file__, __cached__, __loader__ and __package__ are set in the globals dictionary before the module code is executed (Note that this is a minimal set of variables - other variables may be set implicitly as an interpreter implementation detail).

__name__ is set to run_name if this optional argument is not None, to mod_name + '.__main__' if the named module is a package and to the mod_name argument otherwise.

__spec__ will be set appropriately for the actually imported module (that is, __spec__.name will always be mod_name or mod_name + '.__main__', never run_name).

__file__, __cached__, __loader__ and __package__ are set as normal based on the module spec.

If the argument alter_sys is supplied and evaluates to True, then sys.argv[0] is updated with the value of __file__ and sys.modules[__name__] is updated with a temporary module object for the module being executed. Both sys.argv[0] and sys.modules[__name__] are restored to their original values before the function returns.

Note that this manipulation of sys is not thread-safe. Other threads may see the partially initialised module, as well as the altered list of arguments. It is recommended that the sys module be left alone when invoking this function from threaded code.

See also:

The \(-m\) option offering equivalent functionality from the command line.

Changed in version 3.1: Added ability to execute packages by looking for a __main__ submodule.

Changed in version 3.2: Added __cached__ global variable (see PEP 3147).

Changed in version 3.4: Updated to take advantage of the module spec feature added by PEP 451. This allows __cached__ to be set correctly for modules run this way, as well as ensuring the real module name is always accessible as __spec__.name.
**runpy.run_path** *(file_path, init_globals=None, run_name=None)*

Execute the code at the named filesystem location and return the resulting module globals dictionary. As with a script name supplied to the CPython command line, the supplied path may refer to a Python source file, a compiled bytecode file or a valid sys.path entry containing a **main** module (e.g. a zipfile containing a top-level **main**.py file).

For a simple script, the specified code is simply executed in a fresh module namespace. For a valid sys.path entry (typically a zipfile or directory), the entry is first added to the beginning of sys.path. The function then looks for and executes a **main** module using the updated path. Note that there is no special protection against invoking an existing **main** entry located elsewhere on sys.path if there is no such module at the specified location.

The optional dictionary argument *init_globals* may be used to pre-populate the module’s globals dictionary before the code is executed. The supplied dictionary will not be modified. If any of the special global variables below are defined in the supplied dictionary, those definitions are overridden by *run_path()*.

The special global variables **name**, **spec**, **file**, **cached**, **loader** and **package** are set in the globals dictionary before the module code is executed (Note that this is a minimal set of variables - other variables may be set implicitly as an interpreter implementation detail).

**name** is set to *run_name* if this optional argument is not *None* and to '<run_path>' otherwise.

If the supplied path directly references a script file (whether as source or as precompiled byte code), then **file** will be set to the supplied path, and **spec**, **cached**, **loader** and **package** will all be set to *None*.

If the supplied path is a reference to a valid sys.path entry, then **spec** will be set appropriately for the imported **main** module (that is, **spec**.name will always be **main**). **file**, **cached**, **loader** and **package** will be set as normal based on the module spec.

A number of alterations are also made to the sys module. Firstly, sys.path may be altered as described above. sys.argv[0] is updated with the value of file_path and sys.modules[**name**] is updated with a temporary module object for the module being executed. All modifications to items in sys are reverted before the function returns.

Note that, unlike *run_module()* , the alterations made to sys are not optional in this function as these adjustments are essential to allowing the execution of sys.path entries. As the thread-safety limitations still apply, use of this function in threaded code should be either serialised with the import lock or delegated to a separate process.

**See also:**

using-on-interface-options for equivalent functionality on the command line (**python path/to/script**).

New in version 3.2.

Changed in version 3.4: Updated to take advantage of the module spec feature added by PEP 451. This allows **cached** to be set correctly in the case where **main** is imported from a valid sys.path entry rather than being executed directly.

using-on-general - CPython command line details

The *importlib.import_module()* function
31.5 importlib — The implementation of import

New in version 3.1.

Source code: Lib/importlib/__init__.py

31.5.1 Introduction

The purpose of the `importlib` package is two-fold. One is to provide the implementation of the `import` statement (and thus, by extension, the `__import__()` function) in Python source code. This provides an implementation of `import` which is portable to any Python interpreter. This also provides an implementation which is easier to comprehend than one implemented in a programming language other than Python.

Two, the components to implement `import` are exposed in this package, making it easier for users to create their own custom objects (known generically as an `importer`) to participate in the import process.

See also:

- `import` The language reference for the `import` statement.
- Packages specification Original specification of packages. Some semantics have changed since the writing of this document (e.g. redirecting based on `None` in `sys.modules`).
- The `__import__()` function The `import` statement is syntactic sugar for this function.

31.5.2 Functions

`importlib.__import__()` *(name, globals=None, locals=None, fromlist=(), level=0)*

An implementation of the built-in `__import__()` function.

Note: Programmatic importing of modules should use `import_module()` instead of this function.

`importlib.import_module(name, package=None)`

Import a module. The `name` argument specifies what module to import in absolute or relative terms (e.g. either `pkg.mod` or `.mod`). If the name is specified in relative terms, then the `package` argument must be set to the name of the package which is to act as the anchor for resolving the package name (e.g. `import_module('..mod', 'pkg.subpkg')` will import `pkg.mod`).
The `import_module()` function acts as a simplifying wrapper around `importlib.__import__()`. This means all semantics of the function are derived from `importlib.__import__()`. The most important difference between these two functions is that `import_module()` returns the specified package or module (e.g. `pkg.mod`), while `__import__()` returns the top-level package or module (e.g. `pkg`).

If you are dynamically importing a module that was created since the interpreter began execution (e.g., created a Python source file), you may need to call `invalidate_caches()` in order for the new module to be noticed by the import system.

Changed in version 3.3: Parent packages are automatically imported.

```
importlib.find_loader(name, path=None)
```

Find the loader for a module, optionally within the specified `path`. If the module is in `sys.modules`, then `sys.modules[name].__loader__` is returned (unless the loader would be `None` or is not set, in which case `ValueError` is raised). Otherwise a search using `sys.meta_path` is done. `None` is returned if no loader is found.

A dotted name does not have its parents implicitly imported as that requires loading them and that may not be desired. To properly import a submodule you will need to import all parent packages of the submodule and use the correct argument to `path`.

New in version 3.3.

Changed in version 3.4: If `__loader__` is not set, raise `ValueError`, just like when the attribute is set to `None`.

Depreciated since version 3.4: Use `importlib.util.find_spec()` instead.

```
importlib.invalidate_caches()
```

Invalidate the internal caches of finders stored at `sys.meta_path`. If a finder implements `invalidate_caches()` then it will be called to perform the invalidation. This function should be called if any modules are created/installed while your program is running to guarantee all finders will notice the new module's existence.

New in version 3.3.

```
importlib.reload(module)
```

Reload a previously imported `module`. The argument must be a module object, so it must have been successfully imported before. This is useful if you have edited the module source file using an external editor and want to try out the new version without leaving the Python interpreter. The return value is the module object (which can be different if re-importing causes a different object to be placed in `sys.modules`).

When `reload()` is executed:

- Python module's code is recompiled and the module-level code re-executed, defining a new set of objects which are bound to names in the module's dictionary by reusing the `loader` which originally loaded the module. The `init` function of extension modules is not called a second time.
- As with all other objects in Python the old objects are only reclaimed after their reference counts drop to zero.
- The names in the module namespace are updated to point to any new or changed objects.
- Other references to the old objects (such as names external to the module) are not rebound to refer to the new objects and must be updated in each namespace where they occur if that is desired.

There are a number of other caveats:

When a module is reloaded, its dictionary (containing the module's global variables) is retained. Redefinitions of names will override the old definitions, so this is generally not a problem. If the new version of a module does not define a name that was defined by the old version, the old definition remains. This feature can be used to the module's advantage if it maintains a global table or cache of objects — with a `try` statement it can test for the table's presence and skip its initialization if desired:

```
try:
    cache
(continues on next page)
```
except NameError:
    cache = {}

It is generally not very useful to reload built-in or dynamically loaded modules. Reloading `sys.__main__.builtins` and other key modules is not recommended. In many cases extension modules are not designed to be initialized more than once, and may fail in arbitrary ways when reloaded.

If a module imports objects from another module using `from ... import ...`, calling `reload()` for the other module does not redefine the objects imported from it — one way around this is to re-execute the `from` statement, another is to use `import` and qualified names (`module.name`) instead.

If a module instantiates instances of a class, reloading the module that defines the class does not affect the method definitions of the instances — they continue to use the old class definition. The same is true for derived classes.

New in version 3.4.

Changed in version 3.7: `ModuleNotFoundError` is raised when the module being reloaded lacks a `ModuleSpec`.

### 31.5.3 `importlib.abc` — Abstract base classes related to import

**Source code:** Lib/importlib/abc.py

The `importlib.abc` module contains all of the core abstract base classes used by `import`. Some subclasses of the core abstract base classes are also provided to help in implementing the core ABCs.

**ABC hierarchy:**

```
object
  +-- Finder (deprecated)
    |   +-- MetaPathFinder
    |   +-- PathEntryFinder
    +-- Loader
        +-- ResourceLoader --------+
        +-- InspectLoader
            +-- ExecutionLoader -->
                +-- FileLoader
                +-- SourceLoader
```

**class importlib.abc.Finder**

An abstract base class representing a `finder`.

Deprecated since version 3.3: Use `MetaPathFinder` or `PathEntryFinder` instead.

**abstractmethod find_module** (`fullname`, `path=None`)

An abstract method for finding a `loader` for the specified module. Originally specified in PEP 302, this method was meant for use in `sys.meta_path` and in the path-based import subsystem.

Changed in version 3.4: Returns `None` when called instead of raising `NotImplementedError`.

Deprecated since version 3.10: Implement `MetaPathFinder.find_spec()` or `PathEntryFinder.find_spec()` instead.

**class importlib.abc.MetaPathFinder**

An abstract base class representing a `meta path finder`. For compatibility, this is a subclass of `Finder`.

New in version 3.3.

Changed in version 3.10: No longer a subclass of `Finder`. 

1762 Chapter 31. Importing Modules
**find_spec (fullname, path, target=None)**

An abstract method for finding a spec for the specified module. If this is a top-level import, `path` will be `None`. Otherwise, this is a search for a subpackage or module and `path` will be the value of `__path__` from the parent package. If a spec cannot be found, `None` is returned. When passed in, `target` is a module object that the finder may use to make a more educated guess about what spec to return. `importlib.util.spec_from_loader()` may be useful for implementing concrete `MetaPathFinders`.

New in version 3.4.

**find_module (fullname, path)**

A legacy method for finding a loader for the specified module. If this is a top-level import, `path` will be `None`. Otherwise, this is a search for a subpackage or module and `path` will be the value of `__path__` from the parent package. If a loader cannot be found, `None` is returned.

If `find_spec()` is defined, backwards-compatible functionality is provided.

Changed in version 3.4: Returns `None` when called instead of raising `NotImplementedError`. Can use `find_spec()` to provide functionality.

Deprecated since version 3.4: Use `find_spec()` instead.

**invalidate_caches ()**

An optional method which, when called, should invalidate any internal cache used by the finder. Used by `importlib.invalidate_caches()` when invalidating the caches of all finders on `sys.meta_path`.

Changed in version 3.4: Returns `None` when called instead of `NotImplemented`.

**class importlib.abc.PathEntryFinder**

An abstract base class representing a path entry finder. Though it bears some similarities to `MetaPathFinder`, `PathEntryFinder` is meant for use only within the path-based import subsystem provided by `importlib.machinery.PathFinder`.

New in version 3.3.

Changed in version 3.10: No longer a subclass of `Finder`.

**find_spec (fullname, target=None)**

An abstract method for finding a spec for the specified module. The finder will search for the module only within the `path entry` to which it is assigned. If a spec cannot be found, `None` is returned. When passed in, `target` is a module object that the finder may use to make a more educated guess about what spec to return. `importlib.util.spec_from_loader()` may be useful for implementing concrete `PathEntryFinders`.

New in version 3.4.

**find_loader (fullname)**

A legacy method for finding a loader for the specified module. Returns a 2-tuple of `(loader, portion)` where `portion` is a sequence of file system locations contributing to part of a namespace package. The loader may be `None` while specifying `portion` to signify the contribution of the file system locations to a namespace package. An empty list can be used for `portion` to signify the loader is not part of a namespace package. If `loader` is `None` and `portion` is the empty list then no loader or location for a namespace package were found (i.e. failure to find anything for the module).

If `find_spec()` is defined then backwards-compatible functionality is provided.

Changed in version 3.4: Returns `(None, [])` instead of raising `NotImplementedError`. Uses `find_spec()` when available to provide functionality.

Deprecated since version 3.4: Use `find_spec()` instead.

**find_module (fullname)**

A concrete implementation of `Finder.find_module()` which is equivalent to `self.find_loader(fullname)[0]`.

Deprecated since version 3.4: Use `find_spec()` instead.
**invalidate_caches()**

An optional method which, when called, should invalidate any internal cache used by the finder. Used by `importlib.machinery.PathFinder.invalidate_caches()` when invalidating the caches of all cached finders.

**class importlib.abc.Loader**

An abstract base class for a *loader*. See PEP 302 for the exact definition for a loader.

Loaders that wish to support resource reading should implement a `get_resource_reader(fullname)` method as specified by `importlib.abc.ResourceReader`.

Changed in version 3.7: Introduced the optional `get_resource_reader()` method.

**create_module**(spec)

A method that returns the module object to use when importing a module. This method may return `None`, indicating that default module creation semantics should take place.

New in version 3.4.

Changed in version 3.5: Starting in Python 3.6, this method will not be optional when `exec_module()` is defined.

**exec_module**(module)

An abstract method that executes the module in its own namespace when a module is imported or reloaded. The module should already be initialized when `exec_module()` is called. When this method exists, `create_module()` must be defined.

New in version 3.4.

Changed in version 3.6: `create_module()` must also be defined.

**load_module**(fullname)

A legacy method for loading a module. If the module cannot be loaded, `ImportError` is raised, otherwise the loaded module is returned.

If the requested module already exists in `sys.modules`, that module should be used and reloaded. Otherwise the loader should create a new module and insert it into `sys.modules` before any loading begins, to prevent recursion from the import. If the loader inserted a module and the load fails, it must be removed by the loader from `sys.modules`; modules already in `sys.modules` before the loader began execution should be left alone (see `importlib.util.module_for_loader()`).

The loader should set several attributes on the module. (Note that some of these attributes can change when a module is reloaded):

- __name__ The name of the module.
- __file__ The path to where the module data is stored (not set for built-in modules).
- __cached__ The path to where a compiled version of the module is/should be stored (not set when the attribute would be inappropriate).
- __path__ A list of strings specifying the search path within a package. This attribute is not set on modules.
- __package__ The fully-qualified name of the package under which the module was loaded as a submodule (or the empty string for top-level modules). For packages, it is the same as __name__. The `importlib.util.module_for_loader()` decorator can handle the details for __package__.
- __loader__ The loader used to load the module. The `importlib.util.module_for_loader()` decorator can handle the details for __package__.

When `exec_module()` is available then backwards-compatible functionality is provided.

Changed in version 3.4: Raise `ImportError` when called instead of `NotImplementedError`. Functionality provided when `exec_module()` is available.
Deprecated since version 3.4: The recommended API for loading a module is `exec_module()` (and `create_module()`). Loaders should implement it instead of `load_module()`. The import machinery takes care of all the other responsibilities of `load_module()` when `exec_module()` is implemented.

```python
module_repr(module)
```
A legacy method which when implemented calculates and returns the given module’s repr, as a string. The module type’s default `repr()` will use the result of this method as appropriate.

- New in version 3.3.
- Changed in version 3.4: Made optional instead of an abstractmethod.
- Deprecated since version 3.4: The import machinery now takes care of this automatically.

```python
class importlib.abc.ResourceReader
    Superseded by TraversableResources
```
An abstract base class to provide the ability to read resources.

From the perspective of this ABC, a `resource` is a binary artifact that is shipped within a package. Typically this is something like a data file that lives next to the `__init__.py` file of the package. The purpose of this class is to help abstract out the accessing of such data files so that it does not matter if the package and its data file(s) are stored in a e.g. zip file versus on the file system.

For any of methods of this class, a `resource` argument is expected to be a `path-like object` which represents conceptually just a file name. This means that no subdirectory paths should be included in the `resource` argument. This is because the location of the package the reader is for, acts as the “directory”. Hence the metaphor for directories and file names is packages and resources, respectively. This is also why instances of this class are expected to directly correlate to a specific package (instead of potentially representing multiple packages or a module).

Loaders that wish to support resource reading are expected to provide a method called `get_resource_reader(fullname)` which returns an object implementing this ABC’s interface. If the module specified by `fullname` is not a package, this method should return `None`. An object compatible with this ABC should only be returned when the specified module is a package.

- New in version 3.7.
- Abstractmethod `open_resource(resource)`
  Returns an opened, `file-like object` for binary reading of the `resource`.
  If the resource cannot be found, `FileNotFoundError` is raised.

- Abstractmethod `resource_path(resource)`
  Returns the file system path to the `resource`.
  If the resource does not concretely exist on the file system, raise `FileNotFoundError`.

- Abstractmethod `is_resource(name)`
  Returns `True` if the named `name` is considered a resource. `FileNotFoundError` is raised if `name` does not exist.

- Abstractmethod `contents()`
  Returns an `iterable` of strings over the contents of the package. Do note that it is not required that all names returned by the iterator be actual resources, e.g. it is acceptable to return names for which `is_resource()` would be false.
  Allowing non-resource names to be returned is to allow for situations where how a package and its resources are stored is known a priori and the non-resource names would be useful. For instance, returning subdirectory names is allowed so that when it is known that the package and resources are stored on the file system then those subdirectory names can be used directly.
  The abstract method returns an iterable of no items.

```python
class importlib.abc.ResourceLoader
```
An abstract base class for a `loader` which implements the optional PEP 302 protocol for loading arbitrary resources from the storage back-end.
The Python Library Reference, Release 3.10.4

Deprecated since version 3.7: This ABC is deprecated in favour of supporting resource loading through `importlib.abc.ResourceReader`.

**abstractmethod `get_data(path)`**

An abstract method to return the bytes for the data located at `path`. Loaders that have a file-like storage back-end that allows storing arbitrary data can implement this abstract method to give direct access to the data stored. `OSError` is to be raised if the `path` cannot be found. The `path` is expected to be constructed using a module’s `__file__` attribute or an item from a package’s `__path__`.

Changed in version 3.4: Raises `OSError` instead of `NotImplementedError`.

**class `importlib.abc.InspectLoader`**

An abstract base class for a loader which implements the optional PEP 302 protocol for loaders that inspect modules.

**get_code(fullname)**

Return the code object for a module, or `None` if the module does not have a code object (as would be the case, for example, for a built-in module). Raise an `ImportError` if loader cannot find the requested module.

**Note:** While the method has a default implementation, it is suggested that it be overridden if possible for performance.

Changed in version 3.4: No longer abstract and a concrete implementation is provided.

**abstractmethod `get_source(fullname)`**

An abstract method to return the source of a module. It is returned as a text string using universal newlines, translating all recognized line separators into `'\n'` characters. Returns `None` if no source is available (e.g. a built-in module). Raises `ImportError` if the loader cannot find the module specified.

Changed in version 3.4: Raises `ImportError` instead of `NotImplementedError`.

**is_package(fullname)**

An optional method to return a true value if the module is a package, a false value otherwise. `ImportError` is raised if the loader cannot find the module.

Changed in version 3.4: Raises `ImportError` instead of `NotImplementedError`.

**static `source_to_code(data, path='<string>')`**

Create a code object from Python source.

The `data` argument can be whatever the `compile()` function supports (i.e. string or bytes). The `path` argument should be the “path” to where the source code originated from, which can be an abstract concept (e.g. location in a zip file).

With the subsequent code object one can execute it in a module by running `exec(code, module.__dict__)`.

New in version 3.4.

Changed in version 3.5: Made the method static.

**exec_module(module)**

Implementation of `Loader.exec_module()`.

New in version 3.4.

**load_module(fullname)**

Implementation of `Loader.load_module()`.

Deprecated since version 3.4: use `exec_module()` instead.

**class `importlib.abc.ExecutionLoader`**

An abstract base class which inherits from `InspectLoader` that, when implemented, helps a module to be executed as a script. The ABC represents an optional PEP 302 protocol.
abstract method get_filename(fullname)
   An abstract method that is to return the value of __file__ for the specified module. If no path is available, ImportError is raised.

   If source code is available, then the method should return the path to the source file, regardless of whether a bytecode was used to load the module.

   Changed in version 3.4: Raises ImportError instead of NotImplementedError.

class importlib.abc.FileLoader(fullname, path)
   An abstract base class which inherits from ResourceLoader and ExecutionLoader, providing concrete implementations of ResourceLoader.get_data() and ExecutionLoader.get_filename().

   The fullname argument is a fully resolved name of the module the loader is to handle. The path argument is the path to the file for the module.

   New in version 3.3.

   name
      The name of the module the loader can handle.

   path
      Path to the file of the module.

load_module(fullname)
   Calls super's load_module().

   Deprecated since version 3.4: Use Loader.exec_module() instead.

abstract method get_filename(fullname)
   Returns path.

abstract method get_data(path)
   Reads path as a binary file and returns the bytes from it.

class importlib.abc.SourceLoader
   An abstract base class for implementing source (and optionally bytecode) file loading. The class inherits from both ResourceLoader and ExecutionLoader, requiring the implementation of:

   • ResourceLoader.get_data()
   • ExecutionLoader.get_filename() Should only return the path to the source file; sourceless loading is not supported.

   The abstract methods defined by this class are to add optional bytecode file support. Not implementing these optional methods (or causing them to raise NotImplementedError) causes the loader to only work with source code. Implementing the methods allows the loader to work with source and bytecode files; it does not allow for sourceless loading where only bytecode is provided. Bytecode files are an optimization to speed up loading by removing the parsing step of Python's compiler, and so no bytecode-specific API is exposed.

path_stats(path)
   Optional abstract method which returns a dict containing metadata about the specified path. Supported dictionary keys are:

   • 'mtime' (mandatory): an integer or floating-point number representing the modification time of the source code;
   • 'size' (optional): the size in bytes of the source code.

   Any other keys in the dictionary are ignored, to allow for future extensions. If the path cannot be handled, OSError is raised.

   New in version 3.3.

   Changed in version 3.4: Raise OSError instead of NotImplementedError.

path_mtime(path)
   Optional abstract method which returns the modification time for the specified path.
set_data(path, data)
Optional abstract method which writes the specified bytes to a file path. Any intermediate directories which do not exist are to be created automatically.

When writing to the path fails because the path is read-only (errno.EACCES/PermissionError), do not propagate the exception.

Changed in version 3.4: No longer raises NotImplmentedError when called.

get_code(fullname)
Concrete implementation of InspectLoader.get_code().

exec_module(module)
Concrete implementation of Loader.exec_module().
New in version 3.4.

load_module(fullname)
Concrete implementation of Loader.load_module().
Depreciated since version 3.4: Use exec_module() instead.

get_source(fullname)
Concrete implementation of InspectLoader.get_source().

is_package(fullname)
Concrete implementation of InspectLoader.is_package(). A module is determined to be a package if its file path (as provided by ExecutionLoader.get_filename()) is a file named __init__ when the file extension is removed and the module name itself does not end in __init__.

class importlib.abc.Traversable
An object with a subset of pathlib.Path methods suitable for traversing directories and opening files.

New in version 3.9.

abstractmethod name()
The base name of this object without any parent references.

abstractmethod iterdir()
Yield Traversable objects in self.

abstractmethod is_dir()
Return True if self is a directory.

abstractmethod is_file()
Return True if self is a file.

abstractmethod joinpath(child)
Return Traversable child in self.

abstractmethod __truediv__(child)
Return Traversable child in self.

abstractmethod open(mode='r', *args, **kwargs)
mode may be 'r' or 'rb' to open as text or binary. Return a handle suitable for reading (same as pathlib.Path.open).

When opening as text, accepts encoding parameters such as those accepted by io.TextIOWrapper.

read_bytes()
Read contents of self as bytes.

read_text(encoding=None)
Read contents of self as text.
class importlib.abc.TraversableResources
An abstract base class for resource readers capable of serving the files interface. Subclasses ResourceReader and provides concrete implementations of the ResourceReader's abstract methods. Therefore, any loader supplying TraversableReader also supplies ResourceReader.

Loaders that wish to support resource reading are expected to implement this interface.
New in version 3.9.

31.5.4 importlib.resources – Resources

Source code: Lib/importlib/resources.py

New in version 3.7.

This module leverages Python’s import system to provide access to resources within packages. If you can import a package, you can access resources within that package. Resources can be opened or read, in either binary or text mode.

Resources are roughly akin to files inside directories, though it’s important to keep in mind that this is just a metaphor. Resources and packages do not have to exist as physical files and directories on the file system.

Note: This module provides functionality similar to pkg_resources Basic Resource Access without the performance overhead of that package. This makes reading resources included in packages easier, with more stable and consistent semantics.

The standalone backport of this module provides more information on using importlib.resources and migrating from pkg_resources to importlib.resources.

Loaders that wish to support resource reading should implement a get_resource_reader(fullname) method as specified by importlib.abc.ResourceReader.

The following types are defined.

importlib.resources.Package
The Package type is defined as Union[str, ModuleType]. This means that where the function describes accepting a Package, you can pass in either a string or a module. Module objects must have a resolvable __spec__.submodule_search_locations that is not None.

importlib.resources.Resource
This type describes the resource names passed into the various functions in this package. This is defined as Union[str, os.PathLike].

The following functions are available.

importlib.resources.files (package)
Returns an importlib.resources.abc.Traversable object representing the resource container for the package (think directory) and its resources (think files). A Traversable may contain other containers (think subdirectories).

package is either a name or a module object which conforms to the Package requirements.

New in version 3.9.

importlib.resources.as_file (traversable)
Given a importlib.resources.abc.Traversable object representing a file, typically from importlib.resources.files(), return a context manager for use in a with statement. The context manager provides a pathlib.Path object.

Exiting the context manager cleans up any temporary file created when the resource was extracted from e.g. a zip file.
Use `as_file` when the Traversable methods (`read_text`, etc) are insufficient and an actual file on the file system is required.

New in version 3.9.

`importlib.resources.open_binary(package, resource)`

Open for binary reading the resource within package.

*package* is either a name or a module object which conforms to the Package requirements. *resource* is the name of the resource to open within *package*; it may not contain path separators and it may not have sub-resources (i.e., it cannot be a directory). This function returns a `typing.BinaryIO` instance, a binary I/O stream open for reading.

`importlib.resources.open_text(package, resource, encoding='utf-8', errors='strict')`

Open for text reading the resource within package. By default, the resource is opened for reading as UTF-8.

*package* is either a name or a module object which conforms to the Package requirements. *resource* is the name of the resource to open within *package*; it may not contain path separators and it may not have sub-resources (i.e., it cannot be a directory). *encoding* and *errors* have the same meaning as with built-in `open()`.

This function returns a `typing.TextIO` instance, a text I/O stream open for reading.

`importlib.resources.read_binary(package, resource)`

Read and return the contents of the resource within *package* as bytes.

*package* is either a name or a module object which conforms to the Package requirements. *resource* is the name of the resource to open within *package*; it may not contain path separators and it may not have sub-resources (i.e., it cannot be a directory). This function returns the contents of the resource as bytes.

`importlib.resources.read_text(package, resource, encoding='utf-8', errors='strict')`

Read and return the contents of *resource* within *package* as a `str`. By default, the contents are read as strict UTF-8.

*package* is either a name or a module object which conforms to the Package requirements. *resource* is the name of the resource to open within *package*; it may not contain path separators and it may not have sub-resources (i.e., it cannot be a directory). *encoding* and *errors* have the same meaning as with built-in `open()`.

This function returns the contents of the resource as `str`.

`importlib.resources.path(package, resource)`

Return the path to the resource as an actual file system path. This function returns a context manager for use in a `with` statement. The context manager provides a `pathlib.Path` object.

Exiting the context manager cleans up any temporary file created when the resource needs to be extracted from e.g., a zip file.

*package* is either a name or a module object which conforms to the Package requirements. *resource* is the name of the resource to open within *package*; it may not contain path separators and it may not have sub-resources (i.e., it cannot be a directory).

`importlib.resources.is_resource(package, name)`

Return `True` if there is a resource named *name* in the package, otherwise `False`. Remember that directories are not resources! *package* is either a name or a module object which conforms to the Package requirements.

`importlib.resources.contents(package)`

Return an iterable over the named items within the package. The iterable returns `str` resources (e.g., files) and non-resources (e.g., directories). The iterable does not recurse into subdirectories.

*package* is either a name or a module object which conforms to the Package requirements.
31.5.5 importlib.machinery – Importers and path hooks

Source code: Lib/importlib/machinery.py

This module contains the various objects that help import find and load modules.

importlib.machinery.SOURCE_SUFFIXES
  A list of strings representing the recognized file suffixes for source modules.
  New in version 3.3.

importlib.machinery.DEBUG_BYTECODE_SUFFIXES
  A list of strings representing the file suffixes for non-optimized bytecode modules.
  New in version 3.3.
  Deprecated since version 3.5: Use BYTECODE_SUFFIXES instead.

importlib.machinery.OPTIMIZED_BYTECODE_SUFFIXES
  A list of strings representing the file suffixes for optimized bytecode modules.
  New in version 3.3.
  Deprecated since version 3.5: Use BYTECODE_SUFFIXES instead.

importlib.machinery.BYTECODE_SUFFIXES
  A list of strings representing the recognized file suffixes for bytecode modules (including the leading dot).
  New in version 3.3.
  Changed in version 3.5: The value is no longer dependent on __debug__.

importlib.machinery.EXTENSION_SUFFIXES
  A list of strings representing the recognized file suffixes for extension modules.
  New in version 3.3.

importlib.machinery.all_suffixes()
  Returns a combined list of strings representing all file suffixes for modules recognized by the standard import machinery. This is a helper for code which simply needs to know if a filesystem path potentially refers to a module without needing any details on the kind of module (for example, inspect.getmodulename()).
  New in version 3.3.

class importlib.machinery.BuiltinImporter
  An importer for built-in modules. All known built-in modules are listed in sys.builtin_module_names. This class implements the importlib.abc.MetaPathFinder and importlib.abc.InspectLoader ABCs.
  Only class methods are defined by this class to alleviate the need for instantiation.
  Changed in version 3.5: As part of PEP 489, the builtin importer now implements Loader.create_module() and Loader.exec_module() methods.

class importlib.machinery.FrozenImporter
  An importer for frozen modules. This class implements the importlib.abc.MetaPathFinder and importlib.abc.InspectLoader ABCs.
  Only class methods are defined by this class to alleviate the need for instantiation.
  Changed in version 3.4: Gained create_module() and exec_module() methods.

class importlib.machinery.WindowsRegistryFinder
  Finder for modules declared in the Windows registry. This class implements the importlib.abc.MetaPathFinder ABC.
  Only class methods are defined by this class to alleviate the need for instantiation.
  New in version 3.3.
Deprecated since version 3.6: Use site configuration instead. Future versions of Python may not enable this finder by default.

class importlib.machinery.PathFinder

A Finder for sys.path and package __path__ attributes. This class implements the importlib.abc.MetaPathFinder ABC.

Only class methods are defined by this class to alleviate the need for instantiation.

classmethod find_spec(fullname, path=None, target=None)

Class method that attempts to find a spec for the module specified by fullname on sys.path or, if defined, on path. For each path entry that is searched, sys.path_importer_cache is checked. If a non-false object is found then it is used as the path entry finder to look for the module being searched for. If no entry is found in sys.path_importer_cache, then sys.path_hooks is searched for a finder for the path entry and, if found, is stored in sys.path_importer_cache along with being queried about the module. If no finder is ever found then None is both stored in the cache and returned.

New in version 3.4.

Changed in version 3.5: If the current working directory – represented by an empty string – is no longer valid then None is returned but no value is cached in sys.path_importer_cache.

classmethod find_module(fullname, path=None)

A legacy wrapper around find_spec().

Deprecated since version 3.4: Use find_spec() instead.

classmethod invalidate_caches()

Calls importlib.abc.PathEntryFinder.invalidate_caches() on all finders stored in sys.path_importer_cache that define the method. Otherwise entries in sys.path_importer_cache set to None are deleted.

Changed in version 3.7: Entries of None in sys.path_importer_cache are deleted.

Changed in version 3.4: Calls objects in sys.path_hooks with the current working directory for '' (i.e. the empty string).

class importlib.machinery.FileFinder(path, *loader_details)

A concrete implementation of importlib.abc.PathEntryFinder which caches results from the file system.

The path argument is the directory for which the finder is in charge of searching.

The loader_details argument is a variable number of 2-item tuples each containing a loader and a sequence of file suffixes the loader recognizes. The loaders are expected to be callables which accept two arguments of the module’s name and the path to the file found.

The finder will cache the directory contents as necessary, making stat calls for each module search to verify the cache is not outdated. Because cache staleness relies upon the granularity of the operating system’s state information of the file system, there is a potential race condition of searching for a module, creating a new file, and then searching for the module the new file represents. If the operations happen fast enough to fit within the granularity of stat calls, then the module search will fail. To prevent this from happening, when you create a module dynamically, make sure to call importlib.invalidate_caches().

New in version 3.3.

path

The path the finder will search in.

find_spec(fullname, target=None)

Attempt to find the spec to handle fullname within path.

New in version 3.4.

find_loader(fullname)

Attempt to find the loader to handle fullname within path.
The Python Library Reference, Release 3.10.4

Deprecated since version 3.10: Use `find_spec()` instead.

```python
invalide_caches()
```
Clear out the internal cache.

```python
classmethod path_hook(*loader_details)
```
A class method which returns a closure for use on `sys.path_hooks`. An instance of `FileFinder` is
returned by the closure using the path argument given to the closure directly and `loader_details` indirectly.

If the argument to the closure is not an existing directory, `ImportError` is raised.

```python
class importlib.machinery.SourceFileLoader(fullname, path)
```
A concrete implementation of `importlib.abc.SourceLoader` by subclassing `importlib.abc.FileLoader` and providing some concrete implementations of other methods.

New in version 3.3.

```python
name
```
The name of the module that this loader will handle.

```python
path
```
The path to the source file.

```python
is_package(fullname)
```
Return `True` if `path` appears to be for a package.

```python
path_stats(path)
```
Concrete implementation of `importlib.abc.SourceLoader.path_stats()`.

```python
set_data(path, data)
```
Concrete implementation of `importlib.abc.SourceLoader.set_data()`.

```python
load_module(name=None)
```
Concrete implementation of `importlib.abc.Loader.load_module()` where specifying the
name of the module to load is optional.

Deprecated since version 3.6: Use `importlib.abc.Loader.exec_module()` instead.

```python
class importlib.machinery.SourcelessFileLoader(fullname, path)
```
A concrete implementation of `importlib.abc.FileLoader` which can import bytecode files (i.e. no
source code files exist).

Please note that direct use of bytecode files (and thus not source code files) inhibits your modules from being
usable by all Python implementations or new versions of Python which change the bytecode format.

New in version 3.3.

```python
name
```
The name of the module the loader will handle.

```python
path
```
The path to the bytecode file.

```python
is_package(fullname)
```
Determines if the module is a package based on `path`.

```python
get_code(fullname)
```
Returns the code object for `name` created from `path`.

```python
get_source(fullname)
```
Returns `None` as bytecode files have no source when this loader is used.

```python
load_module(name=None)
```
Concrete implementation of `importlib.abc.Loader.load_module()` where specifying the name
of the module to load is optional.

Deprecated since version 3.6: Use `importlib.abc.Loader.exec_module()` instead.
class importlib.machinery.ExtensionFileLoader (fullname, path)
   A concrete implementation of importlib.abc.ExecutionLoader for extension modules.

   The fullname argument specifies the name of the module the loader is to support. The path argument is the path to the extension module’s file.

   New in version 3.3.

   name
      Name of the module the loader supports.

   path
      Path to the extension module.

   create_module (spec)
      Creates the module object from the given specification in accordance with PEP 489.

      New in version 3.5.

   exec_module (module)
      Initializes the given module object in accordance with PEP 489.

      New in version 3.5.

   is_package (fullname)
      Returns True if the file path points to a package’s __init__ module based on EXTENSION_SUFFIXES.

   get_code (fullname)
      Returns None as extension modules lack a code object.

   get_source (fullname)
      Returns None as extension modules do not have source code.

   get_filename (fullname)
      Returns path.

      New in version 3.4.

    class importlib.machinery.ModuleSpec (name, loader, *, origin=None, loader_state=None, is_package=None)
    A specification for a module’s import-system-related state. This is typically exposed as the module’s __spec__ attribute. In the descriptions below, the names in parentheses give the corresponding attribute available directly on the module object. E.g. module.__spec__.origin == module.__file__.

    Note however that while the values are usually equivalent, they can differ since there is no synchronization between the two objects. Thus it is possible to update the module’s __path__ at runtime, and this will not be automatically reflected in __spec__.submodule_search_locations.

    New in version 3.4.

    name
      (__name__)

      A string for the fully-qualified name of the module.

    loader
      (__loader__)

      The Loader that should be used when loading the module. Finders should always set this.

    origin
      (__file__)

      Name of the place from which the module is loaded, e.g. “builtin” for built-in modules and the filename for modules loaded from source. Normally “origin” should be set, but it may be None (the default) which indicates it is unspecified (e.g. for namespace packages).

    submodule_search_locations
ThePythonLibraryReference,Release3.10.4

(__path__)  
List of strings for where to find submodules, if a package (None otherwise).

loader_state  
Container of extra module-specific data for use during loading (or None).

cached  
(__cached__)  
String for where the compiled module should be stored (or None).

parent  
(__package__)  
(Read-only) The fully-qualified name of the package under which the module should be loaded as a submodule (or the empty string for top-level modules). For packages, it is the same as __name__.

has_location  
Boolean indicating whether or not the module’s “origin” attribute refers to a loadable location.

31.5.6 importlib.util – Utility code for importers

Source code: Lib/importlib/util.py

This module contains the various objects that help in the construction of an importer.

importlib.util.MAGIC_NUMBER  
The bytes which represent the bytecode version number. If you need help with loading/writing bytecode then consider importlib.abc.SourceLoader.

New in version 3.4.

importlib.util.cache_from_source(path, debug_override=None, *, optimization=None)  
Return the PEP 3147/PEP 488 path to the byte-compiled file associated with the source path. For example, if path is /foo/bar/baz.py the return value would be /foo/bar/__/pycache__/baz.cpython-32.pyc for Python 3.2. The cpython-32 string comes from the current magic tag (see get_tag()); if sys.implementation.cache_tag is not defined then NotImplemented will be raised.

The optimization parameter is used to specify the optimization level of the bytecode file. An empty string represents no optimization, so /foo/bar/baz.py with an optimization of '' will result in a bytecode path of /foo/bar/__/pycache__/baz.cpython-32.pyc. None causes the interpreter’s optimization level to be used. Any other value’s string representation is used, so /foo/bar/baz.py with an optimization of 2 will lead to the bytecode path of /foo/bar/__/pycache__/baz.cpython-32.opt-2.pyc. The string representation of optimization can only be alphanumerical, else ValueError is raised.

The debug_override parameter is deprecated and can be used to override the system’s value for __debug__. A True value is the equivalent of setting optimization to the empty string. A False value is the same as setting optimization to 1. If both debug_override an optimization are not None then TypeError is raised.

New in version 3.4.

Changed in version 3.5: The optimization parameter was added and the debug_override parameter was deprecated.

Changed in version 3.6: Accepts a path-like object.

importlib.util.source_from_cache(path)  
Given the path to a PEP 3147 file name, return the associated source code file path. For example, if path is /foo/bar/__/pycache__/baz.cpython-32.pyc the returned path would be /foo/bar/baz.py. path need not exist, however if it does not conform to PEP 3147 or PEP 488 format, a ValueError is raised. If sys.implementation.cache_tag is not defined, NotImplemented is raised.
importlib.util.decode_source(source_bytes)
Decodethegivenbytesrepresentingsourcecodeandreturnitasastringwithuniversalnewlines(asrequired
by importlib.abc.InspectLoader.get_source()).

New in version 3.4.

importlib.util.resolve_name(name, package)
Resolvearelativemodulenametoanabsoluteone.

If name has no leading dots, then name is simply returned. This allows for usage such as
importlib.util.resolve_name('sys', __spec__.parent) without doing a check to see if the package
argument is needed.

ImportError is raised if name is a relative module name but package is a false value (e.g. None or
the empty string). ImportError is also raised a relative name would escape its containing package (e.g.
requesting ..bacon from within the spam package).

New in version 3.4.

importlib.util.find_spec(name, package=None)
Find the spec for a module, optionally relative to the specified package name. If the module is in sys.
modules, then sys.modules[name].__spec__ is returned (unless the spec would be None or is not
set, in which case ValueError is raised). Otherwise a search using sys.meta_path is done. None is
returned if no spec is found.

If name is for a submodule (contains a dot), the parent module is automatically imported.

name and package work the same as for import_module().

New in version 3.4.

Changed in version 3.7: Raises ModuleNotFoundError instead of AttributeError if package is in
fact not a package (i.e. lacks a __path__ attribute).

importlib.util.module_from_spec(spec)
Create anew module based on spec and spec.loader.create_module.

If spec.loader.create_module does not return None, then any pre-existing attributes will not be
reset. Also, no AttributeError will be raised if triggered while accessing spec or setting an attribute on
the module.

This function is preferred over using types.ModuleType to create a new module as spec is used to set as
many import-controlled attributes on the module as possible.

New in version 3.5.

@importlib.util.module_for_loader
A decorator for importlib.abc.Loader.load_module() to handle selecting the proper module
object to load with. The decorated method is expected to have a call signature taking two positional arguments
(e.g. load_module(self, module)) for which the second argument will be the module object to be
used by the loader. Note that the decorator will not work on static methods because of the assumption of two
arguments.

The decorated method will take in the name of the module to be loaded as expected for a loader. If the
module is not found in sys.modules then a new one is constructed. Regardless of where the module
came from, __loader__ set to self and __package__ is set based on what importlib.abc.
InspectLoader.is_package() returns (if available). These attributes are set unconditionally to support
reloading.
If an exception is raised by the decorated method and a module was added to \texttt{sys.modules}, then the module will be removed to prevent a partially initialized module from being left in \texttt{sys.modules}. If the module was already in \texttt{sys.modules} then it is left alone.

Changed in version 3.3: \_\_\_loader\_\_ and \_\_\_package\_\_ are automatically set (when possible).

Changed in version 3.4: Set \_\_\_name\_\_, \_\_\_loader\_\_ \_\_\_package\_\_ unconditionally to support reloading.

Deprecated since version 3.4: The import machinery now directly performs all the functionality provided by this function.

\@importlib.util.set\_\_loader

A decorator for \texttt{importlib.abc.Loader.load\_module()} to set the \_\_\_loader\_\_ attribute on the returned module. If the attribute is already set the decorator does nothing. It is assumed that the first positional argument to the wrapped method (i.e. self) is what \_\_\_loader\_\_ should be set to.

Changed in version 3.4: Set \_\_\_loader\_\_ if set to None, as if the attribute does not exist.

Deprecated since version 3.4: The import machinery takes care of this automatically.

\@importlib.util.set\_\_package

A decorator for \texttt{importlib.abc.Loader.load\_module()} to set the \_\_\_package\_\_ attribute on the returned module. If \_\_\_package\_\_ is set and has a value other than None it will not be changed.

Deprecated since version 3.4: The import machinery takes care of this automatically.

\texttt{importlib.util.spec\_\_from\_\_loader(name, loader, *, origin=None, is\_\_package=None)}

A factory function for creating a ModuleSpec instance based on a loader. The parameters have the same meaning as they do for ModuleSpec. The function uses available loader APIs, such as \texttt{InspectLoader.is\_\_package()}, to fill in any missing information on the spec.

New in version 3.4.

\texttt{importlib.util.spec\_\_from\_\_file\_\_location(name, location, *, loader=None, submodule\_\_search\_\_locations=None)}

A factory function for creating a ModuleSpec instance based on the path to a file. Missing information will be filled in on the spec by making use of loader APIs and by the implication that the module will be file-based.

New in version 3.4.

Changed in version 3.6: Accepts a \texttt{path-like object}.

\texttt{importlib.util.source\_\_hash(source\_\_bytes)}

Return the hash of \texttt{source\_\_bytes} as bytes. A hash-based .\texttt{pyc} file embeds the \texttt{source\_\_hash()} of the corresponding source file’s contents in its header.

New in version 3.7.

\texttt{class importlib.util.LazyLoader(loader)}

A class which postpones the execution of the loader of a module until the module has an attribute accessed.

This class \textbf{only} works with loaders that define \texttt{exec\_\_module()} as control over what module type is used for the module is required. For those same reasons, the loader’s \texttt{create\_\_module()} method must return \texttt{None} or a type for which its \_\_\_class\_\_ attribute can be mutated along with not using \texttt{slots}. Finally, modules which substitute the object placed into \texttt{sys\_\_modules} will not work as there is no way to properly replace the module references throughout the interpreter safely; \texttt{ValueError} is raised if such a substitution is detected.

\textbf{Note:} For projects where startup time is critical, this class allows for potentially minimizing the cost of loading a module if it is never used. For projects where startup time is not essential then use of this class is \textbf{heavily} discouraged due to error messages created during loading being postponed and thus occurring out of context.

New in version 3.5.
Changed in version 3.6: Began calling `create_module()`, removing the compatibility warning for `importlib.machinery.BuiltinImporter` and `importlib.machinery.ExtensionFileLoader`.

```python
classmethod factory(loader)
```

A static method which returns a callable that creates a lazy loader. This is meant to be used in situations where the loader is passed by class instead of by instance.

```python
suffixes = importlib.machinery.SOURCE_SUFFIXES
loader = importlib.machinery.SourceFileLoader
lazy_loader = importlib.util.LazyLoader.factory(loader)
finder = importlib.machinery.FileFinder(path, (lazy_loader, suffixes))
```

### 31.5.7 Examples

#### Importing programmatically

To programmatically import a module, use `importlib.import_module()`.

```python
import importlib
itertools = importlib.import_module('itertools')
```

#### Checking if a module can be imported

If you need to find out if a module can be imported without actually doing the import, then you should use `importlib.util.find_spec()`.

```python
import importlib.util
import sys

# For illustrative purposes.
name = 'itertools'

if name in sys.modules:
    print(f"{name!r} already in sys.modules")
elif (spec := importlib.util.find_spec(name)) is not None:
    # If you chose to perform the actual import ...
    module = importlib.util.module_from_spec(spec)
    sys.modules[name] = module
    spec.loader.exec_module(module)
    print(f"]{name!r} has been imported")
else:
    print(f"can't find the {name!r} module")
```

#### Importing a source file directly

To import a Python source file directly, use the following recipe (Python 3.5 and newer only):

```python
import importlib.util
import sys

# For illustrative purposes.
import tokenize
file_path = tokenize.__file__
module_name = tokenize.__name__
```

(continues on next page)
Implementing lazy imports

The example below shows how to implement lazy imports:

```python
>>> import importlib.util
>>> import sys
>>> def lazy_import(name):
...     spec = importlib.util.spec_from_file_location(module_name, file_path)
...     module = importlib.util.module_from_spec(spec)
...     sys.modules[module_name] = module
...     spec.loader.exec_module(module)
...     return module
...     lazy_typing = lazy_import("typing")
>>> #lazy_typing is a real module object,
>>> #but it is not loaded in memory yet.
>>> lazy_typing.TYPE_CHECKING
False
```

Setting up an importer

For deep customizations of import, you typically want to implement an `importer`. This means managing both the `finder` and `loader` side of things. For finders there are two flavours to choose from depending on your needs: a `meta path finder` or a `path entry finder`. The former is what you would put on `sys.meta_path` while the latter is what you create using a `path entry hook` on `sys.path_hooks` which works with `sys.path` entries to potentially create a finder. This example will show you how to register your own importers so that import will use them (for creating an importer for yourself, read the documentation for the appropriate classes defined within this package):

```python
import importlib.machinery
import sys

# For illustrative purposes only.
SpamMetaPathFinder = importlib.machinery.PathFinder
SpamPathEntryFinder = importlib.machinery.FileFinder
loader_details = (importlib.machinery.SourceFileLoader,
                   importlib.machinery.SOURCE_SUFFIXES)

# Setting up a meta path finder.
# Make sure to put the finder in the proper location in the list in terms of
# priority.
sys.meta_path.append(SpamMetaPathFinder)

# Setting up a path entry finder.
# Make sure to put the path hook in the proper location in the list in terms
# of priority.
sys.path_hooks.append(SpamPathEntryFinder.path_hook(loader_details))
```
Approximating `importlib.import_module()`

Import itself is implemented in Python code, making it possible to expose most of the import machinery through `importlib`. The following helps illustrate the various APIs that `importlib` exposes by providing an approximate implementation of `importlib.import_module()` (Python 3.4 and newer for the `importlib` usage, Python 3.6 and newer for other parts of the code).

```python
import importlib.util
import sys

def import_module(name, package=None):
    """An approximate implementation of import."""
    absolute_name = importlib.util.resolve_name(name, package)
    try:
        return sys.modules[absolute_name]
    except KeyError:
        pass

    path = None
    if '.' in absolute_name:
        parent_name, _, child_name = absolute_name.rpartition('.
')
        parent_module = import_module(parent_name)
        path = parent_module.__spec__.submodule_search_locations
    for finder in sys.meta_path:
        spec = finder.find_spec(absolute_name, path)
        if spec is not None:
            break
    else:
        msg = f'No module named {absolute_name!r}'
        raise ModuleNotFoundError(msg, name=absolute_name)
    module = importlib.util.module_from_spec(spec)
sys.modules[absolute_name] = module
spec.loader.exec_module(module)
    if path is not None:
        setattr(parent_module, child_name, module)
    return module
```

31.6 Using `importlib.metadata`

New in version 3.8.

Changed in version 3.10: `importlib.metadata` is no longer provisional.

Source code: `Lib/importlib/metadata/__init__.py`

`importlib.metadata` is a library that provides for access to installed package metadata. Built in part on Python’s import system, this library intends to replace similar functionality in the entry point API and metadata API of `pkg_resources`. Along with `importlib.resources` in Python 3.7 and newer (backported as `importlib_resources` for older versions of Python), this can eliminate the need to use the older and less efficient `pkg_resources` package.

By “installed package” we generally mean a third-party package installed into Python’s `site-packages` directory via tools such as `pip`. Specifically, it means a package with either a discoverable `dist-info` or `egg-info` directory, and metadata defined by PEP 566 or its older specifications. By default, package metadata can live on the file system or in zip archives on `sys.path`. Through an extension mechanism, the metadata can live almost anywhere.
31.6.1 Overview

Let’s say you wanted to get the version string for a package you’ve installed using pip. We start by creating a virtual environment and installing something into it:

```bash
$ python3 -m venv example
$ source example/bin/activate
(example) $ pip install wheel
```

You can get the version string for wheel by running the following:

```python
(example) $ python
>>> from importlib.metadata import version
>>> version('wheel')
'0.32.3'
```

You can also get the set of entry points keyed by group, such as `console_scripts`, `distutils.commands` and others. Each group contains a sequence of `EntryPoint` objects.

You can get the `metadata for a distribution`:

```python
>>> list(metadata('wheel'))
```

You can also get a `distribution’s version number`, list its `constituent files`, and get a list of the distribution’s `Distribution requirements`.

31.6.2 Functional API

This package provides the following functionality via its public API.

Entry points

The `entry_points()` function returns a collection of entry points. Entry points are represented by `EntryPoint` instances; each `EntryPoint` has a `.name`, `.group`, and `.value` attributes and a `.load()` method to resolve the value. There are also `.module`, `.attr`, and `.extras` attributes for getting the components of the `.value` attribute.

Query all entry points:

```python
>>> eps = entry_points()
```

The `entry_points()` function returns an `EntryPoints` object, a sequence of all `EntryPoint` objects with names and groups attributes for convenience:

```python
>>> sorted(eps.groups)
```

`EntryPoints` has a `select` method to select entry points matching specific properties. Select entry points in the `console_scripts` group:

```python
>>> scripts = eps.select(group=’console_scripts’)
```

Equivalently, since `entry_points` passes keyword arguments through to select:
The group and name are arbitrary values defined by the package author and usually a client will wish to resolve all entry points for a particular group. Read the setuptools docs for more information on entry points, their definition, and usage.

Compatibility Note

The “selectable” entry points were introduced in importlib_metadata 3.6 and Python 3.10. Prior to those changes, entry_points accepted no parameters and always returned a dictionary of entry points, keyed by group. For compatibility, if no parameters are passed to entry_points, a SelectableGroups object is returned, implementing that dict interface. In the future, calling entry_points with no parameters will return an EntryPoints object. Users should rely on the selection interface to retrieve entry points by group.

Distribution metadata

Every distribution includes some metadata, which you can extract using the metadata() function:

```python
>>> wheel_metadata = metadata('wheel')
```

The keys of the returned data structure, a PackageMetadata, name the metadata keywords, and the values are returned unparsed from the distribution metadata:

```python
>>> wheel_metadata['Requires-Python']
'&gt;=2.7, !=3.0.*, !=3.1.*, !=3.2.*, !=3.3.*'
```

PackageMetadata also presents a json attribute that returns all the metadata in a JSON-compatible form per PEP 566:

```python
>>> wheel_metadata.json['requires_python']
'&gt;=2.7, !=3.0.*, !=3.1.*, !=3.2.*, !=3.3.*'
```

Changed in version 3.10: The Description is now included in the metadata when presented through the payload. Line continuation characters have been removed.

New in version 3.10: The json attribute was added.
Distribution versions

The `version()` function is the quickest way to get a distribution’s version number, as a string:

```python
>>> version('wheel')
'0.32.3'
```

Distribution files

You can also get the full set of files contained within a distribution. The `files()` function takes a distribution package name and returns all of the files installed by this distribution. Each file object returned is a `PackagePath`, a `pathlib.PurePath` derived object with additional `dist`, `size`, and `hash` properties as indicated by the metadata. For example:

```python
>>> util = [p for p in files('wheel') if 'util.py' in str(p)][0]
>>> util
PackagePath('wheel/util.py')
>>> util.size
859
>>> util.dist
<importlib.metadata._hooks.PathDistribution object at 0x101e0cef0>
>>> util.hash
<FileHash mode: sha256 value: bYkw5oMccfazVCoYQwKkkemoVyMAFoR34mmKBx8R1NI>
```

Once you have the file, you can also read its contents:

```python
>>> print(util.read_text())
import base64
import sys
...
def as_bytes(s):
    if isinstance(s, text_type):
        return s.encode('utf-8')
    return s
```

You can also use the `locate` method to get the absolute path to the file:

```python
>>> util.locate()
PosixPath('/home/gustav/example/lib/site-packages/wheel/util.py')
```

In the case where the metadata file listing files (RECORD or SOURCES.txt) is missing, `files()` will return `None`. The caller may wish to wrap calls to `files()` in `always_iterable` or otherwise guard against this condition if the target distribution is not known to have the metadata present.

Distribution requirements

To get the full set of requirements for a distribution, use the `requires()` function:

```python
>>> requires('wheel')
['"pytest (>=3.0.0) ; extra == 'test'"', "pytest-cov ; extra == 'test'"]
```
Package distributions

A convenience method to resolve the distribution or distributions (in the case of a namespace package) for top-level Python packages or modules:

```python
>>> packages_distributions()
{'importlib_metadata': ['importlib-metadata'], 'yaml': ['PyYAML'], 'jaraco': ['jaraco.classes', 'jaraco.functools'], ...}
```

New in version 3.10.

31.6.3 Distributions

While the above API is the most common and convenient usage, you can get all of that information from the Distribution class. A Distribution is an abstract object that represents the metadata for a Python package. You can get the Distribution instance:

```python
>>> from importlib.metadata import distribution
>>> dist = distribution('wheel')
```

Thus, an alternative way to get the version number is through the Distribution instance:

```python
>>> dist.version
'0.32.3'
```

There are all kinds of additional metadata available on the Distribution instance:

```python
>>> dist.metadata['Requires-Python']
'==2.7, !=3.0.*, !=3.1.*, !=3.2.*, !=3.3.*'
>>> dist.metadata['License']
'MIT'
```

The full set of available metadata is not described here. See PEP 566 for additional details.

31.6.4 Extending the search algorithm

Because package metadata is not available through sys.path searches, or package loaders directly, the metadata for a package is found through import system finders. To find a distribution package’s metadata, importlib.metadata queries the list of meta path finders on sys.meta_path.

The default PathFinder for Python includes a hook that calls into importlib.metadata. MetadataPathFinder for finding distributions loaded from typical file-system-based paths.

The abstract class importlib.abc.MetaPathFinder defines the interface expected of finders by Python’s import system. importlib.metadata extends this protocol by looking for an optional find_distributions callable on the finders from sys.meta_path and presents this extended interface as the DistributionFinder abstract base class, which defines this abstract method:

```python
@abc.abstractmethod
def find_distributions(context=DistributionFinder.Context()):
    """Return an iterable of all Distribution instances capable of
    loading the metadata for packages for the indicated `context`.
    """
```

The DistributionFinder.Context object provides .path and .name properties indicating the path to search and name to match and may supply other relevant context.

What this means in practice is that to support finding distribution package metadata in locations other than the file system, subclass Distribution and implement the abstract methods. Then from a custom finder, return instances of this derived Distribution in the find_distributions() method.
Python provides a number of modules to assist in working with the Python language. These modules support tokenizing, parsing, syntax analysis, bytecode disassembly, and various other facilities.

These modules include:

### 32.1 ast — Abstract Syntax Trees

**Source code:** Lib/ast.py

The `ast` module helps Python applications to process trees of the Python abstract syntax grammar. The abstract syntax itself might change with each Python release; this module helps to find out programmatically what the current grammar looks like.

An abstract syntax tree can be generated by passing `ast.PyCF_ONLY_AST` as a flag to the `compile()` built-in function, or using the `parse()` helper provided in this module. The result will be a tree of objects whose classes all inherit from `ast.AST`. An abstract syntax tree can be compiled into a Python code object using the built-in `compile()` function.

#### 32.1.1 Abstract Grammar

The abstract grammar is currently defined as follows:

```python
-- ASDL's 4 builtin types are:
-- identifier, int, string, constant

module Python
{
    mod = Module(stmt* body, type_ignore* type_ignores)
        | Interactive(stmt* body)
        | Expression(expr body)
        | FunctionType(expr* argtypes, expr returns)

    stmt = FunctionDef(identifier name, arguments args,
                      stmt* body, expr* decorator_list, expr? returns,
                      string? type_comment)
        | AsyncFunctionDef(identifier name, arguments args,
                           stmt* body, expr* decorator_list, expr? returns,
                           string? type_comment)
        | ClassDef(identifier name,
                   expr* bases,
                   keyword* keywords,
                   stmt* body,
```

(continues on next page)
expr* decorator_list)
| Return(expr? value)
| Delete(expr* targets)
| Assign(expr* targets, expr value, string? type_comment)
| AugAssign(expr target, operator op, expr value)
| -- 'simple' indicates that we annotate simple name without parens
| AnnAssign(expr target, expr annotation, expr? value, int simple)
| -- use 'orelse' because else is a keyword in target languages
| For(expr target, expr iter, stmt* body, stmt* orelse, string? type_~comment)
| AsyncFor(expr target, expr iter, stmt* body, stmt* orelse, string? type~comment)
| While(expr test, stmt* body, stmt* orelse)
| If(expr test, stmt* body, stmt* orelse)
| With(withitem* items, stmt* body, string? type_comment)
| AsyncWith(withitem* items, stmt* body, string? type_comment)
| Match(expr subject, match_case* cases)
| Raise(expr? exc, expr? cause)
| Try(stmt* body, excepthandler* handlers, stmt* orelse, stmt* finalbody)
| Assert(expr test, expr? msg)
| Import(alias* names)
| ImportFrom(identifier? module, alias* names, int? level)
| Global(identifier* names)
| Nonlocal(identifier* names)
| Expr(expr value)
| Pass | Break | Continue
| -- col_offset is the byte offset in the utf8 string the parser uses
attributes (int lineno, int col_offset, int? end_lineno, int? end_col_~offset)
| -- BoolOp() can use left & right?
expr = BoolOp(boolop op, expr* values)
| NamedExpr(expr target, expr value)
| BinOp(expr left, operator op, expr right)
| UnaryOp(unaryop op, expr operand)
| Lambda(arguments args, expr body)
| IfExp(expr test, expr body, expr orelse)
| Dict(expr* keys, expr* values)
| Set(expr* elts)
| ListComp(expr elt, comprehension* generators)
| SetComp(expr elt, comprehension* generators)
| DictComp(expr key, expr value, comprehension* generators)
| GeneratorExp(expr elt, comprehension* generators)
| -- the grammar constrains where yield expressions can occur
| Await(expr value)
| Yield(expr? value)
| YieldFrom(expr value)
| -- need sequences for compare to distinguish between
| -- x < 4 < 3 and (x < 4) < 3
| Compare(expr left, cmpop* ops, expr* comparators)
| Call(expr func, expr* args, keyword* keywords)
| FormattedValue(expr value, int conversion, expr? format_spec)
| JoinedStr(expr* values)
| Constant(constant value, string? kind)
--- the following expression can appear in assignment context
| Attribute(expr value, identifier attr, expr_context ctx)
| Subscript(expr value, expr slice, expr_context ctx)
| Starred(expr value, expr_context ctx)
| Name(identifier id, expr_context ctx)
| List(expr* elts, expr_context ctx)
| Tuple(expr* elts, expr_context ctx)

--- can appear only in Subscript
| Slice(expr? lower, expr? upper, expr? step)

-- col_offset is the byte offset in the utf8 string the parser uses
attributes (int lineno, int col_offset, int? end_lineno, int? end_col_offset)

expr_context = Load | Store | Del

boolop = And | Or

operator = Add | Sub | Mult | MatMult | Div | Mod | Pow | LShift | RShift | BitOr | BitXor | BitAnd | FloorDiv

unaryop = Invert | Not | UAdd | USub

cmpop = Eq | NotEq | Lt | LtE | Gt | GtE | Is | IsNot | In | NotIn

comprehension = (expr target, expr iter, expr? ifs, int? is_async)

excepthandler = ExceptHandler(expr? type, identifier? name, stmt* body)

attributes (int lineno, int col_offset, int? end_lineno, int? end_col_offset)

arithmetic = (arg* posonlyargs, arg* args, arg? vararg, arg* kwonlyargs,
expr? kw_defaults, arg? kwarg, expr? defaults)

decorator = (arg* posonlyargs, arg* args, arg? vararg, arg* kwonlyargs,
expr? kw_defaults, arg? kwarg, expr? defaults)

keyword = (identifier arg, expr? annotation, string? type_comment)

attributes (int lineno, int col_offset, int? end_lineno, int? end_col_offset)

-- keyword arguments supplied to call (NULL identifier for **kwargs)
keyword = (identifier? arg, expr? value)
attributes (int lineno, int col_offset, int? end_lineno, int? end_col_offset)

-- import name with optional 'as' alias.
alias = (identifier name, identifier? asname)
attributes (int lineno, int col_offset, int? end_lineno, int? end_col_offset)

withitem = (expr context_expr, expr? optional_vars)

match_case = (pattern pattern, expr? guard, stmt* body)

pattern = MatchValue(expr value)
| MatchSingleton(constant value)
| MatchSequence(pattern* patterns)
| MatchMapping(expr* keys, pattern* patterns, identifier? rest)
| MatchClass(expr cls, pattern* patterns, identifier? kwd_attrs,
pattern* kwd_patterns)
32.1.2 Node classes

class ast.AST

This is the base of all AST node classes. The actual node classes are derived from the Parser/Python. asdl file, which is reproduced below. They are defined in the _ast C module and re-exported in ast.

There is one class defined for each left-hand side symbol in the abstract grammar (for example, ast.stmt or ast.expr). In addition, there is one class defined for each constructor on the right-hand side; these classes inherit from the classes for the left-hand side trees. For example, ast.BinOp inherits from ast.expr. For production rules with alternatives (aka “sums”), the left-hand side class is abstract: only instances of specific constructor nodes are ever created.

_fields

Each concrete class has an attribute _fields which gives the names of all child nodes.

Each instance of a concrete class has one attribute for each child node, of the type as defined in the grammar. For example, ast.BinOp instances have an attribute left of type ast.expr.

If these attributes are marked as optional in the grammar (using a question mark), the value might be None. If the attributes can have zero-or-more values (marked with an asterisk), the values are represented as Python lists. All possible attributes must be present and have valid values when compiling an AST with compile().

lineno

col_offset

end_lineno

end_col_offset

Instances of ast.expr and ast.stmt subclasses have lineno, col_offset, end_lineno, and end_col_offset attributes. The lineno and end_lineno are the first and last line numbers of source text span (1-indexed so the first line is line 1) and the col_offset and end_col_offset are the corresponding UTF-8 byte offsets of the first and last tokens that generated the node. The UTF-8 offset is recorded because the parser uses UTF-8 internally.

Note that the end positions are not required by the compiler and are therefore optional. The end offset is after the last symbol, for example one can get the source segment of a one-line expression node using source_line[node.col_offset : node.end_col_offset].

The constructor of a class ast.T parses its arguments as follows:

* If there are positional arguments, there must be as many as there are items in T._fields; they will be assigned as attributes of these names.

* If there are keyword arguments, they will set the attributes of the same names to the given values.

For example, to create and populate an ast.UnaryOp node, you could use

```
node = ast.UnaryOp()
node.op = ast.USub()
```
node.operand = ast.Constant()
node.operand.value = 5
node.operand.lineno = 0
node.operand.col_offset = 0
node.lineno = 0
node.col_offset = 0

or the more compact

```
node = ast.UnaryOp(ast.USub(), ast.Constant(5, lineno=0, col_offset=0),
                    lineno=0, col_offset=0)
```

Changed in version 3.8: Class `ast.Constant` is now used for all constants.

Changed in version 3.9: Simple indices are represented by their value, extended slices are represented as tuples.

Deprecated since version 3.8: Old classes `ast.Num`, `ast.Str`, `ast.Bytes`, `ast.NameConstant` and `ast.Ellipsis` are still available, but they will be removed in future Python releases. In the meantime, instantiating them will return an instance of a different class.

Deprecated since version 3.9: Old classes `ast.Index` and `ast.ExtSlice` are still available, but they will be removed in future Python releases. In the meantime, instantiating them will return an instance of a different class.

---

**Note:** The descriptions of the specific node classes displayed here were initially adapted from the fantastic Green Tree Snakes project and all its contributors.

### Literals

**`class ast.Constant(value)`**

A constant value. The `value` attribute of the `Constant` literal contains the Python object it represents. The values represented can be simple types such as a number, string or `None`, but also immutable container types (tuples and frozensets) if all of their elements are constant.

```python
>>> print(ast.dump(ast.parse('123', mode='eval'), indent=4))
Expression(
    body=Constant(value=123))
```

**`class ast.FormattedValue(value, conversion, format_spec)`**

Node representing a single formatting field in an f-string. If the string contains a single formatting field and nothing else the node can be isolated otherwise it appears in `JoinedStr`.

* `value` is any expression node (such as a literal, a variable, or a function call).

* `conversion` is an integer:
  - `-1`: no formatting
  - `115`: `!s` string formatting
  - `114`: `!r` repr formatting
  - `97`: `!a` ascii formatting

* `format_spec` is a `JoinedStr` node representing the formatting of the value, or `None` if no format was specified. Both `conversion` and `format_spec` can be set at the same time.

**`class ast.JoinedStr(values)`**

An f-string, comprising a series of `FormattedValue` and `Constant` nodes.
```python
>>> print(ast.dump(ast.parse('f"sin(a) is {sin(a):.3}"', mode='eval'),
...     indent=4))
Expression(
    body=JoinedStr(
        values=[
            Constant(value='sin('),
            FormattedValue(
                value=Name(id='a', ctx=Load()),
                conversion=-1),
            Constant(value=') is '),
            FormattedValue(
                value=Call(
                    func=Name(id='sin', ctx=Load()),
                    args=[Name(id='a', ctx=Load())],
                    keywords=[]),
                conversion=-1,
                format_spec=JoinedStr(
                    values=[Constant(value=':.3')]))]))
```

```
class ast.List (elts, ctx)
class ast.Tuple (elts, ctx)
A list or tuple. elts holds a list of nodes representing the elements. ctx is Store if the container is an assignment target (i.e. \((x, y)=something\)), and Load otherwise.
```

```python
>>> print(ast.dump(ast.parse('[1, 2, 3]', mode='eval'), indent=4))
Expression(
    body=List(
        elts=[
            Constant(value=1),
            Constant(value=2),
            Constant(value=3)],
        ctx=Load()))
```

```python
>>> print(ast.dump(ast.parse('(1, 2, 3)', mode='eval'), indent=4))
Expression(
    body=Tuple(
        elts=[
            Constant(value=1),
            Constant(value=2),
            Constant(value=3)],
        ctx=Load()))
```

```
class ast.Set (elts)
A set. elts holds a list of nodes representing the set’s elements.
```

```python
>>> print(ast.dump(ast.parse('{1, 2, 3}', mode='eval'), indent=4))
Expression(
    body=Set(
        elts=[
            Constant(value=1),
            Constant(value=2),
            Constant(value=3)]))
```

```
class ast.Dict (keys, values)
A dictionary. keys and values hold lists of nodes representing the keys and the values respectively, in matching order (what would be returned when calling dictionary.keys() and dictionary.values()).

When doing dictionary unpacking using dictionary literals the expression to be expanded goes in the values list, with a None at the corresponding position in keys.
```
>>> print(ast.dump(ast.parse('{"a":1, **d}', mode='eval'), indent=4))
Expression(
    body=Dict(
        keys=[
            Constant(value='a'), None],
        values=[
            Constant(value=1), Name(id='d', ctx=Load())]))

Variables

class ast.Name(id, ctx)
A variable name. id holds the name as a string, and ctx is one of the following types.

class ast.Store
class ast.Del
Variable references can be used to load the value of a variable, to assign a new value to it, or to delete it. Variable references are given a context to distinguish these cases.

>>> print(ast.dump(ast.parse('a'), indent=4))
Module(
    body=[
        Expr(
            value=Name(id='a', ctx=Load()))],
    type_ignores=[])

>>> print(ast.dump(ast.parse('a = 1'), indent=4))
Module(
    body=[
        Assign(
            targets=[
                Name(id='a', ctx=Store()),
                value=Constant(value=1)],
            type_ignores=[]))

>>> print(ast.dump(ast.parse('del a'), indent=4))
Module(
    body=[
        Delete(
            targets=[
                Name(id='a', ctx=Del())],
            type_ignores=[]))

class ast.Starred(value, ctx)
A *var variable reference. value holds the variable, typically a Name node. This type must be used when building a Call node with *args.

>>> print(ast.dump(ast.parse('a, *b = it'), indent=4))
Module(
    body=[
        Assign(
            targets=[
                Tuple(elt=[
                    Name(id='a', ctx=Store()),
                    Starred(value=Name(id='b', ctx=Store())),
                    ctx=Store()])),
            type_ignores=[])]

(continues on next page)
Expressions

class ast.Expr (value)
When an expression, such as a function call, appears as a statement by itself with its return value not used or stored, it is wrapped in this container. value holds one of the other nodes in this section, a Constant, a Name, a Lambda, a Yield or YieldFrom node.

```python
>>> print(ast.dump(ast.parse('a'), indent=4))
Module(
    body=[
        Expr(
            value=UnaryOp(
                op=USub(),
                operand=Name(id='a', ctx=Load()))),
    ],
    type_ignores=[])  
```

class ast.UnaryOp (op, operand)
A unary operation. op is the operator, and operand any expression node.

class ast.UAdd
class ast.USub
class ast.Not
class ast.Invert
Unary operator tokens. Not is the not keyword, Invert is the ~ operator.

```python
>>> print(ast.dump(ast.parse('not x', mode='eval'), indent=4))
Expression(
    body=UnaryOp(
        op=Not(),
        operand=Name(id='x', ctx=Load())))  
```

class ast.BinOp (left, op, right)
A binary operation (like addition or division). op is the operator, and left and right are any expression nodes.

```python
>>> print(ast.dump(ast.parse('x + y', mode='eval'), indent=4))
Expression(
    body=BinOp(
        left=Name(id='x', ctx=Load()),
        op=Add(),
        right=Name(id='y', ctx=Load())))  
```

class ast.Add
class ast.Sub
class ast.Mult
class ast.Div
class ast.FloorDiv
class ast.Mod
class ast.Pow
class ast.LShift
class ast.RShift
class ast.BitOr
class ast.BitXor
class ast.BitAnd
class ast.MatMult
    Binary operator tokens.

class ast.BoolOp (op, values)
    A boolean operation, 'or' or 'and'. op is Or or And. values are the values involved. Consecutive operations with the same operator, such as a or b or c, are collapsed into one node with several values.

This doesn't include not, which is a UnaryOp.

>>> print(ast.dump(ast.parse('x or y', mode='eval'), indent=4))
Expression(
    body=BoolOp(
        op=Or(),
        values=[
            Name(id='x', ctx=Load()),
            Name(id='y', ctx=Load())]))

class ast.And
class ast.Or
    Boolean operator tokens.

class ast.Compare (left, ops, comparators)
    A comparison of two or more values. left is the first value in the comparison, ops the list of operators, and comparators the list of values after the first element in the comparison.

>>> print(ast.dump(ast.parse('1 <= a < 10', mode='eval'), indent=4))
Expression(
    body=Compare(
        left=Constant(value=1),
        ops=[
            LtE(),
            Lt()],
        comparators=[
            Name(id='a', ctx=Load()),
            Constant(value=10)]))

class ast.Eq
class ast.NotEq
class ast.Lt
class ast.LtE
class ast.Gt
class ast.GtE
class ast.Is
class ast.IsNot
class ast.In
class ast.NotIn
    Comparison operator tokens.

class ast.Call (func, args, keywords, starargs, kwargs)
    A function call. func is the function, which will often be a Name or Attribute object. Of the arguments:

    • args holds a list of the arguments passed by position.
    • keywords holds a list of keyword objects representing arguments passed by keyword.

    When creating a Call node, args and keywords are required, but they can be empty lists. starargs and kwargs are optional.

>>> print(ast.dump(ast.parse('func(a, b=c, *d, **e)', mode='eval'), indent=4))
Expression(
    body=Call(
        func=Name(id='func', ctx=Load()),
        args=[
            Name(id='a', ctx=Load()),
            Name(id='b', ctx=Load()),
            Constant(value='c'),
            Name(id='d', ctx=Load()),
            Name(id='e', ctx=Load()),
            Constant(value='d'),
            Constant(value='e')])
        starargs=",
        kwargs={})
)
class ast.keyword(*arg, value)

A keyword argument to a function call or class definition. `arg` is a raw string of the parameter name, `value` is a node to pass in.

class ast.IfExp(test, body, orelse)

An expression such as `a if b else c`. Each field holds a single node, so in the following example, all three are `Name` nodes.

```python
>>> print(ast.dump(ast.parse('a if b else c', mode='eval'), indent=4))
Expression(
    body=IfExp(
        test=Name(id='b', ctx=Load()),
        body=Name(id='a', ctx=Load()),
        orelse=Name(id='c', ctx=Load())))
```

class ast.Attribute(value, attr, ctx)

Attribute access, e.g. `d.keys`. `value` is a node, typically a `Name`. `attr` is a bare string giving the name of the attribute, and `ctx` is `Load`, `Store` or `Del` according to how the attribute is acted on.

```python
>>> print(ast.dump(ast.parse('snake.colour', mode='eval'), indent=4))
Expression(
    body=Attribute(
        value=Name(id='snake', ctx=Load()),
        attr='colour',
        ctx=Load()))
```

class ast.NamedExpr(target, value)

A named expression. This AST node is produced by the assignment expressions operator (also known as the walrus operator). As opposed to the `Assign` node in which the first argument can be multiple nodes, in this case both `target` and `value` must be single nodes.

```python
>>> print(ast.dump(ast.parse('(x := 4)', mode='eval'), indent=4))
Expression(
    body=NamedExpr(
        target=Name(id='x', ctx=Store()),
        value=Constant(value=4)))
```

Subscripting

class ast.Subscript(value, slice, ctx)

A subscript, such as `l[1]`. `value` is the subscripted object (usually sequence or mapping). `slice` is an index, slice or key. It can be a `Tuple` and contain a `Slice`. `ctx` is `Load`, `Store` or `Del` according to the action performed with the subscript.

```python
>>> print(ast.dump(ast.parse('l[1:2, 3]', mode='eval'), indent=4))
Expression(
    body=Subscript(
        value=Name(id='l', ctx=Load()),
        slice=Tuple(
            elts=[Slice(start=None, end=Constant(value=1), step=None), Slice(start=Constant(value=2), end=Constant(value=3), step=None)],
            ctx=Load()))
```
value=Name(id='l', ctx=Load()),
slice=Tuple(
    elts=[
        Slice(
            lower=Constant(value=1),
            upper=Constant(value=2)),
        Constant(value=3)],
    ctx=Load()),
ctx=Load()))

class ast.Slice(lower, upper, step)

Regular slicing (on the form lower:upper or lower:upper:step). Can occur only inside the slice field of Subscript, either directly or as an element of Tuple.

>>> print(ast.dump(ast.parse('l[1:2]', mode='eval'), indent=4))
Expression(
    body=Subscript(
        value=Name(id='l', ctx=Load()),
        slice=Slice(
            lower=Constant(value=1),
            upper=Constant(value=2)),
        ctx=Load()))

Comprehensions

class ast.ListComp(elt, generators)
class ast.SetComp(elt, generators)
class ast.GeneratorExp(elt, generators)
class ast.DictComp(key, value, generators)

List and set comprehensions, generator expressions, and dictionary comprehensions. elt (or key and value) is a single node representing the part that will be evaluated for each item.

generators is a list of comprehension nodes.

>>> print(ast.dump(ast.parse('[x for x in numbers]', mode='eval'), indent=4))
Expression(
    body=ListComp(
        elt=Name(id='x', ctx=Load()),
        generators=[
            comprehension(
                target=Name(id='x', ctx=Store()),
                iter=Name(id='numbers', ctx=Load()),
                ifs=[],
                is_async=0)]))

>>> print(ast.dump(ast.parse('{x: x**2 for x in numbers}', mode='eval'), indent=4))
Expression(
    body=DictComp(
        key=Name(id='x', ctx=Load()),
        value=BinOp(
            left=Name(id='x', ctx=Load()),
            op=Pow(),
            right=Constant(value=2)),
        generators=[
            comprehension(
                target=Name(id='x', ctx=Store()),
                iter=Name(id='numbers', ctx=Load()),
                ifs=[],
                is_async=0)]))
>>> print(ast.dump(ast.parse('{x for x in numbers}', mode='eval'), indent=4))
Expression(
    body=SetComp(
        elt=Name(id='x', ctx=Load()),
        generators=[
            comprehension(
                target=Name(id='x', ctx=Store()),
                iter=Name(id='numbers', ctx=Load()),
                ifs=[],
                is_async=0)])
)

class ast.comprehension(target, iter, ifs, is_async)

One for clause in a comprehension. target is the reference to use for each element - typically a Name or Tuple node. iter is the object to iterate over. ifs is a list of test expressions: each for clause can have multiple ifs.

is_async indicates a comprehension is asynchronous (using an async for instead of for). The value is an integer (0 or 1).

>>> print(ast.dump(ast.parse('[ord(c) for line in file for c in line]', mode='eval'), indent=4)) # Multiple comprehensions in one.
Expression(
    body=ListComp(
        elt=Call(
            func=Name(id='ord', ctx=Load()),
            args=[Name(id='c', ctx=Load())],
            keywords=[]),
        generators=[
            comprehension(
                target=Name(id='line', ctx=Store()),
                iter=Name(id='file', ctx=Load()),
                ifs=[],
                is_async=0),
            comprehension(
                target=Name(id='c', ctx=Store()),
                iter=Name(id='line', ctx=Load()),
                ifs=[],
                is_async=0)])
)

>>> print(ast.dump(ast.parse('(n**2 for n in it if n>5 if n<10)', mode='eval'), indent=4)) # generator comprehension
Expression(
    body=GeneratorExp(
        elt=BinOp(
            left=Name(id='n', ctx=Load()),
            op=Pow(),
            right=Constant(value=2)),
        generators=[
            comprehension(
                target=Name(id='n', ctx=Store()),
                iter=Name(id='it', ctx=Load()),
                ifs=[
                    Compare(
                        left=Name(id='n', ctx=Load()),
                        ops=[Gt()],
                        comparators=[Constant(value=5)])])
    )
)
Statements

```python
>>> print(ast.dump(ast.parse('[i async for i in soc]', mode='eval'), indent=4)) # Async comprehension  
Expression(
    body=ListComp(
        elt=Name(id='i', ctx=Load()),
        generators=[
            comprehension(
                target=Name(id='i', ctx=Store()),
                iter=Name(id='soc', ctx=Load()),
                ifs=[],
                is_async=1)]))
```

```python
>>> print(ast.dump(ast.parse('a = b = 1'), indent=4)) # Multiple assignment  
Module(
    body=[
        Assign(
            targets=[
                Name(id='a', ctx=Store()),
                Name(id='b', ctx=Store())],
            value=Constant(value=1)),
        type_ignores=[]])
```

```python
>>> print(ast.dump(ast.parse('a,b = c'), indent=4)) # Unpacking  
Module(
    body=[
        Assign(
            targets=[
                Tuple(
                    elts=[
                        Name(id='a', ctx=Store()),
                        Name(id='b', ctx=Store())],
                    ctx=Store())],
            value=Name(id='c', ctx=Load())),
        type_ignores=[]])
```

```python
class ast.AnnAssign(target, annotation, value, simple)  
An assignment with a type annotation. target is a single node and can be a Name, a Attribute or a Subscript. annotation is the annotation, such as a Constant or Name node, value is a single optional node, simple is a boolean integer set to True for a Name node in target that do not appear in between parenthesis and are hence pure names and not expressions.
```
```
>>> print(ast.dump(ast.parse('c: int'), indent=4))
Module(
    body=[
        AnnAssign(
            target=Name(id='c', ctx=Store()),
            annotation=Name(id='int', ctx=Load()),
            simple=1),
        type_ignores=[])

>>> print(ast.dump(ast.parse('(a): int = 1'), indent=4))  # Annotation with parenthesis
Module(
    body=[
        AnnAssign(
            target=Name(id='a', ctx=Store()),
            annotation=Name(id='int', ctx=Load()),
            value=Constant(value=1),
            simple=0),
        type_ignores=[])

>>> print(ast.dump(ast.parse('a.b: int'), indent=4))  # Attribute annotation
Module(
    body=[
        AnnAssign(
            target=Attribute(
                value=Name(id='a', ctx=Load()),
                attr='b',
                ctx=Store()),
            annotation=Name(id='int', ctx=Load()),
            simple=0),
        type_ignores=[])

>>> print(ast.dump(ast.parse('a[1]: int'), indent=4))  # Subscript annotation
Module(
    body=[
        AnnAssign(
            target=Subscript(
                value=Name(id='a', ctx=Load()),
                slice=Constant(value=1),
                ctx=Store()),
            annotation=Name(id='int', ctx=Load()),
            simple=0),
        type_ignores=[])
```

class `ast.AugAssign`(target, op, value)

Augmented assignment, such as `a += 1`. In the following example, `target` is a `Name` node for `x` (with the `Store` context), `op` is `Add`, and `value` is a `Constant` with value for 1.

The `target` attribute cannot be of class `Tuple` or `List`, unlike the targets of `Assign`.

```
>>> print(ast.dump(ast.parse('x += 2'), indent=4))
Module(
    body=[
        AugAssign(
            target=Name(id='x', ctx=Store()),
            op=Add(),
            value=Constant(value=2)),
        type_ignores=[])
```

class `ast.Raise`(exc, cause)

A `raise` statement. `exc` is the exception object to be raised, normally a `Call` or `Name`, or None for a standalone `raise`. `cause` is the optional part for `y` in `raise x from y`.
>>> print(ast.dump(ast.parse('raise x from y'), indent=4))
Module(
    body=[
        Raise(
            exc=Name(id='x', ctx=Load()),
            cause=Name(id='y', ctx=Load())),
        type_ignores=[])

class ast.Assert (test, msg)
    An assertion. test holds the condition, such as a Compare node. msg holds the failure message.

>>> print(ast.dump(ast.parse('assert x,y'), indent=4))
Module(
    body=[
        Assert(
            test=Name(id='x', ctx=Load()),
            msg=Name(id='y', ctx=Load())),
        type_ignores=[])

class ast.Delete (targets)
    Represents a del statement. targets is a list of nodes, such as Name, Attribute or Subscript nodes.

>>> print(ast.dump(ast.parse('del x,y,z'), indent=4))
Module(
    body=[
        Delete(
            targets=[
                Name(id='x', ctx=Del()),
                Name(id='y', ctx=Del()),
                Name(id='z', ctx=Del())],
            type_ignores=[])

class ast.Pass
    A pass statement.

>>> print(ast.dump(ast.parse('pass'), indent=4))
Module(
    body=[
        Pass()],
    type_ignores=[])

Other statements which are only applicable inside functions or loops are described in other sections.

Imports

class ast.Import (names)
    An import statement. names is a list of alias nodes.

>>> print(ast.dump(ast.parse('import x,y,z'), indent=4))
Module(
    body=[
        Import(
            names=[
                alias(name='x'),
                alias(name='y'),
                alias(name='z')],
            type_ignores=[])

class ast.ImportFrom (module, names, level)
    Represents from x import y. module is a raw string of the ‘from’ name, without any leading dots, or
None for statements such as `from . import foo; level` is an integer holding the level of the relative import (0 means absolute import).

```python
>>> print(ast.dump(ast.parse('from y import x, y, z'), indent=4))
Module(
    body=[
        ImportFrom(
            module='y',
            names=[
                alias(name='x'),
                alias(name='y'),
                alias(name='z')],
            level=0),
        type_ignores=[])
```

**class ast.alias(name, asname)**

Both parameters are raw strings of the names. `asname` can be `None` if the regular name is to be used.

```python
>>> print(ast.dump(ast.parse('from ..foo.bar import a as b, c'), indent=4))
Module(
    body=[
        ImportFrom(
            module='foo.bar',
            names=[
                alias(name='a', asname='b'),
                alias(name='c')],
            level=2),
        type_ignores=[])
```

## Control flow

**Note:** Optional clauses such as `else` are stored as an empty list if they’re not present.

**class ast.If(test, body, orelse)**

An if statement. `test` holds a single node, such as a `Compare` node. `body` and `orelse` each hold a list of nodes.

`elif` clauses don’t have a special representation in the AST, but rather appear as extra `If` nodes within the `orelse` section of the previous one.

```python
>>> print(ast.dump(ast.parse('"""... if x: ...
... ... ...
... ... elif y: ...
... ... ... ...
... ... else: ...
... ... ... """'), indent=4))
Module(
    body=[
        If(
            test=Name(id='x', ctx=Load()),
            body=[
                Expr(
                    value=Constant(value=Ellipsis))],
            orelse=[
                If(
                    test=Name(id='y', ctx=Load()),
                    body=[
                    ]),
            ],
        type_ignores=[])
```

(continues on next page)
class ast.For (target, iter, body, orelse, type_comment)
A for loop. target holds the variable(s) the loop assigns to, as a single Name, Tuple or List node. iter holds the item to be looped over, again as a single node. body and orelse contain lists of nodes to execute. Those in orelse are executed if the loop finishes normally, rather than via a break statement.

type_comment
type_comment is an optional string with the type annotation as a comment.

```python
>>> print(ast.dump(ast.parse('"for x in y:
... ...
... else:
... ...
... """, indent=4))
Module(
  body=[
    For(
      target=Name(id='x', ctx=Store()),
      iter=Name(id='y', ctx=Load()),
      body=[
        Expr(
          value=Constant(value=Ellipsis)),
      orelse=[
        Expr(
          value=Constant(value=Ellipsis))]),
    type_ignores=[])}
```

class ast.While (test, body, orelse)
A while loop. test holds the condition, such as a Compare node.

```python
>> print(ast.dump(ast.parse('"""while x:
... ...
... else:
... ...
... """, indent=4))
Module(
  body=[
    While(
      test=Name(id='x', ctx=Load()),
      body=[
        Expr(
          value=Constant(value=Ellipsis)),
      orelse=[
        Expr(
          value=Constant(value=Ellipsis))]),
    type_ignores=[])}
```

class ast.Break
class ast.Continue
The break and continue statements.

```python
>>> print(ast.dump(ast.parse("\n... for a in b:
"""'))
```

(continues on next page)
...   if a > 5:
...       break
...   else:
...       continue
...
... """}, indent=4)
Module(
    body=[
        For(
            target=Name(id='a', ctx=Store()),
            iter=Name(id='b', ctx=Load()),
            body=[
                If(
                    test=Compare(
                        left=Name(id='a', ctx=Load()),
                        ops=[
                            Gt()],
                        comparators=[
                            Constant(value=5)]),
                    body=[
                        Break()],
                    orelse=[
                        Continue()]),
                orelse=[]],
            type_ignores=[])
])

class ast.Try(body, handlers, orelse, finalbody)
try blocks. All attributes are list of nodes to execute, except for handlers, which is a list of ExceptHandler nodes.

>>> print(ast.dump(ast.parse("""
... try:
...     ...
... except Exception:
...     ...
... except OtherException as e:
...     ...
... else:
...     ...
... finally:
...     ...
... """"}, indent=4))
Module(
    body=[
        Try(
            body=[
                Expr(
                    value=Constant(value=Ellipsis))],
            handlers=[
                ExceptHandler(
                    type=Name(id='Exception', ctx=Load())),
                    body=[
                        Expr(
                            value=Constant(value=Ellipsis))]),
                ExceptHandler(
                    type=Name(id='OtherException', ctx=Load()),
                    name='e',
                    body=[
                        Expr(
                            value=Constant(value=Ellipsis))])],
            orelse=[])
])

(continues on next page)
class ast.ExceptHandler (type, name, body)  
A single except clause. type is the exception type it will match, typically a Name node (or None for a catch-all except: clause). name is a raw string for the name to hold the exception, or None if the clause doesn’t have as foo. body is a list of nodes.

```python
>>> print(ast.dump(ast.parse('"""...
... try:
... a + 1
... except TypeError:
... pass
... """'), indent=4))
Module(
    body=[
        Try(
            body=[
                Expr(
                    value=BinOp(
                        left=Name(id='a', ctx=Load()),
                        op=Add(),
                        right=Constant(value=1))]),
            handlers=[
                ExceptHandler(
                    type=Name(id='TypeError', ctx=Load()),
                    body=[
                        Pass()]),
                orelse=[],
                finalbody=[]],
            type_ignores=[]]
)```

class ast.With (items, body, type_comment)  
A with block. items is a list of withitem nodes representing the context managers, and body is the indented block inside the context.

type_comment  
type_comment is an optional string with the type annotation as a comment.

class ast.withitem (context_expr, optional_vars)  
A single context manager in a with block. context_expr is the context manager, often a Call node. optional_vars is a Name, Tuple or List for the as foo part, or None if that isn’t used.

```python
>>> print(ast.dump(ast.parse('"""
... with a as b, c as d:
... something(b, d)
... """'), indent=4))
Module(
    body=[
        With(
            items=[
                withitem(
                    context_expr=Name(id='a', ctx=Load()),
                    optional_vars=Name(id='b', ctx=Store())),
                withitem(
                    context_expr=Name(id='c', ctx=Load()),
                    optional_vars=Name(id='d', ctx=Store()))],
```
Pattern matching

```python
class ast.Match(subject, cases)
A match statement. subject holds the subject of the match (the object that is being matched against the cases) and cases contains an iterable of match_case nodes with the different cases.

class ast.match_case(pattern, guard, body)
A single case pattern in a match statement. pattern contains the match pattern that the subject will be matched against. Note that the AST nodes produced for patterns differ from those produced for expressions, even when they share the same syntax.

The guard attribute contains an expression that will be evaluated if the pattern matches the subject.

body contains a list of nodes to execute if the pattern matches and the result of evaluating the guard expression is true.
```

```python
>>> print(ast.dump(ast.parse('"
... match x:
...     case [x] if x>0:
...     ...
...     case tuple():
...     ...
... **")', indent=4))
Module(
    body=[
        Match(
            subject=Name(id='x', ctx=Load()),
            cases=[
                match_case(
                    pattern=MatchSequence(
                        patterns=[
                            MatchAs(name='x')]),
                    guard=Compare(
                        left=Name(id='x', ctx=Load()),
                        ops=[
                            Gt()],
                        comparators=[Constant(value=0))],
                    body=[
                        Expr(
                            value=Constant(value=Ellipsis))]),
                match_case(
                    pattern=MatchClass(
                        cls=Name(id='tuple', ctx=Load()),
                        patterns=[],
                        kwd_attrs=[],
                        kwd_patterns=[]),
                    body=[
                        Expr(
                            value=Constant(value=Ellipsis))])
```
class `ast.MatchValue`(value)
A match literal or value pattern that compares by equality. `value` is an expression node. Permitted value nodes are restricted as described in the match statement documentation. This pattern succeeds if the match subject is equal to the evaluated value.

```python
>>> print(ast.dump(ast.parse(''
...     match x:
...         case "Relevant":
...         ...
...         "**", indent=4))
Module(
    body=[
        Match(
            subject=Name(id='x', ctx=Load()),
            cases=[
                match_case(
                    pattern=MatchValue(
                        value=Constant(value='Relevant')),
                    body=[
                        Expr(
                            value=Constant(value=Ellipsis))])])
        type_ignores=[]])
```

class `ast.MatchSingleton`(value)
A match literal pattern that compares by identity. `value` is the singleton to be compared against: None, True, or False. This pattern succeeds if the match subject is the given constant.

```python
>>> print(ast.dump(ast.parse(''
...     match x:
...         case None:
...         ...
...         "**", indent=4))
Module(
    body=[
        Match(
            subject=Name(id='x', ctx=Load()),
            cases=[
                match_case(
                    pattern=MatchSingleton(value=None),
                    body=[
                        Expr(
                            value=Constant(value=Ellipsis))])])
        type_ignores=[]])
```

class `ast.MatchSequence`(patterns)
A match sequence pattern. `patterns` contains the patterns to be matched against the subject elements if the subject is a sequence. Matches a variable length sequence if one of the subpatterns is a `MatchStar` node, otherwise matches a fixed length sequence.

```python
>>> print(ast.dump(ast.parse(''
...     match x:
...         case [1, 2]:
...         ...
...         "**", indent=4))
Module(
    body=[
        Match(
            subject=Name(id='x', ctx=Load()),
            cases=[
                match_case(
                    pattern=MatchSequence(patterns=[MatchStar()]),
                    body=[
                        Expr(
                            value=Constant(value=Ellipsis))])])
        type_ignores=[]])
```
class ast.MatchStar(name)

Matches the rest of the sequence in a variable length match sequence pattern. If name is not None, a list containing the remaining sequence elements is bound to that name if the overall sequence pattern is successful.

```python
>>> print(ast.dump(ast.parse('"""...
... match x:
...     ... case [1, 2, *rest]:
...         ...
...     ... case ["_
...         ...
...     ... """], indent=4))
Module(
    body=[
        Match(
            subject=Name(id='x', ctx=Load()),
            cases=[
                match_case(
                    pattern=MatchSequence(
                        patterns=[
                            MatchValue(
                                value=Constant(value=1)),
                            MatchValue(
                                value=Constant(value=2)),
                            MatchStar(name='rest')),
                        body=[
                            Expr(
                                value=Constant(value=Ellipsis))]),
                    match_case(
                        pattern=MatchSequence(
                            patterns=[
                                MatchStar(name='rest')),
                        body=[
                            Expr(
                                value=Constant(value=Ellipsis))]),
            type_ignores=[]])
```

class ast.MatchMapping(keys, patterns, rest)

A match mapping pattern. keys is a sequence of expression nodes, patterns is a corresponding sequence of pattern nodes, rest is an optional name that can be specified to capture the remaining mapping elements. Permitted key expressions are restricted as described in the match statement documentation.

This pattern succeeds if the subject is a mapping, all evaluated key expressions are present in the mapping, and the value corresponding to each key matches the corresponding subpattern. If rest is not None, a dict containing the remaining mapping elements is bound to that name if the overall mapping pattern is successful.

```python
>>> print(ast.dump(ast.parse('"""
... match x:
...     ...
...     ...
...     ...
...     ...
...     ...
...     ... """'))
```

(continues on next page)
... case {1: _, 2: _}:
... ...
... case **rest**:
... ...
... **rest}, indent=4)
Module(
    body=[
        Match(
            subject=Name(id='x', ctx=Load()),
            cases=[
                match_case(
                    pattern=MatchMapping(
                        keys=[
                            Constant(value=1),
                            Constant(value=2)],
                        patterns=[
                            MatchAs(),
                            MatchAs()]),
                    body=[
                        Expr(
                            value=Constant(value=Ellipsis))]),
                match_case(
                    pattern=MatchMapping(keys=[], patterns=[], rest='rest'),
                    body=[
                        Expr(
                            value=Constant(value=Ellipsis))])
            ],
            type_ignores=[])

class ast.MatchClass(cls, patterns, kwd_attrs, kwd_patterns)
A match class pattern. cls is an expression giving the nominal class to be matched. patterns is a sequence
of pattern nodes to be matched against the class defined sequence of pattern matching attributes. kwd_attrs
is a sequence of additional attributes to be matched (specified as keyword arguments in the class pattern),
kwd_patterns are the corresponding patterns (specified as keyword values in the class pattern).

This pattern succeeds if the subject is an instance of the nominated class, all positional patterns match the
corresponding class-defined attributes, and any specified keyword attributes match their corresponding pattern.

Note: classes may define a property that returns self in order to match a pattern node against the instance being
matched. Several built-in types are also matched that way, as described in the match statement documentation.

```python
>>> print(ast.dump(ast.parse('""
... match x:
...     case Point2D(0, 0):
...     ... case Point3D(x=0, y=0, z=0):
...     ... **rest}, indent=4))
Module(
    body=[
        Match(
            subject=Name(id='x', ctx=Load()),
            cases=[
                match_case(
                    pattern=MatchClass(
                        cls=Name(id='Point2D', ctx=Load()),
                        patterns=[
                            MatchValue(
                                value=Constant(value=0)),
                            MatchValue(
                                value=Constant(value=0)),
                            kwd_atr
... (continues on next page)
class ast.MatchAs(pattern, name)
A match “as-pattern”, capture pattern or wildcard pattern. pattern contains the match pattern that the subject will be matched against. If the pattern is None, the node represents a capture pattern (i.e. a bare name) and will always succeed.

The name attribute contains the name that will be bound if the pattern is successful. If name is None, pattern must also be None and the node represents the wildcard pattern.

```python
>>> print(ast.dump(ast.parse(''
... match x:
...     case [x] as y:
...     case _:
...     ... ''), indent=4))
Module(
    body=[
        Match(
            subject=Name(id='x', ctx=Load()),
            cases=[
                match_case(
                    pattern=MatchClass(
                        cls=Name(id='Point3D', ctx=Load()),
                        patterns=[],
                        kwd_attrs=['x', 'y', 'z'],
                        kwd_patterns=[
                            MatchValue(value=Constant(value=0)),
                            MatchValue(value=Constant(value=0)),
                            MatchValue(value=Constant(value=0))]),
                    body=[
                        Expr(value=Constant(value=Ellipsis))]),
            type_ignores=[])
```
ceeds. The or-pattern is then deemed to succeed. If none of the subpatterns succeed the or-pattern fails. The `patterns` attribute contains a list of match pattern nodes that will be matched against the subject.

```python
>>> print(ast.dump(ast.parse(""
... match x:
... case [x] | (y):
... ... ...
... ", indent=4))
Module(
    body=[
        Match(
            subject=Name(id='x', ctx=Load()),
            cases=[
                match_case(
                    pattern=MatchOr(
                        patterns=[
                            MatchSequence(
                                patterns=[
                                    MatchAs(name='x')],
                                    MatchAs(name='y'))],
                    body=[
                        Expr(
                            value=Constant(value=Ellipsis))])])])
```

**Function and class definitions**

```python
class ast.FunctionDef (name, args, body, decorator_list, returns, type_comment)
A function definition.

- `name` is a raw string of the function name.
- `args` is an `arguments` node.
- `body` is the list of nodes inside the function.
- `decorator_list` is the list of decorators to be applied, stored outermost first (i.e. the first in the list will be applied last).
- `returns` is the return annotation.

**type_comment**

`type_comment` is an optional string with the type annotation as a comment.
```
```python
class ast.Lambda (args, body)
```
lambda is a minimal function definition that can be used inside an expression. Unlike `FunctionDef`, `body` holds a single node.

```python
>>> print(ast.dump(ast.parse('lambda x,y: ...'), indent=4))
Module(
    body=[
        Expr(
            value=Lambda(
                args=arguments(
                    posonlyargs=[],
                    args=[
                        arg(arg='x'),
                        arg(arg='y')],
                    kwonlyargs=[],
                    kw_defaults=[],
                    defaults=[]),
                body=Constant(value=Ellipsis))]),
        type_ignores=[]])
```
class ast.arguments (posonlyargs, args, vararg, kwonlyargs, kw_defaults, kwarg, defaults)

The arguments for a function.

• posonlyargs, args and kwonlyargs are lists of arg nodes.
• vararg and kwarg are single arg nodes, referring to the *args, **kwargs parameters.
• kw_defaults is a list of default values for keyword-only arguments. If one is None, the corresponding argument is required.
• defaults is a list of default values for arguments that can be passed positionally. If there are fewer defaults, they correspond to the last n arguments.

class ast.arg (arg, annotation, type_comment)

A single argument in a list. arg is a raw string of the argument name, annotation is its annotation, such as a Str or Name node.

type_comment

type_comment is an optional string with the type annotation as a comment

```python
>>> print(ast.dump(ast.parse('"""
... @decorator1
... @decorator2
... def f(a: 'annotation', b=1, c=2, *d, e, f=3, **g) -> 'return annotation':
...     pass
... """), indent=4))
Module(
    body=[
        FunctionDef(
            name='f',
            args=arguments(
                posonlyargs=[],
                args=[
                    arg(arg='a',
                        annotation=Constant(value='annotation')),
                    arg(arg='b'),
                    arg(arg='c')],
                vararg=arg(arg='d'),
                kwonlyargs=[
                    arg(arg='e'),
                    arg(arg='f')],
                kw_defaults=[
                    None,
                    Constant(value=3)],
                kwarg=arg(arg='g'),
                defaults=[
                    Constant(value=1),
                    Constant(value=2)]),
            body=[Pass()]),
        decorator_list=[
            Name(id='decorator1', ctx=Load()),
            Name(id='decorator2', ctx=Load())],
        returns=Constant(value='return annotation'))],
    type_ignores=[])"
```

class ast.Return (value)

A return statement.

```python
>>> print(ast.dump(ast.parse('return 4'), indent=4))
Module(
    body=[
        Return("
```

(continues on next page)
class ast.Yield(value)
class ast.YieldFrom(value)

A yield or yield from expression. Because these are expressions, they must be wrapped in an `Expr` node if the value sent back is not used.

```python
>>> print(ast.dump(ast.parse('yield x'), indent=4))
Module(
    body=[
        Expr(
            value=Yield(
                value=Name(id='x', ctx=Load()))),
            type_ignores=[])

>>> print(ast.dump(ast.parse('yield from x'), indent=4))
Module(
    body=[
        Expr(
            value=YieldFrom(
                value=Name(id='x', ctx=Load()))),
            type_ignores=[])
```

class ast.Global(names)
class ast.Nonlocal(names)

global and nonlocal statements. names is a list of raw strings.

```python
>>> print(ast.dump(ast.parse('global x,y,z'), indent=4))
Module(
    body=[
        Global(
            names=['x',
                   'y',
                   'z']),
            type_ignores=[])

>>> print(ast.dump(ast.parse('nonlocal x,y,z'), indent=4))
Module(
    body=[
        Nonlocal(
            names=['x',
                   'y',
                   'z']),
            type_ignores=[])
```

class ast.ClassDef(name, bases, keywords, starargs, kwargs, body, decorator_list)

A class definition.

- name is a raw string for the class name
- bases is a list of nodes for explicitly specified base classes.
- keywords is a list of keyword nodes, principally for 'metaclass'. Other keywords will be passed to the metaclass, as per PEP-3115.
- starargs and kwargs are each a single node, as in a function call. starargs will be expanded to join the list of base classes, and kwargs will be passed to the metaclass.
- body is a list of nodes representing the code within the class definition.
• `decorator_list` is a list of nodes, as in `FunctionDef`.

```python
>>> print(ast.dump(ast.parse('""
... @decorator1
... @decorator2
... class Foo(base1, base2, metaclass=meta):
...     pass
... """'), indent=4))
Module(
    body=[
        ClassDef(
            name='Foo',
            bases=[
                Name(id='base1', ctx=Load()),
                Name(id='base2', ctx=Load())],
            keywords=[
                keyword(
                    arg='metaclass',
                    value=Name(id='meta', ctx=Load()))],
            body=[
                Pass()],
            decorator_list=[
                Name(id='decorator1', ctx=Load()),
                Name(id='decorator2', ctx=Load())]],
        type_ignores=[])
```

**Async and await**

```python
class ast.AsyncFunctionDef (name, args, body, decorator_list, returns, type_comment)
    An async def function definition. Has the same fields as FunctionDef.
class ast.Await (value)
    An await expression. value is what it waits for. Only valid in the body of an AsyncFunctionDef.
```

```python
>>> print(ast.dump(ast.parse('""
... async def f():
...     await other_func()
... """'), indent=4))
Module(
    body=[
        AsyncFunctionDef(
            name='f',
            args=arguments(
                posonlyargs=[],
                args=[],
                kwonlyargs=[],
                kw_defaults=[],
                defaults=[]),
            body=[
                Expr(
                    value=Await(
                        value=Call(
                            func=Name(id='other_func', ctx=Load()),
                            args=[],
                            keywords=[])),
                    decorator_list=[])],
            type_ignores=[])
```

```python
class ast.AsyncFor (target, iter, body, orelse, type_comment)
class ast.AsyncWith (items, body, type_comment)
    async for loops and async with context managers. They have the same fields as For and With, respectively. Only valid in the body of an AsyncFunctionDef.
```
Note: When a string is parsed by `ast.parse()`, operator nodes (subclasses of `ast.operator`, `ast.unaryop`, `ast.cmpop`, `ast.boolop` and `ast.expr_context`) on the returned tree will be singletons. Changes to one will be reflected in all other occurrences of the same value (e.g. `ast.Add`).

### 32.1.3 `ast` Helpers

Apart from the node classes, the `ast` module defines these utility functions and classes for traversing abstract syntax trees:

```python
ast.parse(source, filename='<unknown>', mode='exec', *, type_comments=False, feature_version=None)
```

Parse the source into an AST node. Equivalent to `compile(source, filename, mode, ast.PyCF_ONLY_AST)`.

If `type_comments=True` is given, the parser is modified to check and return type comments as specified by PEP 484 and PEP 526. This is equivalent to adding `ast.PyCF_TYPE_COMMENTS` to the flags passed to `compile()`. This will report syntax errors for misplaced type comments. Without this flag, type comments will be ignored, and the `type_comment` field on selected AST nodes will always be `None`. In addition, the locations of `# type: ignore` comments will be returned as the `type_ignores` attribute of `Module` (otherwise it is always an empty list).

In addition, if `mode` is `'func_type'`, the input syntax is modified to correspond to PEP 484 “signature type comments”, e.g. `(str, int) -> List[str].

Also, setting `feature_version` to a tuple `(major, minor)` will attempt to parse using that Python version’s grammar. Currently `major` must equal to 3. For example, setting `feature_version=(3, 4)` will allow the use of `async` and `await` as variable names. The lowest supported version is (3, 4); the highest is `sys.version_info[0:2]`.

If source contains a null character (`'0'`), `ValueError` is raised.

**Warning:** Note that successfully parsing source code into an AST object doesn’t guarantee that the source code provided is valid Python code that can be executed as the compilation step can raise further `SyntaxError` exceptions. For instance, the source `return 42` generates a valid AST node for a return statement, but it cannot be compiled alone (it needs to be inside a function node).

In particular, `ast.parse()` won’t do any scoping checks, which the compilation step does.

**Warning:** It is possible to crash the Python interpreter with a sufficiently large/complex string due to stack depth limitations in Python’s AST compiler.

Changed in version 3.8: Added `type_comments, mode='func_type'` and `feature_version`.

```python
ast.unparse(ast_obj)
```

Unparse an `ast.AST` object and generate a string with code that would produce an equivalent `ast.AST` object if parsed back with `ast.parse()`.

**Warning:** The produced code string will not necessarily be equal to the original code that generated the `ast.AST` object (without any compiler optimizations, such as constant tuples/frozensets).

**Warning:** Trying to unpars an highly complex expression would result with `RecursionError`. 

32.1. `ast` — Abstract Syntax Trees 1813
New in version 3.9.

```
ast.literal_eval(node_or_string)
```

Safely evaluate an expression node or a string containing a Python literal or container display. The string or node provided may only consist of the following Python literal structures: strings, bytes, numbers, tuples, lists, dicts, sets, booleans, None and Ellipsis.

This can be used for safely evaluating strings containing Python values from untrusted sources without the need to parse the values oneself. It is not capable of evaluating arbitrarily complex expressions, for example involving operators or indexing.

**Warning:** It is possible to crash the Python interpreter with a sufficiently large/complex string due to stack depth limitations in Python’s AST compiler.

It can raise `ValueError`, `TypeError`, `SyntaxError`, `MemoryError` and `RecursionError` depending on the malformed input.

Changed in version 3.2: Now allows bytes and set literals.

Changed in version 3.9: Now supports creating empty sets with `'set()'`.

Changed in version 3.10: For string inputs, leading spaces and tabs are now stripped.

```
ast.get_docstring(node, clean=True)
```

Return the docstring of the given `node` (which must be a `FunctionDef`, `AsyncFunctionDef`, `ClassDef`, or `Module` node), or None if it has no docstring. If `clean` is true, clean up the docstring’s indentation with `inspect.cleandoc()`.

Changed in version 3.5: `AsyncFunctionDef` is now supported.

```
ast.get_source_segment(source, node, *, padded=False)
```

Get source code segment of the `source` that generated `node`. If some location information (`lineno`, `end_lineno`, `col_offset`, or `end_col_offset`) is missing, return None.

If `padded` is True, the first line of a multi-line statement will be padded with spaces to match its original position.

New in version 3.8.

```
ast.fix_missing_locations(node)
```

When you compile a node tree with `compile()`, the compiler expects `lineno` and `col_offset` attributes for every node that supports them. This is rather tedious to fill in for generated nodes, so this helper adds these attributes recursively where not already set, by setting them to the values of the parent node. It works recursively starting at `node`.

```
ast.increment_lineno(node, n=1)
```

Increment the line number and end line number of each node in the tree starting at `node` by `n`. This is useful to “move code” to a different location in a file.

```
ast.copy_location(new_node, old_node)
```

Copy source location (`lineno`, `col_offset`, `end_lineno`, and `end_col_offset`) from `old_node` to `new_node` if possible, and return `new_node`.

```
ast.iter_fields(node)
```

Yield a tuple of `(fieldname, value)` for each field in `node._fields` that is present on `node`.

```
ast.iter_child_nodes(node)
```

Yield all direct child nodes of `node`, that is, all fields that are nodes and all items of fields that are lists of nodes.

```
ast.walk(node)
```

Recursively yield all descendant nodes in the tree starting at `node` (including `node` itself), in no specified order. This is useful if you only want to modify nodes in place and don’t care about the context.
class ast.NodeVisitor
A node visitor base class that walks the abstract syntax tree and calls a visitor function for every node found. This function may return a value which is forwarded by the visit() method.

This class is meant to be subclassed, with the subclass adding visitor methods.

visit (node)
Visit a node. The default implementation calls the method called self.visit_classname where classname is the name of the node class, or generic_visit() if that method doesn’t exist.

generic_visit (node)
This visitor calls visit() on all children of the node.

Note that child nodes of nodes that have a custom visitor method won’t be visited unless the visitor calls generic_visit() or visits them itself.

Don’t use the NodeVisitor if you want to apply changes to nodes during traversal. For this a special visitor exists (NodeTransformer) that allows modifications.

Deprecated since version 3.8: Methods visit_Num(), visit_Str(), visit_Bytes(), visit_NameConstant() and visit_Ellipsis() are deprecated now and will not be called in future Python versions. Add the visit_Constant() method to handle all constant nodes.

class ast.NodeTransformer
A NodeVisitor subclass that walks the abstract syntax tree and allows modification of nodes.

The NodeTransformer will walk the AST and use the return value of the visitor methods to replace or remove the old node. If the return value of the visitor method is None, the node will be removed from its location, otherwise it is replaced with the return value. The return value may be the original node in which case no replacement takes place.

Here is an example transformer that rewrites all occurrences of name lookups (foo) to data['foo']:

class RewriteName(NodeTransformer):
    def visit_Name(self, node):
        return Subscript(
            value=Name(id='data', ctx=Load()),
            slice=Constant(value=node.id),
            ctx=node.ctx
        )

Keep in mind that if the node you’re operating on has child nodes you must either transform the child nodes yourself or call the generic_visit() method for the node first.

For nodes that were part of a collection of statements (that applies to all statement nodes), the visitor may also return a list of nodes rather than just a single node.

If NodeTransformer introduces new nodes (that weren’t part of original tree) without giving them location information (such as lineno), fix_missing_locations() should be called with the new sub-tree to recalculate the location information:

tree = ast.parse('foo', mode='eval')
new_tree = fix_missing_locations(RewriteName().visit(tree))

Usually you use the transformer like this:

node = YourTransformer().visit(node)

ast.dump (node, annotate_fields=True, include_attributes=False, *, indent=None)  
Return a formatted dump of the tree in node. This is mainly useful for debugging purposes. If annotate_fields is true (by default), the returned string will show the names and the values for fields. If annotate_fields is false, the result string will be more compact by omitting unambiguous field names. Attributes such as line numbers and column offsets are not dumped by default. If this is wanted, include_attributes can be set to true.
If `indent` is a non-negative integer or string, then the tree will be pretty-printed with that indent level. An indent level of 0, negative, or "" will only insert newlines. `None` (the default) selects the single line representation. Using a positive integer indent indents that many spaces per level. If `indent` is a string (such as "\t"), that string is used to indent each level.

Changed in version 3.9: Added the `indent` option.

### 32.1.4 Compiler Flags

The following flags may be passed to `compile()` in order to change effects on the compilation of a program:

- **ast.\texttt{PyCF\_ALLOW\_TOP\_LEVEL\_AWAIT}**
  Enables support for top-level `await`, `async for`, `async with` and async comprehensions.

New in version 3.8.

- **ast.\texttt{PyCF\_ONLY\_AST}**
  Generates and returns an abstract syntax tree instead of returning a compiled code object.

- **ast.\texttt{PyCF\_TYPE\_COMMENTS}**
  Enables support for PEP 484 and PEP 526 style type comments (# type: `<type>`, # type: ignore `<stuff>`).

New in version 3.8.

### 32.1.5 Command-Line Usage

New in version 3.9.

The `ast` module can be executed as a script from the command line. It is as simple as:

```
python -m ast [-m <mode>] [-a] [infile]
```

The following options are accepted:

- **\texttt{-h, --help}**
  Show the help message and exit.

- **\texttt{-m <mode>}**
  Specify what kind of code must be compiled, like the `mode` argument in `parse()`.

- **\texttt{--mode <mode>}**
  Specify what kind of code must be compiled, like the `mode` argument in `parse()`.

- **\texttt{--no-type-comments}**
  Don’t parse type comments.

- **\texttt{-a, --include-attributes}**
  Include attributes such as line numbers and column offsets.

- **\texttt{-i <indent>}**
  Indentation of nodes in AST (number of spaces).

If `infile` is specified its contents are parsed to AST and dumped to stdout. Otherwise, the content is read from stdin.

**See also:**

Green Tree Snakes, an external documentation resource, has good details on working with Python ASTs.

ASTTokens annotates Python ASTs with the positions of tokens and text in the source code that generated them. This is helpful for tools that make source code transformations.

leoAst.py unifies the token-based and parse-tree-based views of python programs by inserting two-way links between tokens and ast nodes.
LibCST parses code as a Concrete Syntax Tree that looks like an ast tree and keeps all formatting details. It’s useful for building automated refactoring (codemod) applications and linters.

Parso is a Python parser that supports error recovery and round-trip parsing for different Python versions (in multiple Python versions). Parso is also able to list multiple syntax errors in your python file.

## 32.2 symtable — Access to the compiler’s symbol tables

**Source code:** Lib/symtable.py

Symbol tables are generated by the compiler from AST just before bytecode is generated. The symbol table is responsible for calculating the scope of every identifier in the code. `symtable` provides an interface to examine these tables.

### 32.2.1 Generating Symbol Tables

```python
symtable.symtable(code, filename, compile_type)
```

Return the toplevel `SymbolTable` for the Python source `code`. `filename` is the name of the file containing the code. `compile_type` is like the `mode` argument to `compile()`.

### 32.2.2 Examining Symbol Tables

```python
class symtable.SymbolTable
```

A namespace table for a block. The constructor is not public.

- `get_type()`
  - Return the type of the symbol table. Possible values are 'class', 'module', and 'function'.

- `get_id()`
  - Return the table’s identifier.

- `get_name()`
  - Return the table’s name. This is the name of the class if the table is for a class, the name of the function if the table is for a function, or 'top' if the table is global (`get_type()` returns 'module').

- `get_lineno()`
  - Return the number of the first line in the block this table represents.

- `is_optimized()`
  - Return `True` if the locals in this table can be optimized.

- `is_nested()`
  - Return `True` if the block is a nested class or function.

- `has_children()`
  - Return `True` if the block has nested namespaces within it. These can be obtained with `get_children()`.

- `get_identifiers()`
  - Return a list of names of symbols in this table.

- `lookup(name)`
  - Lookup `name` in the table and return a `Symbol` instance.

- `get_symbols()`
  - Return a list of `Symbol` instances for names in the table.

- `get_children()`
  - Return a list of the nested symbol tables.
class symtable.Function
    A namespace for a function or method. This class inherits SymbolTable.

    get_parameters()
        Return a tuple containing names of parameters to this function.

    get_locals()
        Return a tuple containing names of locals in this function.

    getGlobals()
        Return a tuple containing names of globals in this function.

    getNonlocals()
        Return a tuple containing names of nonlocals in this function.

    getFrees()
        Return a tuple containing names of free variables in this function.

class symtable.Class
    A namespace of a class. This class inherits SymbolTable.

    getMethods()
        Return a tuple containing the names of methods declared in the class.

class symtable.Symbol
    An entry in a SymbolTable corresponding to an identifier in the source. The constructor is not public.

    getName()
        Return the symbol’s name.

    isReferenced()
        Return True if the symbol is used in its block.

    isImported()
        Return True if the symbol is created from an import statement.

    isParameter()
        Return True if the symbol is a parameter.

    isGlobal()
        Return True if the symbol is global.

    isNonlocal()
        Return True if the symbol is nonlocal.

    isDeclaredGlobal()
        Return True if the symbol is declared global with a global statement.

    isLocal()
        Return True if the symbol is local to its block.

    isAnnotated()
        Return True if the symbol is annotated.

    isFree()
        Return True if the symbol is referenced in its block, but not assigned to.

    isAssigned()
        Return True if the symbol is assigned to in its block.

    isNamespace()
        Return True if name binding introduces new namespace.

        If the name is used as the target of a function or class statement, this will be true.

        For example:
Note that a single name can be bound to multiple objects. If the result is `True`, the name may also be bound to other objects, like an int or list, that does not introduce a new namespace.

```python
>>> table = symtable.symtable("def some_func(): pass", "string", "exec")
>>> table.lookup("some_func").is_namespace()
True
```

```
32.3 token — Constants used with Python parse trees
```

This module provides constants which represent the numeric values of leaf nodes of the parse tree (terminal tokens). Refer to the file `Grammar/Tokens` in the Python distribution for the definitions of the names in the context of the language grammar. The specific numeric values which the names map to may change between Python versions.

The module also provides a mapping from numeric codes to names and some functions. The functions mirror definitions in the Python C header files.

```python
token.tok_name
    Dictionary mapping the numeric values of the constants defined in this module back to name strings, allowing more human-readable representation of parse trees to be generated.

token.ISTERMINAL(x)
    Return `True` for terminal token values.

token.ISNONTERMINAL(x)
    Return `True` for non-terminal token values.

token.ISEOF(x)
    Return `True` if `x` is the marker indicating the end of input.
```

The token constants are:

```python
token.ENDMARKER
token.NAME
token.NUMBER
token.STRING
token.NEWLINE
token.INDENT
token.DEDENT
token.LPAR
    Token value for "(".

token.RPAR
    Token value for ")".

token.LSQB
    Token value for "[".
```
token. RSQB
  Token value for " ] ".

token. COLON
  Token value for " : ".

token. COMMA
  Token value for " , ".

token. SEMI
  Token value for " ; ".

token. PLUS
  Token value for " + ".

token. MINUS
  Token value for " - ".

token. STAR
  Token value for " * ".

token. SLASH
  Token value for " / ".

token. VBAR
  Token value for " | ".

token. AMPER
  Token value for " & ".

token. LESS
  Token value for " < ".

token. GREATER
  Token value for " > ".

token. EQUAL
  Token value for " = ".

token. DOT
  Token value for " . ".

token. PERCENT
  Token value for " % ".

token. LBRACE
  Token value for " { ".

token. RBRACE
  Token value for " } ".

token. EQEQUAL
  Token value for " == ".

token. NOTEQUAL

token.ASYNC

token.TYPE_IGNORE
The following token type values aren’t used by the C tokenizer but are needed for the `tokenize` module.

- **token**.TYPE_COMMENT
  - Token value used to indicate a comment.

- **token**.NL
  - Token value used to indicate a non-terminating newline. The `NEWLINE` token indicates the end of a logical line of Python code; NL tokens are generated when a logical line of code is continued over multiple physical lines.

- **token**.ENCODING
  - Token value that indicates the encoding used to decode the source bytes into text. The first token returned by `tokenize.tokenize()` will always be an ENCODING token.

- **token**.TYPE_COMMENT
  - Token value indicating that a type comment was recognized. Such tokens are only produced when `ast.parse()` is invoked with `type_comments=True`.

Changed in version 3.5: Added `AWAIT` and `ASYNC` tokens.

Changed in version 3.7: Added `COMMENT`, `NL` and `ENCODING` tokens.

Changed in version 3.7: Removed `AWAIT` and `ASYNC` tokens. “async” and “await” are now tokenized as `NAME` tokens.

Changed in version 3.8: Added `TYPE_COMMENT`, `TYPE_IGNORE`, `COLONEQUAL`. Added `AWAIT` and `ASYNC` tokens back (they’re needed to support parsing older Python versions for `ast.parse()` with `feature_version` set to 6 or lower).

### 32.4 keyword — Testing for Python keywords

Source code: Lib/keyword.py

This module allows a Python program to determine if a string is a keyword or soft keyword.

- **keyword**.iskeyword(s)
  - Return True if `s` is a Python keyword.

- **keyword**.kwlist
  - Sequence containing all the keywords defined for the interpreter. If any keywords are defined to only be active when particular `__future__` statements are in effect, these will be included as well.

- **keyword**.issoftkeyword(s)
  - Return True if `s` is a Python soft keyword.

    New in version 3.9.

- **keyword**.softkwlist
  - Sequence containing all the soft keywords defined for the interpreter. If any soft keywords are defined to only be active when particular `__future__` statements are in effect, these will be included as well.

    New in version 3.9.
32.5 tokenize — Tokenizer for Python source

Source code: Lib/tokenize.py

The tokenize module provides a lexical scanner for Python source code, implemented in Python. The scanner in this module returns comments as tokens as well, making it useful for implementing “pretty-printers”, including colorizers for on-screen displays.

To simplify token stream handling, all operator and delimiter tokens and Ellipsis are returned using the generic OP token type. The exact type can be determined by checking the exact_type property on the named tuple returned from tokenize.tokenize().

32.5.1 Tokenizing Input

The primary entry point is a generator:

```
tokenize.tokenize (readline)
```

The tokenize() generator requires one argument, readline, which must be a callable object which provides the same interface as the io.IOBase.readline() method of file objects. Each call to the function should return one line of input as bytes.

The generator produces 5-tuples with these members: the token type; the token string; a 2-tuple (srow, scol) of ints specifying the row and column where the token begins in the source; a 2-tuple (erow, ecol) of ints specifying the row and column where the token ends in the source; and the line on which the token was found. The line passed (the last tuple item) is the physical line. The 5 tuple is returned as a named tuple with the field names: type string start end line.

The returned named tuple has an additional property named exact_type that contains the exact operator type for OP tokens. For all other token types exact_type equals the named tuple type field.

Changed in version 3.1: Added support for named tuples.

Changed in version 3.3: Added support for exact_type.

```
tokenize() determines the source encoding of the file by looking for a UTF-8 BOM or encoding cookie, according to PEP 263.
```

tokenize.generate_tokens (readline)

Tokenize a source reading unicode strings instead of bytes.

Like tokenize(), the readline argument is a callable returning a single line of input. However, generate_tokens() expects readline to return a str object rather than bytes.

The result is an iterator yielding named tuples, exactly like tokenize(). It does not yield an ENCODING token.

All constants from the token module are also exported from tokenize.

Another function is provided to reverse the tokenization process. This is useful for creating tools that tokenize a script, modify the token stream, and write back the modified script.

```
tokenize.untokenize (iterable)
```

Converts tokens back into Python source code. The iterable must return sequences with at least two elements, the token type and the token string. Any additional sequence elements are ignored.

The reconstructed script is returned as a single string. The result is guaranteed to tokenize back to match the input so that the conversion is lossless and round-trips are assured. The guarantee applies only to the token type and token string as the spacing between tokens (column positions) may change.

It returns bytes, encoded using the ENCODING token, which is the first token sequence output by tokenize(). If there is no encoding token in the input, it returns a str instead.

```
tokenize() needs to detect the encoding of source files it tokenizes. The function it uses to do this is available:
```

32.5. tokenize — Tokenizer for Python source
The `detect_encoding()` function is used to detect the encoding that should be used to decode a Python source file. It requires one argument, `readline`, in the same way as the `tokenize()` generator.

It will call `readline` a maximum of twice, and return the encoding used (as a string) and a list of any lines (not decoded from bytes) it has read in.

It detects the encoding from the presence of a UTF-8 BOM or an encoding cookie as specified in PEP 263. If both a BOM and a cookie are present, but disagree, a `SyntaxError` will be raised. Note that if the BOM is found, 'utf-8-sig' will be returned as an encoding.

If no encoding is specified, then the default of 'utf-8' will be returned.

Use `open()` to open Python source files: it uses `detect_encoding()` to detect the file encoding.

```python
open(filename)
```

Open a file in read only mode using the encoding detected by `detect_encoding()`.

New in version 3.2.

### exception: `TokenError`

Raised when either a docstring or expression that may be split over several lines is not completed anywhere in the file, for example:

```python
***Beginning of docstring
```

or:

```python
[1, 2, 3
```

Note that unclosed single-quoted strings do not cause an error to be raised. They are tokenized as `ERRORTOKEN`, followed by the tokenization of their contents.

### 32.5.2 Command-Line Usage

New in version 3.3.

The `tokenize` module can be executed as a script from the command line. It is as simple as:

```bash
python -m tokenize [-e] [filename.py]
```

The following options are accepted:

- `-h`, `--help`
  - show this help message and exit

- `-e`, `--exact`
  - display token names using the exact type

If `filename.py` is specified its contents are tokenized to stdout. Otherwise, tokenization is performed on stdin.
32.5.3 Examples

Example of a script rewriter that transforms float literals into Decimal objects:

```python
from tokenize import tokenize, untokenize, NUMBER, STRING, NAME, OP
from io import BytesIO

def decistmt(s):
    """Substitute Decimals for floats in a string of statements.
    >>> from decimal import Decimal
    >>> s = 'print(+21.3e-5*-1234/81.7)'
    >>> decistmt(s)
    "print (+Decimal ('21.3e-5')*-Decimal ('1234')/Decimal ('81.7'))"
    The format of the exponent is inherited from the platform C library.
    Known cases are "e-007" (Windows) and "e-07" (not Windows). Since
    we're only showing 12 digits, and the 13th isn't close to 5, the
    rest of the output should be platform-independent.
    >>> exec(s) #doctest: +ELLIPSIS
    -3.21716034272e-0...7
    Output from calculations with Decimal should be identical across all
    platforms.
    >>> exec(decistmt(s))
    -3.217160342717258261933904529E-7
    ""
    result = []
    g = tokenize(BytesIO(s.encode('utf-8')).readline) # tokenize the string
    for toknum, tokval, _, _, _ in g:
        if toknum == NUMBER and '.' in tokval: # replace NUMBER tokens
            result.extend([
                (NAME, 'Decimal'),
                (OP, '('),
                (STRING, repr(tokval)),
                (OP, ')')
            ])
        else:
            result.append((toknum, tokval))
    return untokenize(result).decode('utf-8')
```

Example of tokenizing from the command line. The script:

```python
def say_hello():
    print("Hello, World!")
say_hello()
```

will be tokenized to the following output where the first column is the range of the line/column coordinates where
the token is found, the second column is the name of the token, and the final column is the value of the token (if any)

```
$ python -m tokenize hello.py
0,0-0,0: ENCODING 'utf-8'
1,0-1,3: NAME 'def'
1,4-1,13: NAME 'say_hello'
1,13-1,14: OP '('
1,14-1,15: OP ')'  
1,15-1,16: OP ':
1,16-1,17: NEWLINE '\n'
2,0-2,4: INDENT ' ' 
(continues on next page)```
The exact token type names can be displayed using the `-e` option:

```
$ python -m tokenize -e hello.py
0,0-0,0: ENCODING 'utf-8'
1,0-1,3: NAME 'def'
1,4-1,13: NAME 'say_hello'
1,13-1,14: LPAR '('
1,14-1,15: RPAR ')'
1,15-1,16: COLON ':'
1,16-1,17: NEWLINE '
'
2,0-2,4: INDENT '    '
2,4-2,9: NAME 'print'
2,9-2,10: LPAR '('
2,10-2,25: STRING '"Hello, World!"
2,25-2,26: RPAR )'
2,26-2,27: NEWLINE '
'
3,0-3,1: NL '
'
4,0-4,0: DEDENT ''
4,0-4,9: NAME 'say_hello'
4,9-4,10: OP '('
4,10-4,11: OP ')'
4,11-4,12: NEWLINE '
'
5,0-5,0: ENDMARKER ''
```

Example of tokenizing a file programmatically, reading unicode strings instead of bytes with `generate_tokens()`:

```python
import tokenize

with tokenize.open('hello.py') as f:
    tokens = tokenize.generate_tokens(f.readline)
    for token in tokens:
        print(token)
```

Or reading bytes directly with `tokenize()`:

```python
import tokenize

with open('hello.py', 'rb') as f:
    tokens = tokenize.tokenize(f.readline)
    for token in tokens:
        print(token)
```
32.6  tabnanny — Detection of ambiguous indentation

Source code: Lib/tabnanny.py

For the time being this module is intended to be called as a script. However it is possible to import it into an IDE and use the function `check()` described below.

Note: The API provided by this module is likely to change in future releases; such changes may not be backward compatible.

```
def check(file_or_dir):
    if file_or_dir is a directory and not a symbolic link, then recursively descend the directory tree named by file_or_dir, checking all .py files along the way. If file_or_dir is an ordinary Python source file, it is checked for whitespace related problems. The diagnostic messages are written to standard output using the `print()` function.

def verbose:
    Flag indicating whether to print verbose messages. This is incremented by the `-v` option if called as a script.

def filename_only:
    Flag indicating whether to print only the filenames of files containing whitespace related problems. This is set to true by the `-q` option if called as a script.

def exception:
    Raised by `process_tokens()` if detecting an ambiguous indent. Captured and handled in `check()`.

def process_tokens(tokens):
    This function is used by `check()` to process tokens generated by the `tokenize` module.
```

Module `tokenize` Lexical scanner for Python source code.

32.7  pyclbr — Python module browser support

Source code: Lib/pyclbr.py

The `pyclbr` module provides limited information about the functions, classes, and methods defined in a Python-coded module. The information is sufficient to implement a module browser. The information is extracted from the Python source code rather than by importing the module, so this module is safe to use with untrusted code. This restriction makes it impossible to use this module with modules not implemented in Python, including all standard and optional extension modules.

```
def readmodule(module, path=None):
    Return a dictionary mapping module-level class names to class descriptors. If possible, descriptors for imported base classes are included. Parameter `module` is a string with the name of the module to read; it may be the name of a module within a package. If given, `path` is a sequence of directory paths prepended to `sys.path`, which is used to locate the module source code.

    This function is the original interface and is only kept for back compatibility. It returns a filtered version of the following.

def readmodule_ex(module, path=None):
    Return a dictionary-based tree containing a function or class descriptors for each function and class defined in the module with a `def` or `class` statement. The returned dictionary maps module-level function and class names to their descriptors. Nested objects are entered into the children dictionary of their parent. As with `readmodule`, `module` names the module to be read and `path` is prepended to `sys.path`. If the module being read
```
is a package, the returned dictionary has a key '__path__' whose value is a list containing the package search path.

New in version 3.7: Descriptors for nested definitions. They are accessed through the new children attribute. Each has a new parent attribute.

The descriptors returned by these functions are instances of Function and Class classes. Users are not expected to create instances of these classes.

### 32.7.1 Function Objects

Function objects describe functions defined by `def` statements. They have the following attributes:

- **Function.file**
  - Name of the file in which the function is defined.

- **Function.module**
  - The name of the module defining the function described.

- **Function.name**
  - The name of the function.

- **Function.lineno**
  - The line number in the file where the definition starts.

- **Function.parent**
  - For top-level functions, None. For nested functions, the parent.
  - New in version 3.7.

- **Function.children**
  - A dictionary mapping names to descriptors for nested functions and classes.
  - New in version 3.7.

- **Function.is_async**
  - True for functions that are defined with the `async` prefix, False otherwise.
  - New in version 3.10.

### 32.7.2 Class Objects

Class objects describe classes defined by `class` statements. They have the same attributes as Functions and two more.

- **Class.file**
  - Name of the file in which the class is defined.

- **Class.module**
  - The name of the module defining the class described.

- **Class.name**
  - The name of the class.

- **Class.lineno**
  - The line number in the file where the definition starts.

- **Class.parent**
  - For top-level classes, None. For nested classes, the parent.
  - New in version 3.7.

- **Class.children**
  - A dictionary mapping names to descriptors for nested functions and classes.
  - New in version 3.7.
Class. `super`

A list of `Class` objects which describe the immediate base classes of the class being described. Classes which are named as superclasses but which are not discoverable by `readmodule_ex()` are listed as a string with the class name instead of as `Class` objects.

Class. `methods`

A dictionary mapping method names to line numbers. This can be derived from the newer children dictionary, but remains for back-compatibility.

### 32.8 `py_compile` — Compile Python source files

**Source code:** Lib/py_compile.py

The `py_compile` module provides a function to generate a byte-code file from a source file, and another function used when the module source file is invoked as a script.

Though not often needed, this function can be useful when installing modules for shared use, especially if some of the users may not have permission to write the byte-code cache files in the directory containing the source code.

**exception** `py_compile.PyCompileError`

Exception raised when an error occurs while attempting to compile the file.

`py_compile.compile`(file, cfilee=None, dfilee=None, doraise=False, optimize=-1, invalidation_mode=PycInvalidationMode.TIMESTAMP, quiet=0)

Compile a source file to byte-code and write out the byte-code cache file. The source code is loaded from the file named `file`. The byte-code is written to `cfilee`, which defaults to the PEP 3147/PEP 488 path, ending in `.pyc`. For example, if `file` is `/foo/bar/baz.py` `cfilee` will default to `/foo/bar/__pycache__/baz.cpython-32.pyc` for Python 3.2. If `dfilee` is specified, it is used as the name of the source file in error messages instead of `file`. If `doraise` is true, a `PyCompileError` is raised when an error is encountered while compiling `file`. If `doraise` is false (the default), an error string is written to `sys.stderr`, but no exception is raised. This function returns the path to byte-compiled file, i.e. whatever `cfilee` value was used.

The `doraise` and `quiet` arguments determine how errors are handled while compiling file. If `quiet` is 0 or 1, and `doraise` is false, the default behaviour is enabled: an error string is written to `sys.stderr`, and the function returns `None` instead of a path. If `doraise` is true, a `PyCompileError` is raised instead. However if `quiet` is 2, no message is written, and `doraise` has no effect.

If the path that `cfilee` becomes (either explicitly specified or computed) is a symlink or non-regular file, `FileExistsError` will be raised. This is to act as a warning that import will turn those paths into regular files if it is allowed to write byte-compiled files to those paths. This is a side-effect of import using file renaming to place the final byte-compiled file into place to prevent concurrent file writing issues.

`optimize` controls the optimization level and is passed to the built-in `compile()` function. The default of -1 selects the optimization level of the current interpreter.

`invalidation_mode` should be a member of the `PycInvalidationMode` enum and controls how the generated bytecode cache is invalidated at runtime. The default is `PycInvalidationMode.CHECKED_HASH` if the `SOURCE_DATE_EPOCH` environment variable is set, otherwise the default is `PycInvalidationMode.TIMESTAMP`.

Changed in version 3.2: Changed default value of `cfilee` to be PEP 3147-compliant. Previous default was `file + 'c'` (`'o'` if optimization was enabled). Also added the `optimize` parameter.

Changed in version 3.4: Changed code to use `importlib` for the byte-code cache file writing. This means file creation/writing semantics now match what `importlib` does, e.g. permissions, write-and-move semantics, etc. Also added the caveat that `FileExistsError` is raised if `cfilee` is a symlink or non-regular file.

Changed in version 3.7: The `invalidation_mode` parameter was added as specified in PEP 552. If the `SOURCE_DATE_EPOCH` environment variable is set, `invalidation_mode` will be forced to `PycInvalidationMode.CHECKED_HASH`.

---

**32.8. `py_compile` — Compile Python source files** 1829
class py_compile.PycInvalidationMode

A enumeration of possible methods the interpreter can use to determine whether a bytecode file is up to date with a source file. The .pyc file indicates the desired invalidation mode in its header. See pyc-invalidation for more information on how Python invalidates .pyc files at runtime.

New in version 3.7.

TIMESTAMP

The .pyc file includes the timestamp and size of the source file, which Python will compare against the metadata of the source file at runtime to determine if the .pyc file needs to be regenerated.

CHECKED_HASH

The .pyc file includes a hash of the source file content, which Python will compare against the source at runtime to determine if the .pyc file needs to be regenerated.

UNCHECKED_HASH

Like CHECKED_HASH, the .pyc file includes a hash of the source file content. However, Python will at runtime assume the .pyc file is up to date and not validate the .pyc against the source file at all.

This option is useful when the .pycs are kept up to date by some system external to Python like a build system.

32.8.1 Command-Line Interface

This module can be invoked as a script to compile several source files. The files named in filenames are compiled and the resulting bytecode is cached in the normal manner. This program does not search a directory structure to locate source files; it only compiles files named explicitly. The exit status is nonzero if one of the files could not be compiled.

32.9 compileall — Byte-compile Python libraries

Source code: Lib/compileall.py

This module provides some utility functions to support installing Python libraries. These functions compile Python source files in a directory tree. This module can be used to create the cached byte-code files at library installation time, which makes them available for use even by users who don’t have write permission to the library directories.
32.9.1 Command-line use

This module can work as a script (using `python -m compileall`) to compile Python sources.

directory ...
file ...

Positional arguments are files to compile or directories that contain source files, traversed recursively. If no argument is given, behave as if the command line was -l <directories from sys.path>.

-1

Do not recurse into subdirectories, only compile source code files directly contained in the named or implied directories.

-f

Force rebuild even if timestamps are up-to-date.

-q

Do not print the list of files compiled. If passed once, error messages will still be printed. If passed twice (-qq), all output is suppressed.

-d destdir

Directory prepended to the path to each file being compiled. This will appear in compilation time tracebacks, and is also compiled into the byte-code file, where it will be used in tracebacks and other messages in cases where the source file does not exist at the time the byte-code file is executed.

-s strip_prefix

-p prepend_prefix

Remove (-s) or append (-p) the given prefix of paths recorded in the .pyc files. Cannot be combined with -d.

-x regex

regex is used to search the full path to each file considered for compilation, and if the regex produces a match, the file is skipped.

-i list

Read the file list and add each line that it contains to the list of files and directories to compile. If list is -, read lines from stdin.

-b

Write the byte-code files to their legacy locations and names, which may overwrite byte-code files created by another version of Python. The default is to write files to their PEP 3147 locations and names, which allows byte-code files from multiple versions of Python to coexist.

-r

Control the maximum recursion level for subdirectories. If this is given, then -l option will not be taken into account. `python -m compileall <directory> -r 0` is equivalent to `python -m compileall <directory> -l`.

-j N

Use N workers to compile the files within the given directory. If 0 is used, then the result of `os.cpu_count()` will be used.

--invalidation-mode [timestamp|checked-hash|unchecked-hash]

Control how the generated byte-code files are invalidated at runtime. The timestamp value, means that .pyc files with the source timestamp and size embedded will be generated. The checked-hash and unchecked-hash values cause hash-based pycs to be generated. Hash-based pycs embed a hash of the source file contents rather than a timestamp. See pyc-invalidation for more information on how Python validates bytecode cache files at runtime. The default is timestamp if the SOURCE_DATE_EPOCH environment variable is not set, and checked-hash if the SOURCE_DATE_EPOCH environment variable is set.

-o level

Compile with the given optimization level. May be used multiple times to compile for multiple levels at a time (for example, compileall -o 1 -o 2).
**--dir**

Ignores symlinks pointing outside the given directory.

**--hardlink-dupes**

If two .pyc files with different optimization level have the same content, use hard links to consolidate duplicate files.

Changed in version 3.2: Added the -i, -b and -h options.

Changed in version 3.5: Added the -j, -r, and -q options. -q option was changed to a multilevel value. -b will always produce a byte-code file ending in .pyc, never .pyo.

Changed in version 3.5: Added the --hardlink-dupes option.

Changed in version 3.7: Added the --invalidation-mode option.

There is no command-line option to control the optimization level used by the compile() function, because the Python interpreter itself already provides the option: `python -O -m compileall`.

Similarly, the compile() function respects the sys.pycache_prefix setting. The generated bytecode cache will only be useful if compile() is run with the same sys.pycache_prefix (if any) that will be used at runtime.

### 32.9.2 Public functions

**compileall.compile_dir** (dir, maxlevels=sys.getrecursionlimit(), ddir=None, force=False, rx=None, quiet=0, legacy=False, optimize=-1, workers=1, invalidation_mode=None, *, stripdir=None, prependdir=None, limit_sl_dest=None, hardlink_dupes=False)

Recursively descend the directory tree named by dir, compiling all .py files along the way. Return a true value if all the files compiled successfully, and a false value otherwise.

The maxlevels parameter is used to limit the depth of the recursion; it defaults to sys.getrecursionlimit().

If ddir is given, it is prepended to the path to each file being compiled for use in compilation time tracebacks, and is also compiled in to the byte-code file, where it will be used in tracebacks and other messages in cases where the source file does not exist at the time the byte-code file is executed.

If force is true, modules are re-compiled even if the timestamps are up to date.

If rx is given, its search method is called on the complete path to each file considered for compilation, and if it returns a true value, the file is skipped. This can be used to exclude files matching a regular expression, given as a re.Pattern object.

If quiet is False or 0 (the default), the filenames and other information are printed to standard out. Set to 1, only errors are printed. Set to 2, all output is suppressed.

If legacy is true, byte-code files are written to their legacy locations and names, which may overwrite byte-code files created by another version of Python. The default is to write files to their PEP 3147 locations and names, which allows byte-code files from multiple versions of Python to coexist.

optimize specifies the optimization level for the compiler. It is passed to the built-in compile() function. Accepts also a sequence of optimization levels which lead to multiple compilations of one .py file in one call.

The argument workers specifies how many workers are used to compile files in parallel. The default is to not use multiple workers. If the platform can’t use multiple workers and workers argument is given, then sequential compilation will be used as a fallback. If workers is 0, the number of cores in the system is used. If workers is lower than 0, a ValueError will be raised.

invalidation_mode should be a member of the py_compile.PycInvalidationMode enum and controls how the generated pycs are invalidated at runtime.

The stripdir, prependdir and limit_sl_dest arguments correspond to the -s, -p and -e options described above. They may be specified as str, bytes or os.PathLike.
If `hardlink_dupes` is true and two `.pyc` files with different optimization level have the same content, use hard links to consolidate duplicate files.

Changed in version 3.2: Added the `legacy` and `optimize` parameter.

Changed in version 3.5: Added the `workers` parameter.

Changed in version 3.5: `quiet` parameter was changed to a multilevel value.

Changed in version 3.5: The `legacy` parameter only writes out `.pyc` files, not `.pyo` files no matter what the value of `optimize` is.

Changed in version 3.6: Accepts a `path-like object`.

Changed in version 3.7: The `invalidation_mode` parameter was added.

Changed in version 3.7.2: The `invalidation_mode` parameter’s default value is updated to `None`.

Changed in version 3.8: Setting `workers` to 0 now chooses the optimal number of cores.

Changed in version 3.9: Added `stripdir`, `prependdir`, `limit_sl_dest` and `hardlink_dupes` arguments. Default value of `maxlevels` was changed from 10 to `sys.getrecursionlimit()`.

```python
compileall.compile_file(fullname, ddir=None, force=False, rx=None, quiet=0, legacy=False, optimize=-1, invalidation_mode=None, *, stripdir=None, prependdir=None, limit_sl_dest=None, hardlink_dupes=False)
```

Compile the file with path `fullname`. Return a true value if the file compiled successfully, and a false value otherwise.

If `ddir` is given, it is prepended to the path to the file being compiled for use in compilation time tracebacks, and is also compiled in to the byte-code file, where it will be used in tracebacks and other messages in cases where the source file does not exist at the time the byte-code file is executed.

If `rx` is given, its `search` method is passed the full path name to the file being compiled, and if it returns a true value, the file is not compiled and `True` is returned. This can be used to exclude files matching a regular expression, given as a `re.Pattern` object.

If `quiet` is `False` or 0 (the default), the filenames and other information are printed to standard out. Set to 1, only errors are printed. Set to 2, all output is suppressed.

If `legacy` is true, byte-code files are written to their legacy locations and names, which may overwrite byte-code files created by another version of Python. The default is to write files to their PEP 3147 locations and names, which allows byte-code files from multiple versions of Python to coexist.

`optimize` specifies the optimization level for the compiler. It is passed to the built-in `compile()` function. Accepts also a sequence of optimization levels which lead to multiple compilations of one `.py` file in one call.

`invalidation_mode` should be a member of the `py_compile.PycInvalidationMode` enum and controls how the generated pycs are invalidated at runtime.

The `stripdir`, `prependdir` and `limit_sl_dest` arguments correspond to the `-s`, `-p` and `-e` options described above. They may be specified as `str`, `bytes` or `os.PathLike`.

If `hardlink_dupes` is true and two `.pyc` files with different optimization level have the same content, use hard links to consolidate duplicate files.

New in version 3.2.

Changed in version 3.5: `quiet` parameter was changed to a multilevel value.

Changed in version 3.5: The `legacy` parameter only writes out `.pyc` files, not `.pyo` files no matter what the value of `optimize` is.

Changed in version 3.7: The `invalidation_mode` parameter was added.

Changed in version 3.7.2: The `invalidation_mode` parameter’s default value is updated to `None`.

Changed in version 3.9: Added `stripdir`, `prependdir`, `limit_sl_dest` and `hardlink_dupes` arguments.
The compiled modules support the analysis of CPython bytecode by disassembling it. The CPython bytecode which this module takes as an input is defined in the file include/opcode.h and used by the compiler and the interpreter.

**CPython implementation detail:** Bytecode is an implementation detail of the CPython interpreter. No guarantees are made that bytecode will not be added, removed, or changed between versions of Python. Use of this module should not be considered to work across Python VMs or Python releases.

Changed in version 3.6: Use 2 bytes for each instruction. Previously the number of bytes varied by instruction.

Example: Given the function `myfunc()`:

```python
def myfunc(alist):
    return len(alist)
```

the following command can be used to display the disassembly of `myfunc()`:

```bash
>>> dis.dis(myfunc)
2 0 LOAD_GLOBAL    0 (len)
 2 LOAD_FAST       0 (alist)
 4 CALL_FUNCTION  1
 6 RETURN_VALUE
```
The bytecode analysis API allows pieces of Python code to be wrapped in a `Bytecode` object that provides easy access to details of the compiled code.

```python
class dis.Bytecode(x, *, first_line=None, current_offset=None)
```

Analyse the bytecode corresponding to a function, generator, asynchronous generator, coroutine, method, string of source code, or a code object (as returned by `compile()`).

This is a convenience wrapper around many of the functions listed below, most notably `get_instructions()`, as iterating over a `Bytecode` instance yields the bytecode operations as `Instruction` instances.

If `first_line` is not `None`, it indicates the line number that should be reported for the first source line in the disassembled code. Otherwise, the source line information (if any) is taken directly from the disassembled code object.

If `current_offset` is not `None`, it refers to an instruction offset in the disassembled code. Setting this means `dis()` will display a "current instruction" marker against the specified opcode.

```python
classmethod from_traceback(tb)
```

Construct a `Bytecode` instance from the given traceback, setting `current_offset` to the instruction responsible for the exception.

```python
codeobj
```  
The compiled code object.

```python
first_line
```  
The first source line of the code object (if available)

```python
dis()
```  
Return a formatted view of the bytecode operations (the same as printed by `dis.dis()`, but returned as a multi-line string).

```python
info()
```  
Return a formatted multi-line string with detailed information about the code object, like `code_info()`.

```
>>> bytecode = dis.Bytecode(myfunc)
>>> for instr in bytecode:
...     print(instr.opname)
...LOAD_GLOBAL
LOAD_FAST
CALL_FUNCTION
RETURN_VALUE
```

Example:

32.10.1 Bytecode analysis

New in version 3.4.

Changed in version 3.7: This can now handle coroutine and asynchronous generator objects.
32.10.2 Analysis functions

The `dis` module also defines the following analysis functions that convert the input directly to the desired output. They can be useful if only a single operation is being performed, so the intermediate analysis object isn’t useful:

```python
def code_info(x):
    """Return a formatted multi-line string with detailed code object information for the supplied function, generator, asynchronous generator, coroutine, method, source code string or code object.
    """
    # Detailed code for code_info function...

    # New in version 3.2.
    # Changed in version 3.7: This can now handle coroutine and asynchronous generator objects.
```

```python
def show_code(x, file=None):
    """Print detailed code object information for the supplied function, method, source code string or code object to file (or sys.stdout if file is not specified).
    """
    # Detailed code for show_code function...

    # New in version 3.2.
    # Changed in version 3.4: Added file parameter.
```

```python
def dis(x=None, *, file=None, depth=None):
    """Disassemble the x object. x can denote either a module, a class, a function, a generator, an asynchronous generator, a coroutine, a code object, a string of source code or a byte sequence of raw bytecode. For a module, it disassembles all functions. For a class, it disassembles all methods (including class and static methods). For a code object or sequence of raw bytecode, it prints one line per bytecode instruction. It also recursively disassembles nested code objects (the code of comprehensions, generator expressions and nested functions, and the code used for building nested classes). Strings are first compiled to code objects with the compile() built-in function before being disassembled. If no object is provided, this function disassembles the last traceback.
    """
    # Detailed code for dis function...

    # The disassembly is written as text to the supplied file argument if provided and to sys.stdout otherwise.
    # The maximal depth of recursion is limited by depth unless it is None. depth=0 means no recursion.
    # Changed in version 3.4: Added file parameter.
    # Changed in version 3.7: Implemented recursive disassembling and added depth parameter.
```

```python
def distb(tb=None, *, file=None):
    """Disassemble the top-of-stack function of a traceback, using the last traceback if none was passed. The instruction causing the exception is indicated.
    """
    # Detailed code for distb function...

    # Changed in version 3.4: Added file parameter.
```

```python
def disassemble(code, lasti=-1, *, file=None)
    """Disassemble a code object, indicating the last instruction if lasti was provided. The output is divided in the following columns:
    """
    # Detailed code for disassemble function...
```

```python
def disco(code, lasti=-1, *, file=None)
    """Disassemble a code object, indicating the last instruction if lasti was provided. The output is divided in the following columns:
    """
    # Detailed code for disco function...
```

Chapter 32. Python Language Services
6. operation parameters, and
7. interpretation of the parameters in parentheses.

The parameter interpretation recognizes local and global variable names, constant values, branch targets, and compare operators.

The disassembly is written as text to the supplied file argument if provided and to sys.stdout otherwise.

Changed in version 3.4: Added file parameter.

```
6.
7.
```

### The `dis.get_instructions()` Function

Return an iterator over the instructions in the supplied function, method, source code string or code object.

The iterator generates a series of `Instruction` named tuples giving the details of each operation in the supplied code.

If `first_line` is not `None`, it indicates the line number that should be reported for the first source line in the disassembled code. Otherwise, the source line information (if any) is taken directly from the disassembled code object.

New in version 3.4.

```
6.
7.
```

### The `dis.findlinestarts()` Function

This generator function uses the `co_firstlineno` and `co_lnotab` attributes of the code object `code` to find the offsets which are starts of lines in the source code. They are generated as `(offset, lineno)` pairs. See `Objects/lnotab_notes.txt` for the `co_lnotab` format and how to decode it.

Changed in version 3.6: Line numbers can be decreasing. Before, they were always increasing.

```
6.
7.
```

### The `dis.findlabels()` Function

Detect all offsets in the raw compiled bytecode string `code` which are jump targets, and return a list of these offsets.

```
6.
7.
```

### The `dis.stack_effect()` Function

Compute the stack effect of `opcode` with argument `oparg`.

If the code has a jump target and `jump` is `True`, `stack_effect()` will return the stack effect of jumping. If `jump` is `False`, it will return the stack effect of not jumping. And if `jump` is `None` (default), it will return the maximal stack effect of both cases.

New in version 3.4.

Changed in version 3.8: Added `jump` parameter.

### 32.10.3 Python Bytecode Instructions

The `get_instructions()` function and `Bytecode` class provide details of bytecode instructions as `Instruction` instances:

```
6.
7.
```

```python
class dis.Instruction:
    Details for a bytecode operation
    
    opcode
        numeric code for operation, corresponding to the opcode values listed below and the bytecode values in the Opcode collections.

    opname
        human readable name for operation

    arg
        numeric argument to operation (if any), otherwise None

    argval
        resolved arg value (if known), otherwise same as arg

    argrepr
        human readable description of operation argument
```
offset
start index of operation within bytecode sequence

starts_line
line started by this opcode (if any), otherwise None

is_jump_target
True if other code jumps to here, otherwise False

New in version 3.4.

The Python compiler currently generates the following bytecode instructions.

General instructions

NOP
Do nothing code. Used as a placeholder by the bytecode optimizer.

POP_TOP
Removes the top-of-stack (TOS) item.

ROT_TWO
Swaps the two top-most stack items.

ROT_THREE
Lifts second and third stack item one position up, moves top down to position three.

ROT_FOUR
Lifts second, third and fourth stack items one position up, moves top down to position four.

New in version 3.8.

DUP_TOP
Duplicates the reference on top of the stack.

New in version 3.2.

DUP_TOP_TWO
Duplicates the two references on top of the stack, leaving them in the same order.

New in version 3.2.

Unary operations

Unary operations take the top of the stack, apply the operation, and push the result back on the stack.

UNARY_POSITIVE
Implements \( TOS = +TOS \).

UNARY_NEGATIVE
Implements \( TOS = -TOS \).

UNARY_NOT
Implements \( TOS = \text{not } TOS \).

UNARY_INVERT
Implements \( TOS = \sim TOS \).

GET_ITER
Implements \( TOS = \text{iter}(TOS) \).

GET_YIELD_FROM_ITER
If \( TOS \) is a generator iterator or coroutine object it is left as is. Otherwise, implements \( TOS = \text{iter}(TOS) \).

New in version 3.5.

Binary operations

Binary operations remove the top of the stack (TOS) and the second top-most stack item (TOS1) from the stack. They perform the operation, and put the result back on the stack.
The Python Library Reference, Release 3.10.4

**BINARY_POWER**
Implements \( \text{TOS} = \text{TOS1}^{\ast} \text{TOS}. \)

**BINARY_MULTIPLY**
Implements \( \text{TOS} = \text{TOS1} \ast \text{TOS}. \)

**BINARY_MATRIX_MULTIPLY**
Implements \( \text{TOS} = \text{TOS1} @ \text{TOS}. \)
New in version 3.5.

**BINARY_FLOOR_DIVIDE**
Implements \( \text{TOS} = \text{TOS1} \div \text{TOS}. \)

**BINARY_TRUE_DIVIDE**
Implements \( \text{TOS} = \text{TOS1} / \text{TOS}. \)

**BINARY_MODULO**
Implements \( \text{TOS} = \text{TOS1} \% \text{TOS}. \)

**BINARY_ADD**
Implements \( \text{TOS} = \text{TOS1} + \text{TOS}. \)

**BINARY_SUBTRACT**
Implements \( \text{TOS} = \text{TOS1} - \text{TOS}. \)

**BINARY_SUBSCR**
Implements \( \text{TOS} = \text{TOS1}[\text{TOS}]. \)

**BINARY_LSHIFT**
Implements \( \text{TOS} = \text{TOS1} << \text{TOS}. \)

**BINARY_RSHIFT**
Implements \( \text{TOS} = \text{TOS1} >> \text{TOS}. \)

**BINARY_AND**
Implements \( \text{TOS} = \text{TOS1} \& \text{TOS}. \)

**BINARY_XOR**
Implements \( \text{TOS} = \text{TOS1} ^ \text{TOS}. \)

**BINARY_OR**
Implements \( \text{TOS} = \text{TOS1} | \text{TOS}. \)

In-place operations

In-place operations are like binary operations, in that they remove TOS and TOS1, and push the result back on the stack, but the operation is done in-place when TOS1 supports it, and the resulting TOS may be (but does not have to be) the original TOS1.

**INPLACE_POWER**
Implements in-place \( \text{TOS} = \text{TOS1}^{\ast} \text{TOS}. \)

**INPLACE_MULTIPLY**
Implements in-place \( \text{TOS} = \text{TOS1} \ast \text{TOS}. \)

**INPLACE_MATRIX_MULTIPLY**
Implements in-place \( \text{TOS} = \text{TOS1} @ \text{TOS}. \)
New in version 3.5.

**INPLACE_FLOOR_DIVIDE**
Implements in-place \( \text{TOS} = \text{TOS1} \div \text{TOS}. \)

**INPLACE_TRUE_DIVIDE**
Implements in-place \( \text{TOS} = \text{TOS1} / \text{TOS}. \)

**INPLACE_MODULO**
Implements in-place \( \text{TOS} = \text{TOS1} \% \text{TOS}. \)
INPLACE_ADD
  Implements in-place \( \text{TOS} = \text{TOS1} + \text{TOS} \).

INPLACE_SUBTRACT
  Implements in-place \( \text{TOS} = \text{TOS1} - \text{TOS} \).

INPLACE_LSHIFT
  Implements in-place \( \text{TOS} = \text{TOS1} \ll \text{TOS} \).

INPLACE_RSHIFT
  Implements in-place \( \text{TOS} = \text{TOS1} \gg \text{TOS} \).

INPLACE_AND
  Implements in-place \( \text{TOS} = \text{TOS1} \& \text{TOS} \).

INPLACE_XOR
  Implements in-place \( \text{TOS} = \text{TOS1} ^ \text{TOS} \).

INPLACE_OR
  Implements in-place \( \text{TOS} = \text{TOS1} \mid \text{TOS} \).

STORE_SUBSCR
  Implements \( \text{TOS1}[\text{TOS}] = \text{TOS2} \).

DELETE_SUBSCR
  Implements del \( \text{TOS1}[\text{TOS}] \).

Coroutine opcodes

GET_AWAITABLE
  Implements \( \text{TOS} = \text{get\_awaitable(TOS)} \), where \( \text{get\_awaitable(o)} \) returns \( o \) if \( o \) is a coroutine object or a generator object with the CO ITERABLE_COROUTINE flag, or resolves \( o.__await__ \).
  New in version 3.5.

GET_AITER
  Implements \( \text{TOS} = \text{TOS1}.\_aiter\_() \).
  New in version 3.5.
  Changed in version 3.6: Returning awaitable objects from \_aiter\_ is no longer supported.

GET_ANEXT
  Implements \( \text{PUSH(get\_awaitable(TOS1).\_anext\_()))} \). See GET_AWAITABLE for details about get\_awaitable
  New in version 3.5.

END_ASYNC_FOR
  Terminates an async for loop. Handles an exception raised when awaiting a next item. If TOS is StopAsyncIteration pop 7 values from the stack and restore the exception state using the second three of them. Otherwise re-raise the exception using the three values from the stack. An exception handler block is removed from the block stack.
  New in version 3.8.

BEFORE_ASYNC_WITH
  Resolves \_aenter\_ and \_aexit\_ from the object on top of the stack. Pushes \_aexit\_ and result of \_aenter\_() to the stack.
  New in version 3.5.

SETUP_ASYNC_WITH
  Creates a new frame object.
  New in version 3.5.

Miscellaneous opcodes
PRINT_EXPR
Implements the expression statement for the interactive mode. TOS is removed from the stack and printed. In non-interactive mode, an expression statement is terminated with POP_TOP.

SET_ADD (i)
Calls set.add(TOS1[-i], TOS). Used to implement set comprehensions.

LIST_APPEND (i)
Calls list.append(TOS1[-i], TOS). Used to implement list comprehensions.

MAP_ADD (i)
Calls dict.__setitem__(TOS1[-i], TOS1, TOS). Used to implement dict comprehensions.

New in version 3.1.
Changed in version 3.8: Map value is TOS and map key is TOS1. Before, those were reversed.

For all of the SET_ADD, LIST_APPEND and MAP_ADD instructions, while the added value or key/value pair is popped off, the container object remains on the stack so that it is available for further iterations of the loop.

RETURN_VALUE
Returns with TOS to the caller of the function.

YIELD_VALUE
Pops TOS and yields it from a generator.

YIELD_FROM
Pops TOS and delegates to it as a subiterator from a generator.

New in version 3.3.

SETUP_ANNOTATIONS
Checks whether __annotations__ is defined in locals(), if not it is set up to an empty dict. This opcode is only emitted if a class or module body contains variable annotations statically.

New in version 3.6.

IMPORT_STAR
Loads all symbols not starting with ‘_’ directly from the module TOS to the local namespace. The module is popped after loading all names. This opcode implements from module import *.

POP_BLOCK
Removes one block from the block stack. Per frame, there is a stack of blocks, denoting try statements, and such.

POP_EXCEPT
Removes one block from the block stack. The popped block must be an exception handler block, as implicitly created when entering an except handler. In addition to popping extraneous values from the frame stack, the last three popped values are used to restore the exception state.

RE_RAISE
Re-raises the exception currently on top of the stack. If oparg is non-zero, restores f_lasti of the current frame to its value when the exception was raised.

New in version 3.9.

WITH_EXCEPT_START
Calls the function in position 7 on the stack with the top three items on the stack as arguments. Used to implement the call context_manager.__exit__(*exc_info()) when an exception has occurred in a with statement.

New in version 3.9.

LOAD_ASSERTION_ERROR
Pushes AssertionError onto the stack. Used by the assert statement.

New in version 3.9.
LOAD_BUILD_CLASS
Pushes `builtins.__build_class__()` onto the stack. It is later called by CALL_FUNCTION to construct a class.

SETUP_WITH (delta)
This opcode performs several operations before a with block starts. First, it loads `__exit__()` from the context manager and pushes it onto the stack for later use by WITH_EXCEPTION_START. Then, `__enter__()` is called, and a finally block pointing to `delta` is pushed. Finally, the result of calling the `__enter__()` method is pushed onto the stack. The next opcode will either ignore it (POP_TOP), or store it in (a) variable(s) (STORE_FAST, STORE_NAME, or UNPACK_SEQUENCE).

New in version 3.2.

COPY_DICT_WITHOUT_KEYS
TOS is a tuple of mapping keys, and TOS1 is the match subject. Replace TOS with a dict formed from the items of TOS1, but without any of the keys in TOS.

New in version 3.10.

GET_LEN
Push `len(TOS)` onto the stack.

New in version 3.10.

MATCH_MAPPING
If TOS is an instance of collections.abc.Mapping (or, more technically: if it has the Py_TPFLAGS_MAPPING flag set in its tp_flags), push True onto the stack. Otherwise, push False.

New in version 3.10.

MATCH_SEQUENCE
If TOS is an instance of collections.abc.Sequence and is not an instance of str/bytes/bytearray (or, more technically: if it has the Py_TPFLAGS_SEQUENCE flag set in its tp_flags), push True onto the stack. Otherwise, push False.

New in version 3.10.

MATCH_KEYS
TOS is a tuple of mapping keys, and TOS1 is the match subject. If TOS1 contains all of the keys in TOS, push a tuple containing the corresponding values, followed by True. Otherwise, push None, followed by False.

New in version 3.10.

All of the following opcodes use their arguments.

STORE_NAME (namei)
Implements `name = TOS`. namei is the index of name in the attribute co_names of the code object. The compiler tries to use STORE_FAST or STORE_GLOBAL if possible.

DELETE_NAME (namei)
Implements del name, where namei is the index into co_names attribute of the code object.

UNPACK_SEQUENCE (count)
Unpacks TOS into count individual values, which are put onto the stack right-to-left.

UNPACK_EX (counts)
Implements assignment with a starred target: Unpacks an iterable in TOS into individual values, where the total number of values can be smaller than the number of items in the iterable: one of the new values will be a list of all leftover items.

The low byte of counts is the number of values before the list value, the high byte of counts the number of values after it. The resulting values are put onto the stack right-to-left.

STORE_ATTR (namei)
Implements `TOS.name = TOS1`, where namei is the index of name in co_names.
DELETE_ATTR (namei)
- Implements `del TOS.name`, using `namei` as index into `co_names`.

STORE_GLOBAL (namei)
- Works as `STORE_NAME`, but stores the name as a global.

DELETE_GLOBAL (namei)
- Works as `DELETE_NAME`, but deletes a global name.

LOAD_CONST (consti)
- Pushes `co_consts[consti]` onto the stack.

LOAD_NAME (namei)
- Pushes the value associated with `co_names[namei]` onto the stack.

BUILD_TUPLE (count)
- Creates a tuple consuming `count` items from the stack, and pushes the resulting tuple onto the stack.

BUILD_LIST (count)
- Works as `BUILD_TUPLE`, but creates a list.

BUILD_SET (count)
- Works as `BUILD_TUPLE`, but creates a set.

BUILD_MAP (count)
- Pushes a new dictionary object onto the stack. Pops `2 * count` items so that the dictionary holds `count` entries: `{..., TOS3: TOS2, TOS1: TOS}`.
- Changed in version 3.5: The dictionary is created from stack items instead of creating an empty dictionary pre-sized to hold `count` items.

BUILD_CONST_KEY_MAP (count)
- The version of `BUILD_MAP` specialized for constant keys. Pops the top element on the stack which contains a tuple of keys, then starting from TOS1, pops `count` values to form values in the built dictionary.
- New in version 3.6.

BUILD_STRING (count)
- Concatenates `count` strings from the stack and pushes the resulting string onto the stack.
- New in version 3.6.

LIST_TO_TUPLE
- Pops a list from the stack and pushes a tuple containing the same values.
- New in version 3.9.

LIST_EXTEND (i)
- Calls `list.extend(TOS1[-i], TOS)`. Used to build lists.
- New in version 3.9.

SET_UPDATE (i)
- Calls `set.update(TOS1[-i], TOS)`. Used to build sets.
- New in version 3.9.

DICT_UPDATE (i)
- Calls `dict.update(TOS1[-i], TOS)`. Used to build dicts.
- New in version 3.9.

DICT_MERGE
- Like `DICT_UPDATE` but raises an exception for duplicate keys.
- New in version 3.9.

LOAD_ATTR (namei)
- Replaces TOS with `getattr(TOS, co_names[namei])`. 

32.10. dis — Disassembler for Python bytecode
**COMPARE_OP** *(opname)*

Performs a Boolean operation. The operation name can be found in `cmp_op[opname]`.

**IS_OP** *(invert)*

Performs *is* comparison, or *is not* if `invert` is 1.

New in version 3.9.

**CONTAINS_OP** *(invert)*

Performs *in* comparison, or *not in* if `invert` is 1.

New in version 3.9.

**IMPORT_NAME** *(namei)*

Imports the module `co_names[namei]`. TOS and TOS1 are popped and provide the `fromlist` and `level` arguments of `__import__()`. The module object is pushed onto the stack. The current namespace is not affected: for a proper import statement, a subsequent `STORE_FAST` instruction modifies the namespace.

**IMPORT_FROM** *(namei)*

Loads the attribute `co_names[namei]` from the module found in TOS. The resulting object is pushed onto the stack, to be subsequently stored by a `STORE_FAST` instruction.

**JUMP_FORWARD** *(delta)*

Increments bytecode counter by `delta`.

**POP_JUMP_IF_TRUE** *(target)*

If TOS is true, sets the bytecode counter to `target`. TOS is popped.

New in version 3.1.

**POP_JUMP_IF_FALSE** *(target)*

If TOS is false, sets the bytecode counter to `target`. TOS is popped.

New in version 3.1.

**JUMP_IF_NOT_EXC_MATCH** *(target)*

Tests whether the second value on the stack is an exception matching TOS, and jumps if it is not. Pops two values from the stack.

New in version 3.9.

**JUMP_IF_TRUE_OR_POP** *(target)*

If TOS is true, sets the bytecode counter to `target` and leaves TOS on the stack. Otherwise (TOS is false), TOS is popped.

New in version 3.1.

**JUMP_IF_FALSE_OR_POP** *(target)*

If TOS is false, sets the bytecode counter to `target` and leaves TOS on the stack. Otherwise (TOS is true), TOS is popped.

New in version 3.1.

**JUMP_ABSOLUTE** *(target)*

Set bytecode counter to `target`.

**FOR_ITER** *(delta)*

TOS is an *iterator*. Call its `__next__() method. If this yields a new value, push it on the stack (leaving the iterator below it). If the iterator indicates it is exhausted, TOS is popped, and the byte code counter is incremented by `delta`.

**LOAD_GLOBAL** *(namei)*

Loads the global named `co_names[namei]` onto the stack.

**SETUP_FINALLY** *(delta)*

Pushes a try block from a try-finally or try-except clause onto the block stack. `delta` points to the finally block or the first except block.
LOAD_FAST (var_num)
Pushes a reference to the local co_varnames[var_num] onto the stack.

STORE_FAST (var_num)
Stores TOS into the local co_varnames[var_num].

DELETE_FAST (var_num)
Deletes local co_varnames[var_num].

LOAD_CLOSURE (i)
Pushes a reference to the cell contained in slot i of the cell and free variable storage. The name of the variable is co_cellvars[i] if i is less than the length of co_cellvars. Otherwise it is co_freevars[i - len(co_cellvars)].

LOAD_DEREF (i)
Loads the cell contained in slot i of the cell and free variable storage. Pushes a reference to the object the cell contains on the stack.

LOAD_CLASSDEREF (i)
Much like LOAD_DEREF but first checks the locals dictionary before consulting the cell. This is used for loading free variables in class bodies.
New in version 3.4.

STORE_DEREF (i)
Stores TOS into the cell contained in slot i of the cell and free variable storage.

DELETE_DEREF (i)
Empties the cell contained in slot i of the cell and free variable storage. Used by the del statement.
New in version 3.2.

RAISE_VARARGS (argc)
Raises an exception using one of the 3 forms of the raise statement, depending on the value of argc:
• 0: raise (re-raise previous exception)
• 1: raise TOS (raise exception instance or type at TOS)
• 2: raise TOS1 from TOS (raise exception instance or type at TOS1 with __cause__ set to TOS)

CALL_FUNCTION (argc)
Calls a callable object with positional arguments. argc indicates the number of positional arguments. The top of the stack contains positional arguments, with the right-most argument on top. Below the arguments is a callable object to call. CALL_FUNCTION pops all arguments and the callable object off the stack, calls the callable object with those arguments, and pushes the return value returned by the callable object.

Changed in version 3.6: This opcode is used only for calls with positional arguments.

CALL_FUNCTION_KW (argc)
Calls a callable object with positional (if any) and keyword arguments. argc indicates the total number of positional and keyword arguments. The top element on the stack contains a tuple with the names of the keyword arguments, which must be strings. Below that are the values for the keyword arguments, in the order corresponding to the tuple. Below that are positional arguments, with the right-most parameter on top. Below the arguments is a callable object to call. CALL_FUNCTION_KW pops all arguments and the callable object off the stack, calls the callable object with those arguments, and pushes the return value returned by the callable object.

Changed in version 3.6: Keyword arguments are packed in a tuple instead of a dictionary, argc indicates the total number of arguments.

CALL_FUNCTION_EX (flags)
Calls a callable object with variable set of positional and keyword arguments. If the lowest bit of flags is set, the top of the stack contains a mapping object containing additional keyword arguments. Before the callable is called, the mapping object and iterable object are each “unpacked” and their contents passed in as keyword and positional arguments respectively. CALL_FUNCTION_EX pops all arguments and the callable object off
the stack, calls the callable object with those arguments, and pushes the return value returned by the callable object.

New in version 3.6.

**LOAD_METHOD** *(namei)*

Loads a method named `co_names[namei]` from the TOS object. TOS is popped. This bytecode distinguishes two cases: if TOS has a method with the correct name, the bytecode pushes the unbound method and TOS. TOS will be used as the first argument *(self)* by `CALL_METHOD` when calling the unbound method. Otherwise, NULL and the object return by the attribute lookup are pushed.

New in version 3.7.

**CALL_METHOD** *(argc)*

Calls a method. *argc* is the number of positional arguments. Keyword arguments are not supported. This opcode is designed to be used with `LOAD_METHOD`. Positional arguments are on top of the stack. Below them, the two items described in `LOAD_METHOD` are on the stack (either *self* and an unbound method object or NULL and an arbitrary callable). All of them are popped and the return value is pushed.

New in version 3.7.

**MAKE_FUNCTION** *(flags)*

Pushes a new function object on the stack. From bottom to top, the consumed stack must consist of values if the argument carries a specified flag value

- 0x01 a tuple of default values for positional-only and positional-or-keyword parameters in positional order
- 0x02 a dictionary of keyword-only parameters’ default values
- 0x04 a tuple of strings containing parameters’ annotations
- 0x08 a tuple containing cells for free variables, making a closure
- the code associated with the function (at TOS1)
- the qualified name of the function (at TOS)

Changed in version 3.10: Flag value 0x04 is a tuple of strings instead of dictionary

**BUILD_SLICE** *(argc)*

Pushes a slice object on the stack. *argc* must be 2 or 3. If it is 2, `slice(TOS1, TOS)` is pushed; if it is 3, `slice(TOS2, TOS1, TOS)` is pushed. See the `slice()` built-in function for more information.

**EXTENDED_ARG** *(ext)*

Prefixes any opcode which has an argument too big to fit into the default one byte. *ext* holds an additional byte which act as higher bits in the argument. For each opcode, at most three prefixal `EXTENDED_ARG` are allowed, forming an argument from two-byte to four-byte.

**FORMAT_VALUE** *(flags)*

Used for implementing formatted literal strings (f-strings). Pops an optional `fmt_spec` from the stack, then a required *value*. *flags* is interpreted as follows:

- `(flags & 0x03) == 0x00`: *value* is formatted as-is.
- `(flags & 0x03) == 0x01`: call `str()` on *value* before formatting it.
- `(flags & 0x03) == 0x02`: call `repr()` on *value* before formatting it.
- `(flags & 0x03) == 0x03`: call `ascii()` on *value* before formatting it.
- `(flags & 0x04) == 0x04`: pop `fmt_spec` from the stack and use it, else use an empty `fmt_spec`.

Formatting is performed using `PyObject_Format()`. The result is pushed on the stack.

New in version 3.6.

**MATCH_CLASS** *(count)*

TOS is a tuple of keyword attribute names, TOS1 is the class being matched against, and TOS2 is the match subject. *count* is the number of positional sub-patterns.
Pop TOS. If TOS2 is an instance of TOS1 and has the positional and keyword attributes required by \textit{count} and TOS, set TOS to \texttt{True} and TOS1 to a tuple of extracted attributes. Otherwise, set TOS to \texttt{False}.

New in version 3.10.

\textbf{GEN\_START} (\textit{kind})

Pops TOS. The \textit{kind} operand corresponds to the type of generator or coroutine. The legal kinds are 0 for generator, 1 for coroutine, and 2 for async generator.

New in version 3.10.

\textbf{ROT\_N} (\textit{count})

Lift the top \textit{count} stack items one position up, and move TOS down to position \textit{count}.

New in version 3.10.

\textbf{HAVE\_ARGUMENT}

This is not really an opcode. It identifies the dividing line between opcodes which don’t use their argument and those that do (\texttt{< HAVE\_ARGUMENT} and \texttt{>= HAVE\_ARGUMENT}, respectively).

Changed in version 3.6: Now every instruction has an argument, but opcodes \texttt{< HAVE\_ARGUMENT} ignore it. Before, only opcodes \texttt{>= HAVE\_ARGUMENT} had an argument.

### 32.10.4 Opcode collections

These collections are provided for automatic introspection of bytecode instructions:

\texttt{dis.opname}

Sequence of operation names, indexable using the bytecode.

\texttt{dis.opmap}

Dictionary mapping operation names to bytecodes.

\texttt{dis.cmp\_op}

Sequence of all compare operation names.

\texttt{dis.hasconst}

Sequence of bytecodes that access a constant.

\texttt{dis.hasfree}

Sequence of bytecodes that access a free variable (note that ‘free’ in this context refers to names in the current scope that are referenced by inner scopes or names in outer scopes that are referenced from this scope. It does not include references to global or built-in scopes).

\texttt{dis.hasname}

Sequence of bytecodes that access an attribute by name.

\texttt{dis.hasjrel}

Sequence of bytecodes that have a relative jump target.

\texttt{dis.hasjabs}

Sequence of bytecodes that have an absolute jump target.

\texttt{dis.haslocal}

Sequence of bytecodes that access a local variable.

\texttt{dis.hascompare}

Sequence of bytecodes of Boolean operations.
32.11 pickletools — Tools for pickle developers

Source code: Lib/pickletools.py

This module contains various constants relating to the intimate details of the pickle module, some lengthy comments about the implementation, and a few useful functions for analyzing pickled data. The contents of this module are useful for Python core developers who are working on the pickle; ordinary users of the pickle module probably won’t find the pickletools module relevant.

32.11.1 Command line usage

New in version 3.2.

When invoked from the command line, python -m pickletools will disassemble the contents of one or more pickle files. Note that if you want to see the Python object stored in the pickle rather than the details of pickle format, you may want to use -m pickle instead. However, when the pickle file that you want to examine comes from an untrusted source, -m pickletools is a safer option because it does not execute pickle bytecode.

For example, with a tuple (1, 2) pickled in file x.pickle:

```
$ python -m pickle x.pickle
(1, 2)
$ python -m pickletools x.pickle
  0: \x80 PROTO  3
  2: K BININT1  1
  4: K BININT1  2
  6: \x86 TUPLE2
  7: q BINPUT  0
  9: . STOP
highest protocol among opcodes = 2
```

Command line options

-a, --annotate
Annotate each line with a short opcode description.

-o, --output=<file>
Name of a file where the output should be written.

-l, --indentlevel=<num>
The number of blanks by which to indent a new MARK level.

-m, --memo
When multiple objects are disassembled, preserve memo between disassemblies.

-p, --preamble=<preamble>
When more than one pickle file are specified, print given preamble before each disassembly.
32.11.2 Programmatic Interface

pickletools.dis(pickle, out=None, memo=None, indentlevel=4, annotate=0)

Outputs a symbolic disassembly of the pickle to the file-like object out, defaulting to sys.stdout. pickle can be a string or a file-like object. memo can be a Python dictionary that will be used as the pickle’s memo; it can be used to perform disassemblies across multiple pickles created by the same pickler. Successive levels, indicated by MARK opcodes in the stream, are indented by indentlevel spaces. If a nonzero value is given to annotate, each opcode in the output is annotated with a short description. The value of annotate is used as a hint for the column where annotation should start.

New in version 3.2: The annotate argument.

pickletools.genops(pickle)

Provides an iterator over all of the opcodes in a pickle, returning a sequence of (opcode, arg, pos) triples. opcode is an instance of an OpcodeInfo class; arg is the decoded value, as a Python object, of the opcode’s argument; pos is the position at which this opcode is located. pickle can be a string or a file-like object.

pickletools.optimize(picklestring)

Returns a new equivalent pickle string after eliminating unused PUT opcodes. The optimized pickle is shorter, takes less transmission time, requires less storage space, and unpickles more efficiently.
This chapter describes modules that are only available on MS Windows platforms.

### 33.1 msvcrt — Useful routines from the MS VC++ runtime

These functions provide access to some useful capabilities on Windows platforms. Some higher-level modules use these functions to build the Windows implementations of their services. For example, the `getpass` module uses this in the implementation of the `getpass()` function.

Further documentation on these functions can be found in the Platform API documentation.

The module implements both the normal and wide char variants of the console I/O api. The normal API deals only with ASCII characters and is of limited use for internationalized applications. The wide char API should be used where ever possible.

Changed in version 3.3: Operations in this module now raise `OSError` where `IOError` was raised.

#### 33.1.1 File Operations

**msvcrt.locking**(fd, mode, nbytes)

Lock part of a file based on file descriptor fd from the C runtime. Raises `OSError` on failure. The locked region of the file extends from the current file position for nbytes bytes, and may continue beyond the end of the file. mode must be one of the `LK_*` constants listed below. Multiple regions in a file may be locked at the same time, but may not overlap. Adjacent regions are not merged; they must be unlocked individually.

Raises an auditing event `msvcrt.locking` with arguments fd, mode, nbytes.

- `msvcrt.LK_LOCK`
- `msvcrt.LK_RLCK`
  - Locks the specified bytes. If the bytes cannot be locked, the program immediately tries again after 1 second. If, after 10 attempts, the bytes cannot be locked, `OSError` is raised.

- `msvcrt.LK_NBLCK`
- `msvcrt.LK_NBRLCK`
  - Locks the specified bytes. If the bytes cannot be locked, `OSError` is raised.

- `msvcrt.LK_UNLCK`
  - Unlocks the specified bytes, which must have been previously locked.

- `msvcrt.setmode`(fd, flags)
  - Set the line-end translation mode for the file descriptor fd. To set it to text mode, flags should be `os.O_TEXT`; for binary, it should be `os.O_BINARY`.

- `msvcrt.open_osfhandle`(handle, flags)
  - Create a C runtime file descriptor from the file handle handle. The flags parameter should be a bitwise OR of
os.O_APPEND, os.O_RDONLY, and os.O_TEXT. The returned file descriptor may be used as a parameter to os.fdopen() to create a file object.

Raises an auditing event msvcrt.open_osfhandle with arguments handle, flags.

msvcrt.get_osfhandle(fd)

Return the file handle for the file descriptor fd. Raises OSError if fd is not recognized.

Raises an auditing event msvcrt.get_osfhandle with argument fd.

### 33.1.2 Console I/O

msvcrt.kbhit()

Return True if a keypress is waiting to be read.

msvcrt.getch()

Read a keypress and return the resulting character as a byte string. Nothing is echoed to the console. This call will block if a keypress is not already available, but will not wait for Enter to be pressed. If the pressed key was a special function key, this will return '\000' or '\xe0'; the next call will return the keycode. The Control-C keypress cannot be read with this function.

msvcrt.getwch()

Wide char variant of getch(), returning a Unicode value.

msvcrt.getche()

Similar to getch(), but the keypress will be echoed if it represents a printable character.

msvcrt.getwche()

Wide char variant of getche(), returning a Unicode value.

msvcrt.putch(char)

Print the byte string char to the console without buffering.

msvcrt.putwch(unicode char)

Wide char variant of putch(), accepting a Unicode value.

msvcrt.ungetch(char)

Cause the byte string char to be “pushed back” into the console buffer; it will be the next character read by getch() or getche().

msvcrt.ungetwch(unicode char)

Wide char variant of ungetch(), accepting a Unicode value.

### 33.1.3 Other Functions

msvcrt.heapmin()

Force the malloc() heap to clean itself up and return unused blocks to the operating system. On failure, this raises OSError.

### 33.2 winreg — Windows registry access

These functions expose the Windows registry API to Python. Instead of using an integer as the registry handle, a handle object is used to ensure that the handles are closed correctly, even if the programmer neglects to explicitly close them.

Changed in version 3.3: Several functions in this module used to raise a WindowsError, which is now an alias of OSError.
## 33.2.1 Functions

This module offers the following functions:

### winreg.CloseKey (hkey)
Closes a previously opened registry key. The `hkey` argument specifies a previously opened key.

**Note:** If `hkey` is not closed using this method (or via `hkey.Close()`), it is closed when the `hkey` object is destroyed by Python.

### winreg.ConnectRegistry (computer_name, key)
Establishes a connection to a predefined registry handle on another computer, and returns a handle object. `computer_name` is the name of the remote computer, of the form `r'\computername'`. If None, the local computer is used. `key` is the predefined handle to connect to.

The return value is the handle of the opened key. If the function fails, an `OSError` exception is raised.

Raises an auditing event `winreg.ConnectRegistry` with arguments `computer_name`, `key`.

Changed in version 3.3: See above.

### winreg.CreateKey (key, sub_key)
Creates or opens the specified key, returning a handle object.

`key` is an already open key, or one of the predefined `HKEY_*` constants.

`sub_key` is a string that names the key this method opens or creates.

If `key` is one of the predefined keys, `sub_key` may be None. In that case, the handle returned is the same key handle passed in to the function.

If the key already exists, this function opens the existing key.

The return value is the handle of the opened key. If the function fails, an `OSError` exception is raised.

Raises an auditing event `winreg.CreateKey` with arguments `key`, `sub_key`, `access`.

Raised an auditing event `winreg.OpenKey/result` with argument `key`.

Changed in version 3.3: See above.

### winreg.CreateKeyEx (key, sub_key, reserved=0, access=KEY_WRITE)
Creates or opens the specified key, returning a handle object.

`key` is an already open key, or one of the predefined `HKEY_*` constants.

`sub_key` is a string that names the key this method opens or creates.

`reserved` is a reserved integer, and must be zero. The default is zero.

`access` is an integer that specifies an access mask that describes the desired security access for the key. Default is `KEY_WRITE`. See Access Rights for other allowed values.

If `key` is one of the predefined keys, `sub_key` may be None. In that case, the handle returned is the same key handle passed in to the function.

If the key already exists, this function opens the existing key.

The return value is the handle of the opened key. If the function fails, an `OSError` exception is raised.

Raises an auditing event `winreg.CreateKeyEx` with arguments `key`, `sub_key`, `access`.

New in version 3.2.

Changed in version 3.3: See above.
winreg.DeleteKey(key, sub_key)
    Deletes the specified key.

    key is an already open key, or one of the predefined HKEY_* constants.

    sub_key is a string that must be a subkey of the key identified by the key parameter. This value must not be
    None, and the key may not have subkeys.

    This method can not delete keys with subkeys.

    If the method succeeds, the entire key, including all of its values, is removed. If the method fails, an OSError
    exception is raised.

    Raises an auditing event winreg.DeleteKey with arguments key, sub_key, access.

    Changed in version 3.3: See above.

winreg.DeleteKeyEx(key, sub_key, access=KEY_WOW64_64KEY, reserved=0)
    Deletes the specified key.

    key is an already open key, or one of the predefined HKEY_* constants.

    sub_key is a string that must be a subkey of the key identified by the key parameter. This value must not be
    None, and the key may not have subkeys.

    reserved is a reserved integer, and must be zero. The default is zero.

    access is an integer that specifies an access mask that describes the desired security access for the key. Default
    is KEY_WOW64_64KEY. See Access Rights for other allowed values.

    This method can not delete keys with subkeys.

    If the method succeeds, the entire key, including all of its values, is removed. If the method fails, an OSError
    exception is raised.

    On unsupported Windows versions, NotImplemented Error is raised.

    Raises an auditing event winreg.DeleteKeyEx with arguments key, sub_key, access.

    New in version 3.2.

    Changed in version 3.3: See above.

winreg.DeleteValue(key, value)
    Removes a named value from a registry key.

    key is an already open key, or one of the predefined HKEY_* constants.

    value is a string that identifies the value to remove.

    Raises an auditing event winreg.DeleteValue with arguments key, value.

winreg.EnumKey(key, index)
    Enumerates subkeys of an open registry key, returning a string.

    key is an already open key, or one of the predefined HKEY_* constants.

    index is an integer that identifies the index of the key to retrieve.

    The function retrieves the name of one subkey each time it is called. It is typically called repeatedly until an
    OSError exception is raised, indicating, no more values are available.

    Raises an auditing event winreg.EnumKey with arguments key, index.

    Changed in version 3.3: See above.
winreg.EnumValue(key, index)

Enumerates values of an open registry key, returning a tuple.

key is an already open key, or one of the predefined HKEY_* constants.

index is an integer that identifies the index of the value to retrieve.

The function retrieves the name of one subkey each time it is called. It is typically called repeatedly, until an OSError exception is raised, indicating no more values.

The result is a tuple of 3 items:

<table>
<thead>
<tr>
<th>Index</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>A string that identifies the value name</td>
</tr>
<tr>
<td>1</td>
<td>An object that holds the value data, and whose type depends on the underlying registry type</td>
</tr>
<tr>
<td>2</td>
<td>An integer that identifies the type of the value data (see table in docs for SetValueEx())</td>
</tr>
</tbody>
</table>

Raises an auditing event winreg.EnumValue with arguments key, index.

Changed in version 3.3: See above.

winreg.ExpandEnvironmentStrings(str)

Expands environment variable placeholders %NAME% in strings like REG_EXPAND_SZ:

```python
>>> ExpandEnvironmentStrings('%windir%')
'C:\Windows'
```

Raises an auditing event winreg.ExpandEnvironmentStrings with argument str.

winreg.FlushKey(key)

Writes all the attributes of a key to the registry.

key is an already open key, or one of the predefined HKEY_* constants.

It is not necessary to call FlushKey() to change a key. Registry changes are flushed to disk by the registry using its lazy flusher. Registry changes are also flushed to disk at system shutdown. Unlike CloseKey(), the FlushKey() method returns only when all the data has been written to the registry. An application should only call FlushKey() if it requires absolute certainty that registry changes are on disk.

Note: If you don’t know whether a FlushKey() call is required, it probably isn’t.

winreg.LoadKey(key, sub_key, file_name)

Creates a subkey under the specified key and stores registration information from a specified file into that subkey.

key is a handle returned by ConnectRegistry() or one of the constants HKEY_USERS or HKEY_LOCAL_MACHINE.

sub_key is a string that identifies the subkey to load.

file_name is the name of the file to load registry data from. This file must have been created with the SaveKey() function. Under the file allocation table (FAT) file system, the filename may not have an extension.

A call to LoadKey() fails if the calling process does not have the SE_RESTORE_PRIVILEGE privilege. Note that privileges are different from permissions – see the RegLoadKey documentation for more details.

If key is a handle returned by ConnectRegistry(), then the path specified in file_name is relative to the remote computer.

Raises an auditing event winreg.LoadKey with arguments key, sub_key, file_name.

winreg.OpenKey(key, sub_key, reserved=0, access=KEY_READ)
OpenKeyEx

```python
winreg.OpenKeyEx(key, sub_key, reserved=0, access=\'KEY_READ\')
```

Opens the specified key, returning a `handle object`.

- `key` is an already open key, or one of the predefined `HKEY_* constants`.
- `sub_key` is a string that identifies the sub_key to open.
- `reserved` is a reserved integer, and must be zero. The default is zero.
- `access` is an integer that specifies an access mask that describes the desired security access for the key. Default is `KEY_READ`. See `Access Rights` for other allowed values.

The result is a new handle to the specified key.

If the function fails, `OSError` is raised.

Raises an `auditing event` `winreg.OpenKey` with arguments `key`, `sub_key`, `access`.

Changed in version 3.2: Allow the use of named arguments.

Changed in version 3.3: See above.

QueryInfoKey

```python
winreg.QueryInfoKey(key)
```

Returns information about a key, as a tuple.

- `key` is an already open key, or one of the predefined `HKEY_* constants`.

The result is a tuple of 3 items:

<table>
<thead>
<tr>
<th>Index</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>An integer giving the number of sub keys this key has.</td>
</tr>
<tr>
<td>1</td>
<td>An integer giving the number of values this key has.</td>
</tr>
<tr>
<td>2</td>
<td>An integer giving when the key was last modified (if available) as 100's of nanoseconds since Jan 1, 1601.</td>
</tr>
</tbody>
</table>

Raises an `auditing event` `winreg.QueryInfoKey` with argument `key`.

QueryValue

```python
winreg.QueryValue(key, sub_key)
```

Retrieves the unnamed value for a key, as a string.

- `key` is an already open key, or one of the predefined `HKEY_* constants`.
- `sub_key` is a string that holds the name of the subkey with which the value is associated. If this parameter is `None` or empty, the function retrieves the value set by the `SetValue()` method for the key identified by `key`.

Values in the registry have name, type, and data components. This method retrieves the data for a key’s first value that has a NULL name. But the underlying API call doesn’t return the type, so always use `QueryValueEx()` if possible.

 Raises an `auditing event` `winreg.QueryValue` with arguments `key`, `sub_key`, `value_name`.

QueryValueEx

```python
winreg.QueryValueEx(key, value_name)
```

Retrieves the type and data for a specified value name associated with an open registry key.

- `key` is an already open key, or one of the predefined `HKEY_* constants`.
- `value_name` is a string indicating the value to query.

The result is a tuple of 2 items:

<table>
<thead>
<tr>
<th>Index</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>The value of the registry item.</td>
</tr>
<tr>
<td>1</td>
<td>An integer giving the registry type for this value (see table in docs for <code>SetValueEx()</code>)</td>
</tr>
</tbody>
</table>

Raises an `auditing event` `winreg.QueryValue` with arguments `key`, `sub_key`, `value_name`. 
The Python Library Reference, Release 3.10.4

winreg.SaveKey(key, file_name)
Saves the specified key, and all its subkeys to the specified file.

key is an already open key, or one of the predefined HKEY_* constants.

file_name is the name of the file to save registry data to. This file cannot already exist. If this filename includes an extension, it cannot be used on file allocation table (FAT) file systems by the LoadKey() method.

If key represents a key on a remote computer, the path described by file_name is relative to the remote computer. The caller of this method must possess the SeBackupPrivilege security privilege. Note that privileges are different than permissions – see the Conflicts Between User Rights and Permissions documentation for more details.

This function passes NULL for security_attributes to the API.

Raises an auditing event winreg.SaveKey with arguments key, file_name.

winreg.SetValue(key, sub_key, type, value)
Associates a value with a specified key.

key is an already open key, or one of the predefined HKEY_* constants.

sub_key is a string that names the subkey with which the value is associated.

type is an integer that specifies the type of the data. Currently this must be REG_SZ, meaning only strings are supported. Use the SetValueEx() function for support for other data types.

value is a string that specifies the new value.

If the key specified by the sub_key parameter does not exist, the SetValue function creates it.

Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the registry perform efficiently.

The key identified by the key parameter must have been opened with KEY_SET_VALUE access.

Raises an auditing event winreg.SetValue with arguments key, sub_key, type, value.

winreg.SetValueEx(key, value_name, reserved, type, value)
Stores data in the value field of an open registry key.

key is an already open key, or one of the predefined HKEY_* constants.

value_name is a string that names the subkey with which the value is associated.

reserved can be anything – zero is always passed to the API.

type is an integer that specifies the type of the data. See Value Types for the available types.

value is a string that specifies the new value.

This method can also set additional value and type information for the specified key. The key identified by the key parameter must have been opened with KEY_SET_VALUE access.

To open the key, use the CreateKey() or OpenKey() methods.

Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the registry perform efficiently.

Raises an auditing event winreg.SetValue with arguments key, sub_key, type, value.

winreg.DisableReflectionKey(key)
Disables registry reflection for 32-bit processes running on a 64-bit operating system.

key is an already open key, or one of the predefined HKEY_* constants.

Will generally raise NotImplemented for executed on a 32-bit operating system.

If the key is not on the reflection list, the function succeeds but has no effect. Disabling reflection for a key does not affect reflection of any subkeys.

Raises an auditing event winreg.DisableReflectionKey with argument key.
winreg.EnableReflectionKey(key)
Restores registry reflection for the specified disabled key.
key is an already open key, or one of the predefined HKEY_* constants.
Will generally raise NotImplemented Error if executed on a 32-bit operating system.
Restoring reflection for a key does not affect reflection of any subkeys.
Raises an auditing event winreg.EnableReflectionKey with argument key.

winreg.QueryReflectionKey(key)
Determines the reflection state for the specified key.
key is an already open key, or one of the predefined HKEY_* constants.
Returns True if reflection is disabled.
Will generally raise NotImplemented Error if executed on a 32-bit operating system.
 Raises an auditing event winreg.QueryReflectionKey with argument key.

33.2.2 Constants

The following constants are defined for use in many _winreg functions.

HKEY_* Constants

winreg.HKEY_CLASSES_ROOT
Registry entries subordinate to this key define types (or classes) of documents and the properties associated with those types. Shell and COM applications use the information stored under this key.

winreg.HKEY_CURRENT_USER
Registry entries subordinate to this key define the preferences of the current user. These preferences include the settings of environment variables, data about program groups, colors, printers, network connections, and application preferences.

winreg.HKEY_LOCAL_MACHINE
Registry entries subordinate to this key define the physical state of the computer, including data about the bus type, system memory, and installed hardware and software.

winreg.HKEY_USERS
Registry entries subordinate to this key define the default user configuration for new users on the local computer and the user configuration for the current user.

winreg.HKEY_PERFORMANCE_DATA
Registry entries subordinate to this key allow you to access performance data. The data is not actually stored in the registry; the registry functions cause the system to collect the data from its source.

winreg.HKEY_CURRENT_CONFIG
Contains information about the current hardware profile of the local computer system.

winreg.HKEY_DYN_DATA
This key is not used in versions of Windows after 98.
Access Rights

For more information, see Registry Key Security and Access.

**winreg.KEY_ALL_ACCESS**
Combines the STANDARD_RIGHTS_REQUIRED, KEY_QUERY_VALUE, KEY_SET_VALUE, KEY_CREATE_SUB_KEY, KEY_ENUMERATE_SUB_KEYS, KEY_NOTIFY, and KEY_CREATE_LINK access rights.

**winreg.KEY_WRITE**
Combines the STANDARD_RIGHTS_WRITE, KEY_SET_VALUE, and KEY_CREATE_SUB_KEY access rights.

**winreg.KEY_READ**
Combines the STANDARD_RIGHTS_READ, KEY_QUERY_VALUE, KEY_ENUMERATE_SUB_KEYS, and KEY_NOTIFY values.

**winreg.KEY_EXECUTE**
Equivalent to KEY_READ.

**winreg.KEY_QUERY_VALUE**
Required to query the values of a registry key.

**winreg.KEY_SET_VALUE**
Required to create, delete, or set a registry value.

**winreg.KEY_CREATE_SUB_KEY**
Required to create a subkey of a registry key.

**winreg.KEY_ENUMERATE_SUB_KEYS**
Required to enumerate the subkeys of a registry key.

**winreg.KEY_NOTIFY**
Required to request change notifications for a registry key or for subkeys of a registry key.

**winreg.KEY_CREATE_LINK**
Reserved for system use.

64-bit Specific

For more information, see Accessing an Alternate Registry View.

**winreg.KEY_WOW64_64KEY**
Indicates that an application on 64-bit Windows should operate on the 64-bit registry view.

**winreg.KEY_WOW64_32KEY**
Indicates that an application on 64-bit Windows should operate on the 32-bit registry view.

Value Types

For more information, see Registry Value Types.

**winreg.REG_BINARY**
Binary data in any form.

**winreg.REG_DWORD**
32-bit number.

**winreg.REG_DWORD_LITTLE_ENDIAN**
A 32-bit number in little-endian format. Equivalent to REG_DWORD.

**winreg.REG_DWORD_BIG_ENDIAN**
A 32-bit number in big-endian format.
winreg.REG_EXPAND_SZ
   Null-terminated string containing references to environment variables (%PATH%).

winreg.REG_LINK
   A Unicode symbolic link.

winreg.REG_MULTI_SZ
   A sequence of null-terminated strings, terminated by two null characters. (Python handles this termination automatically.)

winreg.REG_NONE
   No defined value type.

winreg.REG_QWORD
   A 64-bit number.
   New in version 3.6.

winreg.REG_QWORD_LITTLE_ENDIAN
   A 64-bit number in little-endian format. Equivalent to REG_QWORD.
   New in version 3.6.

winreg.REG_RESOURCE_LIST
   A device-driver resource list.

winreg.REG_FULL_RESOURCE_DESCRIPTOR
   A hardware setting.

winreg.REG_RESOURCE_REQUIREMENTS_LIST
   A hardware resource list.

winreg.REG_SZ
   A null-terminated string.

33.2.3 Registry Handle Objects

This object wraps a Windows HKEY object, automatically closing it when the object is destroyed. To guarantee cleanup, you can call either the Close() method on the object, or the CloseKey() function.

All registry functions in this module return one of these objects.

All registry functions in this module which accept a handle object also accept an integer, however, use of the handle object is encouraged.

Handle objects provide semantics for __bool__() – thus

```python
if handle:
    print("Yes")
```

will print Yes if the handle is currently valid (has not been closed or detached).

The object also support comparison semantics, so handle objects will compare true if they both reference the same underlying Windows handle value.

Handle objects can be converted to an integer (e.g., using the built-in int() function), in which case the underlying Windows handle value is returned. You can also use the Detach() method to return the integer handle, and also disconnect the Windows handle from the handle object.

PyHKEY.Close()
   Closes the underlying Windows handle.
   
   If the handle is already closed, no error is raised.

PyHKEY.Detach()
   Detaches the Windows handle from the handle object.
The result is an integer that holds the value of the handle before it is detached. If the handle is already detached or closed, this will return zero.

After calling this function, the handle is effectively invalidated, but the handle is not closed. You would call this function when you need the underlying Win32 handle to exist beyond the lifetime of the handle object.

Raises an auditing event winreg.PyHKEY.Detach with argument key.

PyHKEY.__enter__()
PyHKEY.__exit__(*exc_info)

The HKEY object implements __enter__() and __exit__() and thus supports the context protocol for the with statement:

```python
with OpenKey(HKEY_LOCAL_MACHINE, "foo") as key:
    ...
```

will automatically close key when control leaves the with block.

### 33.3 winsound — Sound-playing interface for Windows

The winsound module provides access to the basic sound-playing machinery provided by Windows platforms. It includes functions and several constants.

winsound.**Beep** (*frequency*, *duration*)

Beep the PC's speaker. The *frequency* parameter specifies frequency, in hertz, of the sound, and must be in the range 37 through 32,767. The *duration* parameter specifies the number of milliseconds the sound should last. If the system is not able to beep the speaker, RuntimeError is raised.

winsound.**PlaySound** (*sound*, *flags*)

Call the underlying PlaySound() function from the Platform API. The *sound* parameter may be a filename, a system sound alias, audio data as a bytes-like object, or None. Its interpretation depends on the value of *flags*, which can be a bitwise ORed combination of the constants described below. If the *sound* parameter is None, any currently playing waveform sound is stopped. If the system indicates an error, RuntimeError is raised.

winsound.**MessageBeep** (*type=*MB_OK*)

Call the underlying MessageBeep() function from the Platform API. This plays a sound as specified in the registry. The *type* argument specifies which sound to play; possible values are -1, MB_ICONASTERISK, MB_ICONEXCLAMATION, MB_ICONHAND, MB_ICONQUESTION, and MB_OK, all described below. The value -1 produces a "simple beep"; this is the final fallback if a sound cannot be played otherwise. If the system indicates an error, RuntimeError is raised.

winsound.**SND_FILENAME**

The *sound* parameter is the name of a WAV file. Do not use with SND_ALIAS.

winsound.**SND_ALIAS**

The *sound* parameter is a sound association name from the registry. If the registry contains no such name, play the system default sound unless SND_NODEFAULT is also specified. If no default sound is registered, raise RuntimeError. Do not use with SND_FILENAME.

All Win32 systems support at least the following; most systems support many more:

<table>
<thead>
<tr>
<th><strong>PlaySound() name</strong></th>
<th>Corresponding Control Panel Sound name</th>
</tr>
</thead>
<tbody>
<tr>
<td>'SystemAsterisk'</td>
<td>Asterisk</td>
</tr>
<tr>
<td>'SystemExclamation'</td>
<td>Exclamation</td>
</tr>
<tr>
<td>'SystemExit'</td>
<td>Exit Windows</td>
</tr>
<tr>
<td>'SystemHand'</td>
<td>Critical Stop</td>
</tr>
<tr>
<td>'SystemQuestion'</td>
<td>Question</td>
</tr>
</tbody>
</table>

For example:
import winsound
# Play Windows exit sound.
winsound.PlaySound("SystemExit", winsound.SND_ALIAS)

# Probably play Windows default sound, if any is registered (because
# ":" probably isn't the registered name of any sound).
winsound.PlaySound(":", winsound.SND_ALIAS)

winsound.SND_LOOP
   Play the sound repeatedly. The SND_ASYNC flag must also be used to avoid blocking. Cannot be used with
   SND_MEMORY.

winsound.SND_MEMORY
   The sound parameter to PlaySound() is a memory image of a WAV file, as a bytes-like object.

   Note: This module does not support playing from a memory image asynchronously, so a combination of this
   flag and SND_ASYNC will raise RuntimeError.

winsound.SND_PURGE
   Stop playing all instances of the specified sound.

   Note: This flag is not supported on modern Windows platforms.

winsound.SND_ASYNC
   Return immediately, allowing sounds to play asynchronously.

winsound.SND_NODEFAULT
   If the specified sound cannot be found, do not play the system default sound.

winsound.SND_NOSTOP
   Do not interrupt sounds currently playing.

winsound.SND_NOWAIT
   Return immediately if the sound driver is busy.

   Note: This flag is not supported on modern Windows platforms.

winsound.MB_ICONASTERISK
   Play the SystemDefault sound.

winsound.MB_ICONEXCLAMATION
   Play the SystemExclamation sound.

winsound.MB_ICONHAND
   Play the SystemHand sound.

winsound.MB_ICONQUESTION
   Play the SystemQuestion sound.

winsound.MB_OK
   Play the SystemDefault sound.
The modules described in this chapter provide interfaces to features that are unique to the Unix operating system, or in some cases to some or many variants of it. Here’s an overview:

### 34.1 posix — The most common POSIX system calls

This module provides access to operating system functionality that is standardized by the C Standard and the POSIX standard (a thinly disguised Unix interface).

Do not import this module directly. Instead, import the module `os`, which provides a portable version of this interface. On Unix, the `os` module provides a superset of the `posix` interface. On non-Unix operating systems the `posix` module is not available, but a subset is always available through the `os` interface. Once `os` is imported, there is no performance penalty in using it instead of `posix`. In addition, `os` provides some additional functionality, such as automatically calling `putenv()` when an entry in `os.environ` is changed.

Errors are reported as exceptions; the usual exceptions are given for type errors, while errors reported by the system calls raise `OSError`.

#### 34.1.1 Large File Support

Several operating systems (including AIX, HP-UX and Solaris) provide support for files that are larger than 2 GiB from a C programming model where int and long are 32-bit values. This is typically accomplished by defining the relevant size and offset types as 64-bit values. Such files are sometimes referred to as large files.

Large file support is enabled in Python when the size of an `off_t` is larger than a long and the long long is at least as large as an `off_t`. It may be necessary to configure and compile Python with certain compiler flags to enable this mode. For example, with Solaris 2.6 and 2.7 you need to do something like:

```bash
CFLAGS="'getconf LFS_CFLAGS'" OPT="-g -O2 $CFLAGS" \
./configure
```

On large-file-capable Linux systems, this might work:

```bash
CFLAGS="'-D_LARGEFILE64_SOURCE -D_FILE_OFFSET_BITS=64'" OPT="-g -O2 $CFLAGS" \
./configure
```
34.1.2 Notable Module Contents

In addition to many functions described in the os module documentation, posix defines the following data item:

posix.environ

A dictionary representing the string environment at the time the interpreter was started. Keys and values are bytes on Unix and str on Windows. For example, environ[b'HOME'] (environ['HOME'] on Windows) is the path name of your home directory, equivalent to getenv("HOME") in C.

Modifying this dictionary does not affect the string environment passed on by execv(), popen() or system(); if you need to change the environment, pass environ to execve() or add variable assignments and export statements to the command string for system() or popen().

Changed in version 3.2: On Unix, keys and values are bytes.

Note: The os module provides an alternate implementation of environ which updates the environment on modification. Note also that updating os.environ will render this dictionary obsolete. Use of the os module version of this is recommended over direct access to the posix module.

34.2 pwd — The password database

This module provides access to the Unix user account and password database. It is available on all Unix versions.

Password database entries are reported as a tuple-like object, whose attributes correspond to the members of the passwd structure (Attribute field below, see <pwd.h>):

<table>
<thead>
<tr>
<th>Index</th>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>pw_name</td>
<td>Login name</td>
</tr>
<tr>
<td>1</td>
<td>pw_passwd</td>
<td>Optional encrypted password</td>
</tr>
<tr>
<td>2</td>
<td>pw_uid</td>
<td>Numerical user ID</td>
</tr>
<tr>
<td>3</td>
<td>pw_gid</td>
<td>Numerical group ID</td>
</tr>
<tr>
<td>4</td>
<td>pw_gecos</td>
<td>User name or comment field</td>
</tr>
<tr>
<td>5</td>
<td>pw_dir</td>
<td>User home directory</td>
</tr>
<tr>
<td>6</td>
<td>pw_shell</td>
<td>User command interpreter</td>
</tr>
</tbody>
</table>

The uid and gid items are integers, all others are strings. KeyError is raised if the entry asked for cannot be found.

Note: In traditional Unix the field pw_passwd usually contains a password encrypted with a DES derived algorithm (see module crypt). However most modern unices use a so-called shadow password system. On those unices the pw_passwd field only contains an asterisk ('*') or the letter 'x' where the encrypted password is stored in a file /etc/shadow which is not world readable. Whether the pw_passwd field contains anything useful is system-dependent. If available, the spwd module should be used where access to the encrypted password is required.

It defines the following items:

pwd.getpwnam(name)

Return the password database entry for the given user name.

pwd.getpwall()

Return a list of all available password database entries, in arbitrary order.

See also:
Module `grp` – An interface to the group database, similar to this.

Module `spwd` – An interface to the shadow password database, similar to this.

### 34.3 `grp` — The group database

This module provides access to the Unix group database. It is available on all Unix versions.

Group database entries are reported as a tuple-like object, whose attributes correspond to the members of the `group` structure (Attribute field below, see `<pwd.h>`):

<table>
<thead>
<tr>
<th>Index</th>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>gr_name</td>
<td>the name of the group</td>
</tr>
<tr>
<td>1</td>
<td>gr_passwd</td>
<td>the (encrypted) group password; often empty</td>
</tr>
<tr>
<td>2</td>
<td>gr_gid</td>
<td>the numerical group ID</td>
</tr>
<tr>
<td>3</td>
<td>gr_mem</td>
<td>all the group member’s user names</td>
</tr>
</tbody>
</table>

The gid is an integer, name and password are strings, and the member list is a list of strings. (Note that most users are not explicitly listed as members of the group they are in according to the password database. Check both databases to get complete membership information. Also note that a `gr_name` that starts with a `+` or `-` is likely to be a YP/NIS reference and may not be accessible via `getgrnam()` or `getgrgid()`.)

It defines the following items:

- `grp.getgrgid(gid)`
  - Return the group database entry for the given numeric group ID. `KeyError` is raised if the entry asked for cannot be found.
  - Deprecated since version 3.6: Since Python 3.6 the support of non-integer arguments like floats or strings in `getgrgid()` is deprecated.

- `grp.getgrnam(name)`
  - Return the group database entry for the given group name. `KeyError` is raised if the entry asked for cannot be found.

- `grp.getgrall()`
  - Return a list of all available group entries, in arbitrary order.

Module `pwd` – An interface to the user database, similar to this.

Module `spwd` – An interface to the shadow password database, similar to this.

### 34.4 `termios` — POSIX style tty control

This module provides an interface to the POSIX calls for tty I/O control. For a complete description of these calls, see `termios(3) Unix manual page. It is only available for those Unix versions that support POSIX `termios` style tty I/O control configured during installation.

All functions in this module take a file descriptor `fd` as their first argument. This can be an integer file descriptor, such as returned by `sys.stdin.fileno()`, or a `file object`, such as `sys.stdin` itself.

This module also defines all the constants needed to work with the functions provided here; these have the same name as their counterparts in C. Please refer to your system documentation for more information on using these terminal control interfaces.

The module defines the following functions:
termios.tcgetattr(fd)
Return a list containing the tty attributes for file descriptor `fd`, as follows: `[iflag, oflag, cflag, lflag, ispeed, ospeed, cc]` where `cc` is a list of the tty special characters (each a string of length 1, except the items with indices `VMIN` and `VTIME`, which are integers when these fields are defined). The interpretation of the flags and the speeds as well as the indexing in the `cc` array must be done using the symbolic constants defined in the `termios` module.

termios.tcsetattr(fd, when, attributes)
Set the tty attributes for file descriptor `fd` from the `attributes`, which is a list like the one returned by `tcgetattr()`. The `when` argument determines when the attributes are changed: `TCSANOW` to change immediately, `TCSADRAIN` to change after transmitting all queued output, or `TCSAFLUSH` to change after transmitting all queued output and discarding all queued input.

termios.tcsendbreak(fd, duration)
Send a break on file descriptor `fd`. A zero `duration` sends a break for 0.25–0.5 seconds; a nonzero `duration` has a system dependent meaning.

termios.tcdrain(fd)
Wait until all output written to file descriptor `fd` has been transmitted.

termios.tcflush(fd, queue)
Discard queued data on file descriptor `fd`. The `queue` selector specifies which queue: `TCIFLUSH` for the input queue, `TCOFLUSH` for the output queue, or `TCIOFLUSH` for both queues.

termios.tcflow(fd, action)
Suspend or resume input or output on file descriptor `fd`. The `action` argument can be `TCOFF` to suspend output, `TCOON` to restart output, `TCIOFF` to suspend input, or `TCION` to restart input.

See also:

Module `tty` Convenience functions for common terminal control operations.

34.4.1 Example

Here’s a function that prompts for a password with echoing turned off. Note the technique using a separate `tcgetattr()` call and a `try ... finally` statement to ensure that the old tty attributes are restored exactly no matter what happens:

```python
def getpass(prompt="Password: "):  
    import termios, sys  
    fd = sys.stdin.fileno()  
    old = termios.tcgetattr(fd)  
    new = termios.tcgetattr(fd)  
    try:  
        termios.tcsetattr(fd, termios.TCSADRAIN, new)  
        passwd = input(prompt)  
    finally:  
        termios.tcsetattr(fd, termios.TCSADRAIN, old)  
    return passwd
```
34.5 tty — Terminal control functions

Source code: Lib/tty.py

The tty module defines functions for putting the tty into cbreak and raw modes. Because it requires the termios module, it will work only on Unix.

The tty module defines the following functions:

- `tty.setraw(fd, when=termios.TCSAFLUSH)`
  Change the mode of the file descriptor `fd` to raw. If `when` is omitted, it defaults to `termios.TCSAFLUSH`, and is passed to `termios.tcsetattr()`.

- `tty.setcbreak(fd, when=termios.TCSAFLUSH)`
  Change the mode of file descriptor `fd` to cbreak. If `when` is omitted, it defaults to `termios.TCSAFLUSH`, and is passed to `termios.tcsetattr()`.

See also:

Module termios  Low-level terminal control interface.

34.6 pty — Pseudo-terminal utilities

Source code: Lib/pty.py

The pty module defines operations for handling the pseudo-terminal concept: starting another process and being able to write to and read from its controlling terminal programatically.

Pseudo-terminal handling is highly platform dependent. This code is mainly tested on Linux, FreeBSD, and macOS (it is supposed to work on other POSIX platforms but it’s not been thoroughly tested).

The pty module defines the following functions:

- `pty.fork()`
  Fork. Connect the child’s controlling terminal to a pseudo-terminal. Return value is `(pid, fd)`. Note that the child gets `pid` 0, and the `fd` is invalid. The parent’s return value is the `pid` of the child, and `fd` is a file descriptor connected to the child’s controlling terminal (and also to the child’s standard input and output).

- `pty.openpty()`
  Open a new pseudo-terminal pair, using `os.openpty()` if possible, or emulation code for generic Unix systems. Return a pair of file descriptors (`master`, `slave`), for the master and the slave end, respectively.

- `pty.spawn(argv, master_read, stdin_read)`
  Spawn a process, and connect its controlling terminal with the current process’s standard io. This is often used to baffle programs which insist on reading from the controlling terminal. It is expected that the process spawned behind the pty will eventually terminate, and when it does `spawn` will return.

  A loop copies STDIN of the current process to the child and data received from the child to STDOUT of the current process. It is not signaled to the child if STDIN of the current process closes down.

  The functions `master_read` and `stdin_read` are passed a file descriptor which they should read from, and they should always return a byte string. In order to force `spawn` to return before the child process exits an empty byte array should be returned to signal end of file.

  The default implementation for both functions will read and return up to 1024 bytes each time the function is called. The `master_read` callback is passed the pseudoterminal’s master file descriptor to read output from the child process, and `stdin_read` is passed file descriptor 0, to read from the parent process’s standard input.

  Returning an empty byte string from either callback is interpreted as an end-of-file (EOF) condition, and that callback will not be called after that. If `stdin_read` signals EOF the controlling terminal can no longer
communicate with the parent process OR the child process. Unless the child process will quit without any input, spawn will then loop forever. If master_read signals EOF the same behavior results (on linux at least).

Return the exit status value from os.waitpid() on the child process.

waitstatus_to_exitcode() can be used to convert the exit status into an exit code.

Raises an auditing event pty.spawn with argument argv.

Changed in version 3.4: spawn() now returns the status value from os.waitpid() on the child process.

### 34.6.1 Example

The following program acts like the Unix command script(1), using a pseudo-terminal to record all input and output of a terminal session in a “typescript”.

```python
import argparse
import os
import pty
import sys
import time

parser = argparse.ArgumentParser()
parser.add_argument('-a', dest='append', action='store_true')
parser.add_argument('-p', dest='use_python', action='store_true')
parser.add_argument('filename', nargs='?', default='typescript')
options = parser.parse_args()

shell = sys.executable if options.use_python else os.environ.get('SHELL', 'sh')
filename = options.filename
mode = 'ab' if options.append else 'wb'

with open(filename, mode) as script:
    def read(fd):
        data = os.read(fd, 1024)
        script.write(data)
        return data

print('Script started, file is', filename)
script.write(('Script started on %s
 % time.asctime()).encode())

pty.spawn(shell, read)

script.write(('Script done on %s
 % time.asctime()).encode())
print('Script done, file is', filename)
```

### 34.7 fcntl — The fcntl and ioctl system calls

This module performs file control and I/O control on file descriptors. It is an interface to the fcntl() and ioctl() Unix routines. For a complete description of these functions, see fcntl(2) and ioctl(2) Unix manual pages.

All functions in this module take a file descriptor fd as their first argument. This can be an integer file descriptor, such as returned by sys.stdin.fileno(), or an io.IOBase object, such as sys.stdin itself, which provides a fileno() that returns a genuine file descriptor.

Changed in version 3.3: Operations in this module used to raise an IOError where they now raise an OSError.

Changed in version 3.8: The fcntl module now contains F_ADD_SEALS, F_GET_SEALS, and F_SEAL_* constants for sealing of os.memfd_create() file descriptors.
Changed in version 3.9: On macOS, the fcntl module exposes the `F_GETPATH` constant, which obtains the path of a file from a file descriptor. On Linux(>=3.15), the fcntl module exposes the `F_OFD_GETLK`, `F_OFD_SETLK` and `F_OFD_SETLKW` constants, which working with open file description locks.

Changed in version 3.10: On Linux >=2.6.11, the fcntl module exposes the `F_GETPIPE_SZ` and `F_SETPIPE_SZ` constants, which allow to check and modify a pipe's size respectively.

The module defines the following functions:

```
fcntl(fd, cmd, arg=0)
```

Perform the operation `cmd` on file descriptor `fd` (file objects providing a `fileno()` method are accepted as well). The values used for `cmd` are operating system dependent, and are available as constants in the `fcntl` module, using the same names as used in the relevant C header files. The argument `arg` can either be an integer value, or a `bytes` object. With an integer value, the return value of this function is the integer return value of the C `fcntl()` call. When the argument is bytes it represents a binary structure, e.g. created by `struct.pack()`. The binary data is copied to a buffer whose address is passed to the C `fcntl()` call. The return value after a successful call is the contents of the buffer, converted to a `bytes` object. The length of the returned object will be the same as the length of the `arg` argument. This is limited to 1024 bytes. If the information returned in the buffer by the operating system is larger than 1024 bytes, this is most likely to result in a segmentation violation or a more subtle data corruption.

If the `fcntl()` fails, an `OSError` is raised.

Raising an auditing event `fcntl.fcntl` with arguments `fd`, `cmd`, `arg`.

```
ioctl(fd, request, arg=0, mutate_flag=True)
```

This function is identical to the `fcntl()` function, except that the argument handling is even more complicated.

The `request` parameter is limited to values that can fit in 32-bits. Additional constants of interest for use as the `request` argument can be found in the `termios` module, under the same names as used in the relevant C header files.

The parameter `arg` can be one of an integer, an object supporting the read-only buffer interface (like `bytes`) or an object supporting the read-write buffer interface (like `bytearray`).

In all but the last case, behaviour is as for the `fcntl()` function.

If a mutable buffer is passed, then the behaviour is determined by the value of the `mutate_flag` parameter.

If it is false, the buffer's mutability is ignored and behaviour is as for a read-only buffer, except that the 1024 byte limit mentioned above is avoided – so long as the buffer you pass is at least as long as what the operating system wants to put there, things should work.

If `mutate_flag` is true (the default), then the buffer is (in effect) passed to the underlying `ioctl()` system call, the latter's return code is passed back to the calling Python, and the buffer's new contents reflect the action of the `ioctl()`. This is a slight simplification, because if the supplied buffer is less than 1024 bytes long it is first copied into a static buffer 1024 bytes long which is then passed to `ioctl()` and copied back into the supplied buffer.

If the `ioctl()` fails, an `OSError` exception is raised.

An example:

```
>>> import array, fcntl, struct, termios, os
>>> os.getpgrp()
13341
>>> struct.unpack('h', fcntl.ioctl(0, termios.TIOCGPGRP, " "))[0]
13341
>>> buf = array.array('h', [0])
>>> fcntl.ioctl(0, termios.TIOCGPGRP, buf, 1)
0
>>> buf
array('h', [13341])
```

Raising an auditing event `fcntl.ioctl` with arguments `fd`, `request`, `arg`.

34.7. **fcntl** — The `fcntl` and `ioctl` system calls
fcntl.flock(fd, operation)
Perform the lock operation operation on file descriptor fd (file objects providing a fileno() method are accepted as well). See the Unix manual flock(2) for details. (On some systems, this function is emulated using fcntl().)

If the flock() fails, an OSError exception is raised.

Raises an auditing event fcntl.flock with arguments fd, operation.

fcntl.lockf(fd, cmd, len=0, start=0, whence=0)
This is essentially a wrapper around the fcntl() locking calls. fd is the file descriptor (file objects providing a fileno() method are accepted as well) of the file to lock or unlock, and cmd is one of the following values:

• LOCK_UN – unlock
• LOCK_SH – acquire a shared lock
• LOCK_EX – acquire an exclusive lock

When cmd is LOCK_SH or LOCK_EX, it can also be bitwise ORed with LOCK_NB to avoid blocking on lock acquisition. If LOCK_NB is used and the lock cannot be acquired, an OSError will be raised and the exception will have an errno attribute set to EACCES or EAGAIN (depending on the operating system; for portability, check for both values). On at least some systems, LOCK_EX can only be used if the file descriptor refers to a file opened for writing.

len is the number of bytes to lock, start is the byte offset at which the lock starts, relative to whence, and whence is as with io.IOBase.seek(), specifically:

• 0 – relative to the start of the file (os.SEEK_SET)
• 1 – relative to the current buffer position (os.SEEK_CUR)
• 2 – relative to the end of the file (os.SEEK_END)

The default for start is 0, which means to start at the beginning of the file. The default for len is 0 which means to lock to the end of the file. The default for whence is also 0.

Raises an auditing event fcntl.lockf with arguments fd, cmd, len, start, whence.

Examples (all on a SVR4 compliant system):

import struct, fcntl, os

f = open(...)  
rv = fcntl.fcntl(f, fcntl.F_SETFL, os.O_NDELAY)

lockdata = struct.pack('hhllhh', fcntl.F_WRLCK, 0, 0, 0, 0, 0)  
rv = fcntl.fcntl(f, fcntl.F_SETLK, lockdata)

Note that in the first example the return value variable rv will hold an integer value; in the second example it will hold a bytes object. The structure lay-out for the lockdata variable is system dependent — therefore using the flock() call may be better.

See also:

Module os If the locking flags _SHLOCK and _EXLOCK are present in the os module (on BSD only), the os.open() function provides an alternative to the lockf() and flock() functions.
This module provides basic mechanisms for measuring and controlling system resources utilized by a program. Symbolic constants are used to specify particular system resources and to request usage information about either the current process or its children.

An OSError is raised on syscall failure.

**exception** resource.error

A deprecated alias of OSError.

Changed in version 3.3: Following PEP 3151, this class was made an alias of OSError.

### 34.8.1 Resource Limits

Resources usage can be limited using the `setrlimit()` function described below. Each resource is controlled by a pair of limits: a soft limit and a hard limit. The soft limit is the current limit, and may be lowered or raised by a process over time. The soft limit can never exceed the hard limit. The hard limit can be lowered to any value greater than the soft limit, but not raised. (Only processes with the effective UID of the super-user can raise a hard limit.)

The specific resources that can be limited are system dependent. They are described in the `getrlimit(2)` man page. The resources listed below are supported when the underlying operating system supports them; resources which cannot be checked or controlled by the operating system are not defined in this module for those platforms.

**resource.RLIM_INFINITY**

Constant used to represent the limit for an unlimited resource.

**resource.getrlimit(resource)**

Returns a tuple `(soft, hard)` with the current soft and hard limits of `resource`. Raises ValueError if an invalid resource is specified, or error if the underlying system call fails unexpectedly.

**resource.setrlimit(resource, limits)**

Sets new limits of consumption of `resource`. The `limits` argument must be a tuple `(soft, hard)` of two integers describing the new limits. A value of RLIM_INFINITY can be used to request a limit that is unlimited.

Raises ValueError if an invalid resource is specified, if the new soft limit exceeds the hard limit, or if a process tries to raise its hard limit. Specifying a limit of RLIM_INFINITY when the hard or system limit for that resource is not unlimited will result in a ValueError. A process with the effective UID of super-user can request any valid limit value, including unlimited, but ValueError will still be raised if the requested limit exceeds the system imposed limit.

`setrlimit` may also raise error if the underlying system call fails.

VxWorks only supports setting RLIMIT_NOFILE.

Raises an auditing event resource.setrlimit with arguments resource, limits.

**resource.prlimit(pid, resource[, limits])**

Combines `setrlimit()` and `getrlimit()` in one function and supports to get and set the resources limits of an arbitrary process. If `pid` is 0, then the call applies to the current process. `resource` and `limits` have the same meaning as in `setrlimit()`, except that `limits` is optional.

When `limits` is not given the function returns the `resource` limit of the process `pid`. When `limits` is given the `resource` limit of the process is set and the former resource limit is returned.

Raises ProcessLookupError when `pid` can’t be found and PermissionError when the user doesn’t have CAP_SYS_RESOURCE for the process.

 Raises an auditing event resource.prlimit with arguments pid, resource, limits.

**Availability:** Linux 2.6.36 or later with glibc 2.13 or later.
New in version 3.4.

These symbols define resources whose consumption can be controlled using the `setrlimit()` and `getrlimit()` functions described below. The values of these symbols are exactly the constants used by C programs.

The Unix man page for `getrlimit(2)` lists the available resources. Note that not all systems use the same symbol or same value to denote the same resource. This module does not attempt to mask platform differences — symbols not defined for a platform will not be available from this module on that platform.

**resource.RLIMIT_CORE**
The maximum size (in bytes) of a core file that the current process can create. This may result in the creation of a partial core file if a larger core would be required to contain the entire process image.

**resource.RLIMIT_CPU**
The maximum amount of processor time (in seconds) that a process can use. If this limit is exceeded, a `SIGXCPU` signal is sent to the process. (See the `signal` module documentation for information about how to catch this signal and do something useful, e.g. flush open files to disk.)

**resource.RLIMITFSIZE**
The maximum size of a file which the process may create.

**resource.RLIMIT_DATA**
The maximum size (in bytes) of the process’s heap.

**resource.RLIMIT_STACK**
The maximum size (in bytes) of the call stack for the current process. This only affects the stack of the main thread in a multi-threaded process.

**resource.RLIMIT_RSS**
The maximum resident set size that should be made available to the process.

**resource.RLIMIT_NPROC**
The maximum number of processes the current process may create.

**resource.RLIMIT_NOFILE**
The maximum number of open file descriptors for the current process.

**resource.RLIMIT_OFI LE**
The BSD name for `RLIMIT_NOFILE`.

**resource.RLIMIT_MEMLOCK**
The maximum address space which may be locked in memory.

**resource.RLIMIT_VMEM**
The largest area of mapped memory which the process may occupy.

**resource.RLIMIT_AS**
The maximum area (in bytes) of address space which may be taken by the process.

**resource.RLIMIT_MSGQUEUE**
The number of bytes that can be allocated for POSIX message queues.

*Availability:* Linux 2.6.8 or later.

New in version 3.4.

**resource.RLIMIT_NICE**
The ceiling for the process’s nice level (calculated as 20 - rlim_cur).

*Availability:* Linux 2.6.12 or later.

New in version 3.4.

**resource.RLIMIT_RTPRIO**
The ceiling of the real-time priority.

*Availability:* Linux 2.6.12 or later.

New in version 3.4.
resource.RLIMIT_RTTIME
The time limit (in microseconds) on CPU time that a process can spend under real-time scheduling without making a blocking syscall.

Availability: Linux 2.6.25 or later.
New in version 3.4.

resource.RLIMIT_SIGPENDING
The number of signals which the process may queue.

Availability: Linux 2.6.8 or later.
New in version 3.4.

resource.RLIMIT_SBSIZE
The maximum size (in bytes) of socket buffer usage for this user. This limits the amount of network memory, and hence the amount of mbufs, that this user may hold at any time.

Availability: FreeBSD 9 or later.
New in version 3.4.

resource.RLIMIT_SWAP
The maximum size (in bytes) of the swap space that may be reserved or used by all of this user id's processes. This limit is enforced only if bit 1 of the vm.overcommit sysctl is set. Please see tuning(7) for a complete description of this sysctl.

Availability: FreeBSD 9 or later.
New in version 3.4.

resource.RLIMIT_NPTS
The maximum number of pseudo-terminals created by this user id.

Availability: FreeBSD 9 or later.
New in version 3.4.

resource.RLIMIT_KQUEUES
The maximum number of kqueues this user id is allowed to create.

Availability: FreeBSD 11 or later.
New in version 3.10.

34.8.2 Resource Usage

These functions are used to retrieve resource usage information:

resource.getusage(who)
This function returns an object that describes the resources consumed by either the current process or its children, as specified by the who parameter. The who parameter should be specified using one of the RUSAGE_* constants described below.

A simple example:

```python
from resource import *
import time

# a non CPU-bound task
time.sleep(3)
print(getusage(RUSAGE_SELF))

# a CPU-bound task
for i in range(10 ** 8):
```

(continues on next page)
The fields of the return value each describe how a particular system resource has been used, e.g. amount of

time spent running is user mode or number of times the process was swapped out of main memory. Some

values are dependent on the clock tick interval, e.g. the amount of memory the process is using.

For backward compatibility, the return value is also accessible as a tuple of 16 elements.

The fields ru_utime and ru_stime of the return value are floating point values representing the amount of
time spent executing in user mode and the amount of time spent executing in system mode, respectively. The
remaining values are integers. Consult the getrusage(2) man page for detailed information about these
values. A brief summary is presented here:

<table>
<thead>
<tr>
<th>Index</th>
<th>Field</th>
<th>Resource</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>ru_utime</td>
<td>time in user mode (float seconds)</td>
</tr>
<tr>
<td>1</td>
<td>ru_stime</td>
<td>time in system mode (float seconds)</td>
</tr>
<tr>
<td>2</td>
<td>ru_maxrss</td>
<td>maximum resident set size</td>
</tr>
<tr>
<td>3</td>
<td>ru_ixrss</td>
<td>shared memory size</td>
</tr>
<tr>
<td>4</td>
<td>ru_idrss</td>
<td>unshared memory size</td>
</tr>
<tr>
<td>5</td>
<td>ru_isrss</td>
<td>unshared stack size</td>
</tr>
<tr>
<td>6</td>
<td>ru_minflt</td>
<td>page faults not requiring I/O</td>
</tr>
<tr>
<td>7</td>
<td>ru_majflt</td>
<td>page faults requiring I/O</td>
</tr>
<tr>
<td>8</td>
<td>ru_nswap</td>
<td>number of swap outs</td>
</tr>
<tr>
<td>9</td>
<td>ru_inblock</td>
<td>block input operations</td>
</tr>
<tr>
<td>10</td>
<td>ru_oublock</td>
<td>block output operations</td>
</tr>
<tr>
<td>11</td>
<td>ru_msgsnd</td>
<td>messages sent</td>
</tr>
<tr>
<td>12</td>
<td>ru_msgrcv</td>
<td>messages received</td>
</tr>
<tr>
<td>13</td>
<td>ru_nsignals</td>
<td>signals received</td>
</tr>
<tr>
<td>14</td>
<td>ru_nvcsw</td>
<td>voluntary context switches</td>
</tr>
<tr>
<td>15</td>
<td>ru_nivcsw</td>
<td>involuntary context switches</td>
</tr>
</tbody>
</table>

This function will raise a ValueError if an invalid who parameter is specified. It may also raise error
exception in unusual circumstances.

resource.getpagesize()  
Returns the number of bytes in a system page. (This need not be the same as the hardware page size.)

The following RUSAGE_* symbols are passed to the getrusage() function to specify which processes informa-
tion should be provided for.

resource.RUSAGE_SELF  
Pass to getrusage() to request resources consumed by the calling process, which is the sum of resources
used by all threads in the process.

resource.RUSAGE_CHILDREN  
Pass to getrusage() to request resources consumed by child processes of the calling process which have
been terminated and waited for.

resource.RUSAGE_BOTH  
Pass to getrusage() to request resources consumed by both the current process and child processes. May
not be available on all systems.

resource.RUSAGE_THREAD  
Pass to getrusage() to request resources consumed by the current thread. May not be available on all
systems.

New in version 3.2.
34.9 syslog — Unix syslog library routines

This module provides an interface to the Unix syslog library routines. Refer to the Unix manual pages for a detailed description of the syslog facility.

This module wraps the system syslog family of routines. A pure Python library that can speak to a syslog server is available in the logging.handlers module as SysLogHandler.

The module defines the following functions:

**syslog.syslog**(message)

**syslog.syslog**(priority, message)

Send the string message to the system logger. A trailing newline is added if necessary. Each message is tagged with a priority composed of a facility and a level. The optional priority argument, which defaults to LOG_INFO, determines the message priority. If the facility is not encoded in priority using logical-or (LOG_INFO | LOG_USER), the value given in the openlog() call is used.

If openlog() has not been called prior to the call to syslog(), openlog() will be called with no arguments.

*Raises an auditing event* syslog.syslog with arguments priority, message.

**syslog.openlog**(ident[, logoption[, facility]])

Logging options of subsequent syslog() calls can be set by calling openlog(). syslog() will call openlog() with no arguments if the log is not currently open.

The optional ident keyword argument is a string which is prepended to every message, and defaults to sys.argv[0] with leading path components stripped. The optional logoption keyword argument (default is 0) is a bit field – see below for possible values to combine. The optional facility keyword argument (default is LOG_USER) sets the default facility for messages which do not have a facility explicitly encoded.

*Raises an auditing event* syslog.openlog with arguments ident, logoption, facility.

Changed in version 3.2: In previous versions, keyword arguments were not allowed, and ident was required. The default for ident was dependent on the system libraries, and often was python instead of the name of the Python program file.

**syslog.closelog**()

Reset the syslog module values and call the system library closelog().

This causes the module to behave as it does when initially imported. For example, openlog() will be called on the first syslog() call (if openlog() hasn’t already been called), and ident and other openlog() parameters are reset to defaults.

*Raises an auditing event* syslog.closelog with no arguments.

**syslog.setlogmask**(maskpri)

Set the priority mask to maskpri and return the previous mask value. Calls to syslog() with a priority level not set in maskpri are ignored. The default is to log all priorities. The function LOG_MASK(pri) calculates the mask for the individual priority pri. The function LOG_UPTO(pri) calculates the mask for all priorities up to and including pri.

*Raises an auditing event* syslog.setlogmask with argument maskpri.

The module defines the following constants:

**Priority levels (high to low):** LOG_EMERG, LOG_ALERT, LOG_CRIT, LOG_ERR, LOG_WARNING, LOG_NOTICE, LOG_INFO, LOG_DEBUG.

**Facilities:** LOG_KERN, LOG_USER, LOG_MAIL, LOG_DAEMON, LOG_AUTH, LOG_LPR, LOG_NEWS, LOG_UUCP, LOG_CRON, LOG_SYSLOG, LOG_LOCAL0 to LOG_LOCAL7, and, if defined in <syslog.h>, LOG_AUTHPRIV.

**Log options:** LOG_PID, LOG_CONS, LOG_NDELAY, and, if defined in <syslog.h>, LOG_ODELAY, LOG_NOWAIT, and LOG_PERROR.
34.9.1 Examples

Simple example

A simple set of examples:

```python
import syslog

syslog.syslog('Processing started')
if error:
    syslog.syslog(syslog.LOG_ERR, 'Processing started')
```

An example of setting some log options, these would include the process ID in logged messages, and write the messages to the destination facility used for mail logging:

```python
syslog.openlog(logoption=syslog.LOG_PID, facility=syslog.LOG_MAIL)
syslog.syslog('E-mail processing initiated...')
```
The modules described in this chapter are deprecated and only kept for backwards compatibility. They have been superseded by other modules.

35.1 aifc — Read and write AIFF and AIFC files

Source code: Lib/aifc.py

Deprecated since version 3.11: The `aifc` module is deprecated (see PEP 594 for details).

This module provides support for reading and writing AIFF and AIFF-C files. AIFF is Audio Interchange File Format, a format for storing digital audio samples in a file. AIFF-C is a newer version of the format that includes the ability to compress the audio data.

Audio files have a number of parameters that describe the audio data. The sampling rate or frame rate is the number of times per second the sound is sampled. The number of channels indicate if the audio is mono, stereo, or quadro. Each frame consists of one sample per channel. The sample size is the size in bytes of each sample. Thus a frame consists of `nchannels * samplesize` bytes, and a second’s worth of audio consists of `nchannels * samplesize * framerate` bytes.

For example, CD quality audio has a sample size of two bytes (16 bits), uses two channels (stereo) and has a frame rate of 44,100 frames/second. This gives a frame size of 4 bytes (2*2), and a second’s worth occupies `2*2*44100` bytes (176,400 bytes).

Module `aifc` defines the following function:

```
aifc.open(file, mode=None)
```

Open an AIFF or AIFF-C file and return an object instance with methods that are described below. The argument `file` is either a string naming a file or a `file object. mode` must be 'r' or 'rb' when the file must be opened for reading, or 'w' or 'wb' when the file must be opened for writing. If omitted, `file.mode` is used if it exists, otherwise 'rb' is used. When used for writing, the file object should be seekable, unless you know ahead of time how many samples you are going to write in total and use `writeframesraw()` and `setnframes()`. The `open()` function may be used in a `with` statement. When the `with` block completes, the `close()` method is called.

Changed in version 3.4: Support for the `with` statement was added.

Objects returned by `open()` when a file is opened for reading have the following methods:

```
aifc.getnchannels()
```

Return the number of audio channels (1 for mono, 2 for stereo).

```
aifc.getsampwidth()
```

Return the size in bytes of individual samples.

```
aifc.getframerate()
```

Return the sampling rate (number of audio frames per second).
The Python Library Reference, Release 3.10.4

```
aifc.getnframes()
    Return the number of audio frames in the file.

aifc.getcomptype()
    Return a bytes array of length 4 describing the type of compression used in the audio file. For AIFF files, the returned value is b'NONE'.

aifc.getcomppname()
    Return a bytes array convertible to a human-readable description of the type of compression used in the audio file. For AIFF files, the returned value is b'not compressed'.

aifc.getparams()
    Returns a namedtuple(nchannels, sampwidth, framerate, nframes, comptype, compname), equivalent to output of the get*() methods.

aifc.getmarkers()
    Return a list of markers in the audio file. A marker consists of a tuple of three elements. The first is the mark ID (an integer), the second is the mark position in frames from the beginning of the data (an integer), the third is the name of the mark (a string).

aifc.getmark(id)
    Return the tuple as described in getmarkers() for the mark with the given id.

aifc.readframes(nframes)
    Read and return the next nframes frames from the audio file. The returned data is a string containing for each frame the uncompressed samples of all channels.

aifc.rewind()
    Rewind the read pointer. The next readframes() will start from the beginning.

aifc.setpos(pos)
    Seek to the specified frame number.

aifc.tell()
    Return the current frame number.

aifc.close()
    Close the AIFF file. After calling this method, the object can no longer be used.

Objects returned by open() when a file is opened for writing have all the above methods, except for readframes() and setpos(). In addition the following methods exist. The get*() methods can only be called after the corresponding set*() methods have been called. Before the first writeframes() or writeframesraw(), all parameters except for the number of frames must be filled in.

aifc.aiff()
    Create an AIFF file. The default is that an AIFF-C file is created, unless the name of the file ends in '.aiff' in which case the default is an AIFF file.

aifc.aifc()
    Create an AIFF-C file. The default is that an AIFF-C file is created, unless the name of the file ends in '.aiff' in which case the default is an AIFF file.

aifc.setnchannels(nchannels)
    Specify the number of channels in the audio file.

aifc.setsampwidth(width)
    Specify the size in bytes of audio samples.

aifc.setframerate(rate)
    Specify the sampling frequency in frames per second.

aifc.setnframes(nframes)
    Specify the number of frames that are to be written to the audio file. If this parameter is not set, or not set correctly, the file needs to support seeking.
```
The Python Library Reference, Release 3.10.4

aifc. setcomptype (type, name)
Specify the compression type. If not specified, the audio data will not be compressed. In AIFF files, compression is not possible. The name parameter should be a human-readable description of the compression type as a bytes array, the type parameter should be a bytes array of length 4. Currently the following compression types are supported: b'NONE', b'ULAW', b'ALAW', b'G722'.

aifc. setparams (nchannels, sampwidth, framerate, comptype, compname)
Set all the above parameters at once. The argument is a tuple consisting of the various parameters. This means that it is possible to use the result of a getparams() call as argument to setparams().

aifc. setmark (id, pos, name)
Add a mark with the given id (larger than 0), and the given name at the given position. This method can be called at any time before close().

aifc. tell ()
Return the current write position in the output file. Useful in combination with setmark().

aifc. writeframes (data)
Write data to the output file. This method can only be called after the audio file parameters have been set.

aifc. writeframesraw (data)
Like writeframes(), except that the header of the audio file is not updated.

aifc. close ()
Close the AIFF file. The header of the file is updated to reflect the actual size of the audio data. After calling this method, the object can no longer be used.

35.2 asynchat — Asynchronous socket command/response handler

Source code: Lib/asynchat.py

Deprecated since version 3.6: asynchat will be removed in Python 3.12 (PEP 594). Please use asyncio instead.

Note: This module exists for backwards compatibility only. For new code we recommend using asyncio.

This module builds on the asyncore infrastructure, simplifying asynchronous clients and servers and making it easier to handle protocols whose elements are terminated by arbitrary strings, or are of variable length. asynchat defines the abstract class async_chat that you subclass, providing implementations of the collect_incoming_data() and found_terminator() methods. It uses the same asynchronous loop as asyncore, and the two types of channel, asyncore.dispatcher and asynchat.async_chat, can freely be mixed in the channel map. Typically an asyncore.dispatcher server channel generates new asynchat. async_chat channel objects as it receives incoming connection requests.

class asynchat.async_chat
This class is an abstract subclass of asyncore.dispatcher. To make practical use of the code you must subclass async_chat, providing meaningful collect_incoming_data() and found_terminator() methods. The asyncore.dispatcher methods can be used, although not all make sense in a message/response context.

Like asyncore.dispatcher, async_chat defines a set of events that are generated by an analysis of socket conditions after a select() call. Once the polling loop has been started the async_chat object's methods are called by the event-processing framework with no action on the part of the programmer.

Two class attributes can be modified, to improve performance, or possibly even to conserve memory.
The asynchronous input buffer size (default 4096).

The asynchronous output buffer size (default 4096).

Unlike `asyncore.dispatcher`, `async_chat` allows you to define a FIFO queue of producers. A producer need have only one method, `more()`, which should return data to be transmitted on the channel. The producer indicates exhaustion (i.e. that it contains no more data) by having its `more()` method return the empty bytes object. At this point the `async_chat` object removes the producer from the queue and starts using the next producer, if any. When the producer queue is empty the `handle_write()` method does nothing. You use the channel object’s `set_terminator()` method to describe how to recognize the end of, or an important breakpoint in, an incoming transmission from the remote endpoint.

To build a functioning `async_chat` subclass your input methods `collect_incoming_data()` and `found_terminator()` must handle the data that the channel receives asynchronously. The methods are described below.

```python
async_chat.close_when_done()
```

Pushes a `None` on to the producer queue. When this producer is popped off the queue it causes the channel to be closed.

```python
async_chat.collect_incoming_data(data)
```

Called with `data` holding an arbitrary amount of received data. The default method, which must be overridden, raises a `NotImplementedError` exception.

```python
async_chat.discard_buffers()
```

In emergencies this method will discard any data held in the input and/or output buffers and the producer queue.

```python
async_chat.found_terminator()
```

Called when the incoming data stream matches the termination condition set by `set_terminator()`. The default method, which must be overridden, raises a `NotImplementedError` exception. The buffered input data should be available via an instance attribute.

```python
async_chat.get_terminator()
```

Returns the current terminator for the channel.

```python
async_chat.push(data)
```

Pushes data on to the channel’s queue to ensure its transmission. This is all you need to do to have the channel write the data out to the network, although it is possible to use your own producers in more complex schemes to implement encryption and chunking, for example.

```python
async_chat.push_with_producer(producer)
```

Takes a producer object and adds it to the producer queue associated with the channel. When all currently-pushed producers have been exhausted the channel will consume this producer’s data by calling its `more()` method and send the data to the remote endpoint.

```python
async_chat.set_terminator(term)
```

Sets the terminating condition to be recognized on the channel. `term` may be any of three types of value, corresponding to three different ways to handle incoming protocol data.

<table>
<thead>
<tr>
<th>term</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>string</td>
<td>Will call <code>found_terminator()</code> when the string is found in the input stream</td>
</tr>
<tr>
<td>integer</td>
<td>Will call <code>found_terminator()</code> when the indicated number of characters have been received</td>
</tr>
<tr>
<td>None</td>
<td>The channel continues to collect data forever</td>
</tr>
</tbody>
</table>

Note that any data following the terminator will be available for reading by the channel after `found_terminator()` is called.
35.2.1 asynchat Example

The following partial example shows how HTTP requests can be read with `async_chat`. A web server might create an `http_request_handler` object for each incoming client connection. Notice that initially the channel terminator is set to match the blank line at the end of the HTTP headers, and a flag indicates that the headers are being read.

Once the headers have been read, if the request is of type POST (indicating that further data are present in the input stream) then the `Content-Length:` header is used to set a numeric terminator to read the right amount of data from the channel.

The `handle_request()` method is called once all relevant input has been marshalled, after setting the channel terminator to `None` to ensure that any extraneous data sent by the web client are ignored.

```python
def __init__(self, sock, addr, sessions, log):
    async_chat.async_chat.__init__(self, sock=sock)
    self.addr = addr
    self.sessions = sessions
    self.ibuffer = []
    self.obuffer = b"
    self.set_terminator(b"\r\n\r\n")
    self.reading_headers = True
    self.handle = False
    self.cgid = None
    self.log = log

def collect_incoming_data(self, data):
    """Buffer the data""
    self.ibuffer.append(data)

def found_terminator(self):
    if self.reading_headers:
        self.reading_headers = False
        self.parse_headers(b"".join(self.ibuffer))
        self.ibuffer = []
        if self.op.upper() == b"POST":
            clen = self.headers.getheader("content-length")
            self.set_terminator(int(clen))
        else:
            self.handle = True
            self.set_terminator(None)
            self.handle_request()
    elif not self.handle:
        self.set_terminator(None)  # browsers sometimes over-send
        self.cgid = parse(self.headers, b"".join(self.ibuffer))
        self.handle = True
        self.ibuffer = []
        self.handle_request()```

35.3 asyncore — Asynchronous socket handler

Source code: Lib/asyncore.py

Deprecated since version 3.6: asyncore will be removed in Python 3.12 (PEP 594). Please use asyncio instead.

Note: This module exists for backwards compatibility only. For new code we recommend using asyncio.

This module provides the basic infrastructure for writing asynchronous socket service clients and servers.

There are only two ways to have a program on a single processor do “more than one thing at a time.” Multi-threaded programming is the simplest and most popular way to do it, but there is another very different technique, that lets you have nearly all the advantages of multi-threading, without actually using multiple threads. It’s really only practical if your program is largely I/O bound. If your program is processor bound, then pre-emptive scheduled threads are probably what you really need. Network servers are rarely processor bound, however.

If your operating system supports the select() system call in its I/O library (and nearly all do), then you can use it to juggle multiple communication channels at once; doing other work while your I/O is taking place in the “background.” Although this strategy can seem strange and complex, especially at first, it is in many ways easier to understand and control than multi-threaded programming. The asyncore module solves many of the difficult problems for you, making the task of building sophisticated high-performance network servers and clients a snap. For “conversational” applications and protocols the companion asynchat module is invaluable.

The basic idea behind both modules is to create one or more network channels, instances of class asyncore.dispatcher and asynchat.async_chat. Creating the channels adds them to a global map, used by the loop() function if you do not provide it with your own map.

Once the initial channel(s) is(are) created, calling the loop() function activates channel service, which continues until the last channel (including any that have been added to the map during asynchronous service) is closed.

asyncore.loop([timeout[, use_poll[, map[, count]]]])

Enter a polling loop that terminates after count passes or all open channels have been closed. All arguments are optional. The count parameter defaults to None, resulting in the loop terminating only when all channels have been closed. The timeout argument sets the timeout parameter for the appropriate select() or poll() call, measured in seconds; the default is 30 seconds. The use_poll parameter, if true, indicates that poll() should be used in preference to select() (the default is False).

The map parameter is a dictionary whose items are the channels to watch. As channels are closed they are deleted from their map. If map is omitted, a global map is used. Channels (instances of asyncore.dispatcher, asynchat.async_chat and subclasses thereof) can freely be mixed in the map.

class asyncore.dispatcher

The dispatcher class is a thin wrapper around a low-level socket object. To make it more useful, it has a few methods for event-handling which are called from the asynchronous loop. Otherwise, it can be treated as a normal non-blocking socket object.

The firing of low-level events at certain times or in certain connection states tells the asynchronous loop that certain higher-level events have taken place. For example, if we have asked for a socket to connect to another host, we know that the connection has been made when the socket becomes writable for the first time (at this point you know that you may write to it with the expectation of success). The implied higher-level events are:

<table>
<thead>
<tr>
<th>Event</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>handle_connect()</td>
<td>Implied by the first read or write event</td>
</tr>
<tr>
<td>handle_close()</td>
<td>Implied by a read event with no data available</td>
</tr>
<tr>
<td>handle_accepted()</td>
<td>Implied by a read event on a listening socket</td>
</tr>
</tbody>
</table>

During asynchronous processing, each mapped channel’s readable() and writable() methods are used to determine whether the channel’s socket should be added to the list of channels select()ed or poll()ed for read and write events.
Thus, the set of channel events is larger than the basic socket events. The full set of methods that can be overridden in your subclass follows:

**handle_read()**
Called when the asynchronous loop detects that a `read()` call on the channel’s socket will succeed.

**handle_write()**
Called when the asynchronous loop detects that a writable socket can be written. Often this method will implement the necessary buffering for performance. For example:

```python
def handle_write(self):
    sent = self.send(self.buffer)
    self.buffer = self.buffer[sent:]
```

**handle_expt()**
Called when there is out of band (OOB) data for a socket connection. This will almost never happen, as OOB is tenuously supported and rarely used.

**handle_connect()**
Called when the active opener’s socket actually makes a connection. Might send a “welcome” banner, or initiate a protocol negotiation with the remote endpoint, for example.

**handle_close()**
Called when the socket is closed.

**handle_error()**
Called when an exception is raised and not otherwise handled. The default version prints a condensed traceback.

**handle_accept()**
Called on listening channels (passive openers) when a connection can be established with a new remote endpoint that has issued a `connect()` call for the local endpoint. Deprecated in version 3.2; use `handle_accepted()` instead.

Deprecated since version 3.2.

**handle_accepted(sock, addr)**
Called on listening channels (passive openers) when a connection has been established with a new remote endpoint that has issued a `connect()` call for the local endpoint. `sock` is a new socket object usable to send and receive data on the connection, and `addr` is the address bound to the socket on the other end of the connection.

New in version 3.2.

**readable()**
Called each time around the asynchronous loop to determine whether a channel’s socket should be added to the list on which read events can occur. The default method simply returns `True`, indicating that by default, all channels will be interested in read events.

**writable()**
Called each time around the asynchronous loop to determine whether a channel’s socket should be added to the list on which write events can occur. The default method simply returns `True`, indicating that by default, all channels will be interested in write events.

In addition, each channel delegates or extends many of the socket methods. Most of these are nearly identical to their socket partners.

**create_socket(family=socket.AF_INET, type=socket.SOCK_STREAM)**
This is identical to the creation of a normal socket, and will use the same options for creation. Refer to the `socket` documentation for information on creating sockets.

Changed in version 3.3: `family` and `type` arguments can be omitted.

**connect(address)**
As with the normal socket object, `address` is a tuple with the first element the host to connect to, and the second the port number.
**send**(data)
Send *data* to the remote end-point of the socket.

**recv**(buffer_size)
Read at most *buffer_size* bytes from the socket’s remote end-point. An empty bytes object implies that the channel has been closed from the other end.

Note that **recv()** may raise **BlockingIOError**, even though **select.select()** or **select.poll()** has reported the socket ready for reading.

**listen**(backlog)
Listen for connections made to the socket. The *backlog* argument specifies the maximum number of queued connections and should be at least 1; the maximum value is system-dependent (usually 5).

**bind**(address)
Bind the socket to *address*. The socket must not already be bound. (The format of *address* depends on the address family — refer to the socket documentation for more information.) To mark the socket as reusable (setting the SO_REUSEADDR option), call the dispatcher object’s **set_reuse_addr()** method.

**accept()**
Accept a connection. The socket must be bound to an address and listening for connections. The return value can be either None or a pair (conn, address) where *conn* is a new socket object usable to send and receive data on the connection, and *address* is the address bound to the socket on the other end of the connection. When None is returned it means the connection didn’t take place, in which case the server should just ignore this event and keep listening for further incoming connections.

**close()**
Close the socket. All future operations on the socket object will fail. The remote end-point will receive no more data (after queued data is flushed). Sockets are automatically closed when they are garbage-collected.

**class** asyncore.dispatcher_with_send
A **dispatcher** subclass which adds simple buffered output capability, useful for simple clients. For more sophisticated usage use **asyncio.async_chat**.

**class** asyncore.file_dispatcher
A **file_dispatcher** takes a file descriptor or **file object** along with an optional map argument and wraps it for use with the **poll()** or **loop()** functions. If provided a file object or anything with a **fileno()** method, that method will be called and passed to the **file_wrapper** constructor.

**Availability**: Unix.

**class** asyncore.file_wrapper
A **file_wrapper** takes an integer file descriptor and calls **os.dup()** to duplicate the handle so that the original handle may be closed independently of the **file_wrapper**. This class implements sufficient methods to emulate a socket for use by the **file_dispatcher** class.

**Availability**: Unix.

### 35.3.1 asyncore Example basic HTTP client

Here is a very basic HTTP client that uses the **dispatcher** class to implement its socket handling:

```python
import asyncio

class HTTPClient(asyncore.dispatcher):
    def __init__(self, host, path):
        asyncio.dispatcher.__init__(self)
        self.create_socket()
        self.connect((host, 80))
        self.buffer = bytes('GET %s HTTP/1.0\r\nHost: %s\r\n\r\n' %
```

(continues on next page)
(continued from previous page)

```python
def handle_connect(self):
    pass

def handle_close(self):
    self.close()

def handle_read(self):
    print(self.recv(8192))

def writable(self):
    return (len(self.buffer) > 0)

def handle_write(self):
    sent = self.send(self.buffer)
    self.buffer = self.buffer[:sent]
```

```python
client = HTTPClient('www.python.org', '/')
asyncore.loop()
```

35.3.2 asyncore Example basic echo server

Here is a basic echo server that uses the `dispatcher` class to accept connections and dispatches the incoming connections to a handler:

```python
import asyncore

class EchoHandler(asyncore.dispatcher_with_send):
    def handle_read(self):
        data = self.recv(8192)
        if data:
            self.send(data)

class EchoServer(asyncore.dispatcher):
    def __init__(self, host, port):
        asyncore.dispatcher.__init__(self)
        self.create_socket()
        self.set_reuse_addr()
        self.bind((host, port))
        self.listen(5)

    def handle_accepted(self, self, sock, addr):
        print('Incoming connection from %s' % repr(addr))
        handler = EchoHandler(sock)

server = EchoServer('localhost', 8080)
asyncore.loop()
```
35.4 audioop — Manipulate raw audio data

Deprecated since version 3.11: The audioop module is deprecated (see PEP 594 for details).

The audioop module contains some useful operations on sound fragments. It operates on sound fragments consisting of signed integer samples 8, 16, 24 or 32 bits wide, stored in bytes-like objects. All scalar items are integers, unless specified otherwise.

Changed in version 3.4: Support for 24-bit samples was added. All functions now accept any bytes-like object. String input now results in an immediate error.

This module provides support for a-LAW, u-LAW and Intel/DVI ADPCM encodings. A few of the more complicated operations only take 16-bit samples, otherwise the sample size (in bytes) is always a parameter of the operation.

The module defines the following variables and functions:

```python
exception audioop.error
This exception is raised on all errors, such as unknown number of bytes per sample, etc.

audioop.add(fragment1, fragment2, width)
Return a fragment which is the addition of the two samples passed as parameters. width is the sample width in bytes, either 1, 2, 3 or 4. Both fragments should have the same length. Samples are truncated in case of overflow.

audioop.adpcm2lin(adpcmfragment, width, state)
Decode an Intel/DVI ADPCM coded fragment to a linear fragment. See the description of lin2adpcm() for details on ADPCM coding. Return a tuple (sample, newstate) where the sample has the width specified in width.

audioop.alaw2lin(fragment, width)
Convert sound fragments in a-LAW encoding to linearly encoded sound fragments. a-LAW encoding always uses 8 bits samples, so width refers only to the sample width of the output fragment here.

audioop.avg(fragment, width)
Return the average over all samples in the fragment.

audioop.avgpp(fragment, width)
Return the average peak-peak value over all samples in the fragment. No filtering is done, so the usefulness of this routine is questionable.

audioop.bias(fragment, width, bias)
Return a fragment that is the original fragment with a bias added to each sample. Samples wrap around in case of overflow.

audioop.byteswap(fragment, width)
"Byteswap" all samples in a fragment and returns the modified fragment. Converts big-endian samples to little-endian and vice versa.
New in version 3.4.

audioop.cross(fragment, width)
Return the number of zero crossings in the fragment passed as an argument.

audioop.findfactor(fragment, reference)
Return a factor F such that \( \text{rms}(\text{add}(\text{fragment}, \text{mul}(\text{reference}, -F))) \) is minimal, i.e., return the factor with which you should multiply reference to make it match as well as possible to fragment. The fragments should both contain 2-byte samples.

The time taken by this routine is proportional to \( \text{len(fragment)} \).

audioop.findfit(fragment, reference)
Try to match reference as well as possible to a portion of fragment (which should be the longer fragment). This is (conceptually) done by taking slices out of fragment, using findfactor() to compute the best match,
and minimizing the result. The fragments should both contain 2-byte samples. Return a tuple \((\text{offset}, \text{factor})\) where \(\text{offset}\) is the (integer) offset into \text{fragment} where the optimal match started and \(\text{factor}\) is the (floating-point) factor as per \text{findfactor()}.

\text{audioop}.\text{findmax}(\text{fragment}, \text{length})

Search \text{fragment} for a slice of length \text{length} samples (not bytes!) with maximum energy, i.e., return \(i\) for which \(\text{rms}([\text{fragment}[i*2:(i+\text{length})*2]])\) is maximal. The fragments should both contain 2-byte samples.

The routine takes time proportional to \(\text{len}(\text{fragment})\).

\text{audioop}.\text{getsample}(\text{fragment}, \text{width}, \text{index})

Return the value of sample \text{index} from the fragment.

\text{audioop}.\text{lin2adpcm}(\text{fragment}, \text{width}, \text{state})

Convert samples to 4 bit Intel/DVI ADPCM encoding. ADPCM coding is an adaptive coding scheme, whereby each 4 bit number is the difference between one sample and the next, divided by a (varying) step. The Intel/DVI ADPCM algorithm has been selected for use by the IMA, so it may well become a standard.

\text{state} is a tuple containing the state of the coder. The coder returns a tuple \((\text{adpcmfrag}, \text{newstate})\), and the \text{newstate} should be passed to the next call of \text{lin2adpcm()}. In the initial call, \text{None} can be passed as the state. \text{adpcmfrag} is the ADPCM coded fragment packed 2 4-bit values per byte.

\text{audioop}.\text{lin2alaw}(\text{fragment}, \text{width})

Convert samples in the audio fragment to a-LAW encoding and return this as a bytes object. a-LAW is an audio encoding format whereby you get a dynamic range of about 13 bits using only 8 bit samples. It is used by the Sun audio hardware, among others.

\text{audioop}.\text{lin2lin}(\text{fragment}, \text{width}, \text{newwidth})

Convert samples between 1-, 2-, 3- and 4-byte formats.

\textbf{Note:} In some audio formats, such as .WAV files, 16, 24 and 32 bit samples are signed, but 8 bit samples are unsigned. So when converting to 8 bit wide samples for these formats, you need to also add 128 to the result:

\begin{verbatim}
new_frames = audioop.lin2lin(frames, old_width, 1)
new_frames = audioop.bias(new_frames, 1, 128)
\end{verbatim}

The same, in reverse, has to be applied when converting from 8 to 16, 24 or 32 bit width samples.

\text{audioop}.\text{lin2ulaw}(\text{fragment}, \text{width})

Convert samples in the audio fragment to u-LAW encoding and return this as a bytes object. u-LAW is an audio encoding format whereby you get a dynamic range of about 14 bits using only 8 bit samples. It is used by the Sun audio hardware, among others.

\text{audioop}.\text{max}(\text{fragment}, \text{width})

Return the maximum of the absolute value of all samples in a fragment.

\text{audioop}.\text{maxpp}(\text{fragment}, \text{width})

Return the maximum peak-peak value in the sound fragment.

\text{audioop}.\text{minmax}(\text{fragment}, \text{width})

Return a tuple consisting of the minimum and maximum values of all samples in the sound fragment.

\text{audioop}.\text{mul}(\text{fragment}, \text{width}, \text{factor})

Return a fragment that has all samples in the original fragment multiplied by the floating-point value \text{factor}. Samples are truncated in case of overflow.

\text{audioop}.\text{ratecv}(\text{fragment}, \text{width}, \text{nchannels}, \text{inrate}, \text{outrate}, \text{state}[\text{weightA}[\text{weightB}]])

Convert the frame rate of the input fragment.

\text{state} is a tuple containing the state of the converter. The converter returns a tuple \((\text{newfragment}, \text{newstate})\), and \text{newstate} should be passed to the next call of \text{ratecv()}. The initial call should pass \text{None} as the state.
The weightA and weightB arguments are parameters for a simple digital filter and default to 1 and 0 respectively.

**audioop.reverse(fragment, width)**
Reverse the samples in a fragment and returns the modified fragment.

**audioop.rms(fragment, width)**
Return the root-mean-square of the fragment, i.e. \( \sqrt{\frac{\text{sum}(S_i^2)}{n}} \).

This is a measure of the power in an audio signal.

**audioop.tomono(fragment, width, lfactor, rfactor)**
Convert a stereo fragment to a mono fragment. The left channel is multiplied by lfactor and the right channel by rfactor before adding the two channels to give a mono signal.

**audioop.tostereo(fragment, width, lfactor, rfactor)**
Generate a stereo fragment from a mono fragment. Each pair of samples in the stereo fragment are computed from the mono sample, whereby left channel samples are multiplied by lfactor and right channel samples by rfactor.

**audioop.ulaw2lin(fragment, width)**
Convert sound fragments in u-LAW encoding to linearly encoded sound fragments. u-LAW encoding always uses 8 bits samples, so width refers only to the sample width of the output fragment here.

Note that operations such as mul() or max() make no distinction between mono and stereo fragments, i.e. all samples are treated equal. If this is a problem the stereo fragment should be split into two mono fragments first and recombined later. Here is an example of how to do that:

```python
def mul_stereo(sample, width, lfactor, rfactor):
    lsample = audioop.tomono(sample, width, 1, 0)
    rsample = audioop.tomono(sample, width, 0, 1)
    lsample = audioop.mul(lsample, width, lfactor)
    rsample = audioop.mul(rsample, width, rfactor)
    lsample = audioop.tostereo(lsample, width, 1, 0)
    rsample = audioop.tostereo(rsample, width, 0, 1)
    return audioop.add(lsample, rsample, width)
```

If you use the ADPCM coder to build network packets and you want your protocol to be stateless (i.e. to be able to tolerate packet loss) you should not only transmit the data but also the state. Note that you should send the initial state (the one you passed to lin2adpcm()) along to the decoder, not the final state (as returned by the coder). If you want to use struct.Struct to store the state in binary you can code the first element (the predicted value) in 16 bits and the second (the delta index) in 8.

The ADPCM coders have never been tried against other ADPCM coders, only against themselves. It could well be that I misinterpreted the standards in which case they will not be interoperable with the respective standards.

The find*() routines might look a bit funny at first sight. They are primarily meant to do echo cancellation. A reasonably fast way to do this is to pick the most energetic piece of the output sample, locate that in the input sample and subtract the whole output sample from the input sample:

```python
def echocancel(outputdata, inputdata):
    pos = audioop.findmax(outputdata, 800)  # one tenth second
    out_test = outputdata[pos*2:]
    in_test = inputdata[pos*2:]
    ipos, factor = audioop.findfit(in_test, out_test)
    # Optional (for better cancellation):
    # factor = audioop.findfactor(in_test[ipos*2:ipos*2+len(out_test)],
    # out_test)
    pref = '\0'*(pos+ipos+2)
    post = '\0'*(len(inputdata)-len(pref)+len(outputdata))
    outputdata = pref + audioop.mul(outputdata, 2, -factor) + post
    return audioop.add(inputdata, outputdata, 2)
```
35.5 cgi — Common Gateway Interface support

Source code: Lib/cgi.py

Deprecated since version 3.11: The `cgi` module is deprecated (see PEP 594 for details).

Support module for Common Gateway Interface (CGI) scripts.

This module defines a number of utilities for use by CGI scripts written in Python.

35.5.1 Introduction

A CGI script is invoked by an HTTP server, usually to process user input submitted through an HTML `<FORM>` or `<ISINDEX>` element.

Most often, CGI scripts live in the server's special `cgi-bin` directory. The HTTP server places all sorts of information about the request (such as the client's hostname, the requested URL, the query string, and lots of other goodies) in the script's shell environment, executes the script, and sends the script's output back to the client.

The script's input is connected to the client too, and sometimes the form data is read this way; at other times the form data is passed via the “query string” part of the URL. This module is intended to take care of the different cases and provide a simpler interface to the Python script. It also provides a number of utilities that help in debugging scripts, and the latest addition is support for file uploads from a form (if your browser supports it).

The output of a CGI script should consist of two sections, separated by a blank line. The first section contains a number of headers, telling the client what kind of data is following. Python code to generate a minimal header section looks like this:

```python
print("Content-Type: text/html")   # HTML is following
print()                           # blank line, end of headers
```

The second section is usually HTML, which allows the client software to display nicely formatted text with header, in-line images, etc. Here's Python code that prints a simple piece of HTML:

```python
print("<TITLE>CGI script output</TITLE>")
print("<H1>This is my first CGI script</H1>")
print("Hello, world!")
```

35.5.2 Using the cgi module

Begin by writing `import cgi`.

When you write a new script, consider adding these lines:

```python
import cgitb
cgitb.enable()
```

This activates a special exception handler that will display detailed reports in the web browser if any errors occur. If you'd rather not show the guts of your program to users of your script, you can have the reports saved to files instead, with code like this:

```python
import cgitb
cgitb.enable(display=0, logdir="/path/to/logdir")
```

It's very helpful to use this feature during script development. The reports produced by `cgitb` provide information that can save you a lot of time in tracking down bugs. You can always remove the `cgitb` line later when you have tested your script and are confident that it works correctly.
To get at submitted form data, use the `FieldStorage` class. If the form contains non-ASCII characters, use the `encoding` keyword parameter set to the value of the encoding defined for the document. It is usually contained in the `META` tag in the HEAD section of the HTML document or by the `Content-Type` header. This reads the form contents from the standard input or the environment (depending on the value of various environment variables set according to the CGI standard). Since it may consume standard input, it should be instantiated only once.

The `FieldStorage` instance can be indexed like a Python dictionary. It allows membership testing with the `in` operator, and also supports the standard dictionary method `keys()` and the built-in function `len()`. Form fields containing empty strings are ignored and do not appear in the dictionary; to keep such values, provide a true value for the optional `keep_blank_values` keyword parameter when creating the `FieldStorage` instance.

For instance, the following code (which assumes that the `Content-Type` header and blank line have already been printed) checks that the fields `name` and `addr` are both set to a non-empty string:

```python
form = cgi.FieldStorage()
if "name" not in form or "addr" not in form:
    print("<H1>Error</H1>"
print("Please fill in the name and addr fields.")
return
print("<p>name:", form["name"].value)
print("<p>addr:", form["addr"].value)
...further form processing here...
```

Here the fields, accessed through `form[key]`, are themselves instances of `FieldStorage` (or `MiniFieldStorage`, depending on the form encoding). The `value` attribute of the instance yields the string value of the field. The `getvalue()` method returns this string value directly; it also accepts an optional second argument as a default to return if the requested key is not present.

If the submitted form data contains more than one field with the same name, the object retrieved by `form[key]` is not a `FieldStorage` or `MiniFieldStorage` instance but a list of such instances. Similarly, in this situation, `form.getvalue(key)` would return a list of strings. If you expect this possibility (when your HTML form contains multiple fields with the same name), use the `getlist()` method, which always returns a list of values (so that you do not need to special-case the single item case). For example, this code concatenates any number of `username` fields, separated by commas:

```python
value = form.getlist("username")
usernames = ",".join(value)
```

If a field represents an uploaded file, accessing the value via the `value` attribute or the `getvalue()` method reads the entire file in memory as bytes. This may not be what you want. You can test for an uploaded file by testing either the `filename` attribute or the `file` attribute. You can then read the data from the `file` attribute before it is automatically closed as part of the garbage collection of the `FieldStorage` instance (the `read()` and `readline()` methods will return bytes):

```python
fileitem = form["userfile"]
if fileitem.file:
    # It's an uploaded file; count lines
    linecount = 0
    while True:
        line = fileitem.file.readline()
        if not line: break
        linecount = linecount + 1
```

FieldStorage objects also support being used in a `with` statement, which will automatically close them when done.

If an error is encountered when obtaining the contents of an uploaded file (for example, when the user interrupts the form submission by clicking on a Back or Cancel button) the `done` attribute of the object for the field will be set to the value `-1.`

The file upload draft standard entertains the possibility of uploading multiple files from one field (using a recursive `multipart/*` encoding). When this occurs, the item will be a dictionary-like `FieldStorage` item. This can be
determined by testing its type attribute, which should be multipart/form-data (or perhaps another MIME type matching multipart/*). In this case, it can be iterated over recursively just like the top-level form object.

When a form is submitted in the “old” format (as the query string or as a single data part of type application/x-www-form-urlencoded), the items will actually be instances of the class MiniFieldStorage. In this case, the list, file, and filename attributes are always None.

A form submitted via POST that also has a query string will contain both FieldStorage and MiniFieldStorage items.

Changed in version 3.4: The file attribute is automatically closed upon the garbage collection of the creating FieldStorage instance.

Changed in version 3.5: Added support for the context management protocol to the FieldStorage class.

### 35.5.3 Higher Level Interface

The previous section explains how to read CGI form data using the FieldStorage class. This section describes a higher level interface which was added to this class to allow one to do it in a more readable and intuitive way. The interface doesn’t make the techniques described in previous sections obsolete — they are still useful to process file uploads efficiently, for example.

The interface consists of two simple methods. Using the methods you can process form data in a generic way, without the need to worry whether only one or more values were posted under one name.

In the previous section, you learned to write following code anytime you expected a user to post more than one value under one name:

```python
item = form.getvalue("item")
if isinstance(item, list):
    # The user is requesting more than one item.
else:
    # The user is requesting only one item.
```

This situation is common for example when a form contains a group of multiple checkboxes with the same name:

```
<input type="checkbox" name="item" value="1" />
<input type="checkbox" name="item" value="2" />
```

In most situations, however, there’s only one form control with a particular name in a form and then you expect and need only one value associated with this name. So you write a script containing for example this code:

```python
user = form.getvalue("user").upper()
```

The problem with the code is that you should never expect that a client will provide valid input to your scripts. For example, if a curious user appends another user=foo pair to the query string, then the script would crash, because in this situation the getvalue("user") method call returns a list instead of a string. Calling the upper() method on a list is not valid (since lists do not have a method of this name) and results in an AttributeError exception.

Therefore, the appropriate way to read form data values was to always use the code which checks whether the obtained value is a single value or a list of values. That’s annoying and leads to less readable scripts.

A more convenient approach is to use the methods getfirst() and getlist() provided by this higher level interface.

**FieldStorage.getfirst**(name, default=None)

This method always returns only one value associated with form field name. The method returns only the first value in case that more values were posted under such name. Please note that the order in which the values are received may vary from browser to browser and should not be counted on.¹ If no such form field or value

¹ Note that some recent versions of the HTML specification do state what order the field values should be supplied in, but knowing whether a request was received from a conforming browser, or even from a browser at all, is tedious and error-prone.
exists then the method returns the value specified by the optional parameter default. This parameter defaults to None if not specified.

FieldStorage.getlist(name)

This method always returns a list of values associated with form field name. The method returns an empty list if no such form field or value exists for name. It returns a list consisting of one item if only one such value exists.

Using these methods you can write nice compact code:

```python
import cgi
form = cgi.FieldStorage()
user = form.getfirst("user", ").upper()  # This way it's safe.
for item in form.getlist("item"):
    do_something(item)
```

### 35.5.4 Functions

These are useful if you want more control, or if you want to employ some of the algorithms implemented in this module in other circumstances.

**cgi.parse** (fp=None, environ=os.environ, keep_blank_values=False, strict_parsing=False, separator='&')

Parse a query in the environment or from a file (the file defaults to sys.stdin). The keep_blank_values, strict_parsing and separator parameters are passed to urllib.parse.parse_qs() unchanged.

**cgi.parse_multipart** (fp, pdict, encoding='utf-8', errors='replace', separator='&')

Parse input of type multipart/form-data (for file uploads). Arguments are fp for the input file, pdict for a dictionary containing other parameters in the Content-Type header, and encoding, the request encoding.

Returns a dictionary just like urllib.parse.parse_qs(): keys are the field names, each value is a list of values for that field. For non-file fields, the value is a list of strings.

This is easy to use but not much good if you are expecting megabytes to be uploaded — in that case, use the FieldStorage class instead which is much more flexible.

Changed in version 3.7: Added the encoding and errors parameters. For non-file fields, the value is now a list of strings, not bytes.

Changed in version 3.10: Added the separator parameter.

**cgi.parse_header** (string)

Parse a MIME header (such as Content-Type) into a main value and a dictionary of parameters.

**cgi.test**()

Robust test CGI script, usable as main program. Writes minimal HTTP headers and formats all information provided to the script in HTML format.

**cgi.print_environ**()

Format the shell environment in HTML.

**cgi.print_form** (form)

Format a form in HTML.

**cgi.print_directory**()

Format the current directory in HTML.

**cgi.print_environ_usage**()

Print a list of useful (used by CGI) environment variables in HTML.
35.5.5 Caring about security

There’s one important rule: if you invoke an external program (via \texttt{os.system()}, \texttt{os.popen()} or other functions with similar functionality), make very sure you don’t pass arbitrary strings received from the client to the shell. This is a well-known security hole whereby clever hackers anywhere on the web can exploit a gullible CGI script to invoke arbitrary shell commands. Even parts of the URL or field names cannot be trusted, since the request doesn’t have to come from your form!

To be on the safe side, if you must pass a string gotten from a form to a shell command, you should make sure the string contains only alphanumeric characters, dashes, underscores, and periods.

35.5.6 Installing your CGI script on a Unix system

Read the documentation for your HTTP server and check with your local system administrator to find the directory where CGI scripts should be installed; usually this is in a directory \texttt{cgi-bin} in the server tree.

Make sure that your script is readable and executable by “others”; the Unix file mode should be \texttt{0o755} octal (use \texttt{chmod 0755 filename}). Make sure that the first line of the script contains \texttt{#!/} starting in column 1 followed by the pathname of the Python interpreter, for instance:

\begin{verbatim}
#!/usr/local/bin/python
\end{verbatim}

Make sure the Python interpreter exists and is executable by “others”.

Make sure that any files your script needs to read or write are readable or writable, respectively, by “others” — their mode should be \texttt{0o644} for readable and \texttt{0o666} for writable. This is because, for security reasons, the HTTP server executes your script as user “nobody”, without any special privileges. It can only read (write, execute) files that everybody can read (write, execute). The current directory at execution time is also different (it is usually the server’s cgi-bin directory) and the set of environment variables is also different from what you get when you log in. In particular, don’t count on the shell’s search path for executables (\texttt{PATH}) or the Python module search path (\texttt{PYTHONPATH}) to be set to anything interesting.

If you need to load modules from a directory which is not on Python’s default module search path, you can change the path in your script, before importing other modules. For example:

\begin{verbatim}
import sys
sys.path.insert(0, "/usr/home/joe/lib/python")
sys.path.insert(0, "/usr/local/lib/python")
\end{verbatim}

(This way, the directory inserted last will be searched first!)

Instructions for non-Unix systems will vary; check your HTTP server’s documentation (it will usually have a section on CGI scripts).

35.5.7 Testing your CGI script

Unfortunately, a CGI script will generally not run when you try it from the command line, and a script that works perfectly from the command line may fail mysteriously when run from the server. There’s one reason why you should still test your script from the command line: if it contains a syntax error, the Python interpreter won’t execute it at all, and the HTTP server will most likely send a cryptic error to the client.

Assuming your script has no syntax errors, yet it does not work, you have no choice but to read the next section.
35.5.8 Debugging CGI scripts

First of all, check for trivial installation errors — reading the section above on installing your CGI script carefully can save you a lot of time. If you wonder whether you have understood the installation procedure correctly, try installing a copy of this module file (cgi.py) as a CGI script. When invoked as a script, the file will dump its environment and the contents of the form in HTML format. Give it the right mode etc., and send it a request. If it's installed in the standard cgi-bin directory, it should be possible to send it a request by entering a URL into your browser of the form:

```
http://yourhostname/cgi-bin/cgi.py?name=Joe+Blow&addr=At+Home
```

If this gives an error of type 404, the server cannot find the script — perhaps you need to install it in a different directory. If it gives another error, there's an installation problem that you should fix before trying to go any further. If you get a nicely formatted listing of the environment and form content (in this example, the fields should be listed as “addr” with value “At Home” and “name” with value “Joe Blow”), the cgi.py script has been installed correctly. If you follow the same procedure for your own script, you should now be able to debug it.

The next step could be to call the cgi module's test() function from your script: replace its main code with the single statement

```
cgi.test()
```

This should produce the same results as those gotten from installing the cgi.py file itself.

When an ordinary Python script raises an unhandled exception (for whatever reason: of a typo in a module name, a file that can’t be opened, etc.), the Python interpreter prints a nice traceback and exits. While the Python interpreter will still do this when your CGI script raises an exception, most likely the traceback will end up in one of the HTTP server's log files, or be discarded altogether.

Fortunately, once you have managed to get your script to execute some code, you can easily send tracebacks to the web browser using the cgitb module. If you haven’t done so already, just add the lines:

```
import cgitb
cgitb.enable()
```

to the top of your script. Then try running it again; when a problem occurs, you should see a detailed report that will likely make apparent the cause of the crash.

If you suspect that there may be a problem in importing the cgitb module, you can use an even more robust approach (which only uses built-in modules):

```
import sys
sys.stderr = sys.stdout
print("Content-Type: text/plain")
print()
...your code here...
```

This relies on the Python interpreter to print the traceback. The content type of the output is set to plain text, which disables all HTML processing. If your script works, the raw HTML will be displayed by your client. If it raises an exception, most likely after the first two lines have been printed, a traceback will be displayed. Because no HTML interpretation is going on, the traceback will be readable.
35.5.9 Common problems and solutions

- Most HTTP servers buffer the output from CGI scripts until the script is completed. This means that it is not possible to display a progress report on the client's display while the script is running.
- Check the installation instructions above.
- Check the HTTP server's log files. `tail -f logfile` in a separate window may be useful!
- Always check a script for syntax errors first, by doing something like `python script.py`.
- If your script does not have any syntax errors, try adding `import cgitb; cgitb.enable()` to the top of the script.
- When invoking external programs, make sure they can be found. Usually, this means using absolute path names — `PATH` is usually not set to a very useful value in a CGI script.
- When reading or writing external files, make sure they can be read or written by the userid under which your CGI script will be running: this is typically the userid under which the web server is running, or some explicitly specified userid for a web server's `suexec` feature.
- Don’t try to give a CGI script a set-uid mode. This doesn’t work on most systems, and is a security liability as well.

35.6 cgitb — Traceback manager for CGI scripts

Source code: Lib/cgitb.py

Deprecated since version 3.11: The `cgitb` module is deprecated (see PEP 594 for details).

The `cgitb` module provides a special exception handler for Python scripts. (Its name is a bit misleading. It was originally designed to display extensive traceback information in HTML for CGI scripts. It was later generalized to also display this information in plain text.) After this module is activated, if an uncaught exception occurs, a detailed, formatted report will be displayed. The report includes a traceback showing excerpts of the source code for each level, as well as the values of the arguments and local variables to currently running functions, to help you debug the problem. Optionally, you can save this information to a file instead of sending it to the browser.

To enable this feature, simply add this to the top of your CGI script:

```python
import cgitb
cgitb.enable()
```

The options to the `enable()` function control whether the report is displayed in the browser and whether the report is logged to a file for later analysis.

`cgitb.enable(display=1, logdir=None, context=5, format='html')`

This function causes the `cgitb` module to take over the interpreter's default handling for exceptions by setting the value of `sys.excepthook`.

The optional argument `display` defaults to `1` and can be set to `0` to suppress sending the traceback to the browser. If the argument `logdir` is present, the traceback reports are written to files. The value of `logdir` should be a directory where these files will be placed. The optional argument `context` is the number of lines of context to display around the current line of source code in the traceback; this defaults to `5`. If the optional argument `format` is "html", the output is formatted as HTML. Any other value forces plain text output. The default value is "html".

`cgitb.text(info, context=5)`

This function handles the exception described by `info` (a 3-tuple containing the result of `sys.exc_info()`), formatting its traceback as text and returning the result as a string. The optional argument `context` is the number of lines of context to display around the current line of source code in the traceback; this defaults to `5`. 
cgitb.html (info, context=5)

This function handles the exception described by info (a 3-tuple containing the result of sys.exc_info()), formatting its traceback as HTML and returning the result as a string. The optional argument context is the number of lines of context to display around the current line of source code in the traceback; this defaults to 5.

cgitb.handler (info=None)

This function handles an exception using the default settings (that is, show a report in the browser, but don't log to a file). This can be used when you've caught an exception and want to report it using cgitb. The optional info argument should be a 3-tuple containing an exception type, exception value, and traceback object, exactly like the tuple returned by sys.exc_info(). If the info argument is not supplied, the current exception is obtained from sys.exc_info().

35.7 chunk — Read IFF chunked data

Source code: Lib/chunk.py

Deprecated since version 3.11: The chunk module is deprecated (see PEP 594 for details).

This module provides an interface for reading files that use EA IFF 85 chunks.1 This format is used in at least the Audio Interchange File Format (AIFF/AIFF-C) and the Real Media File Format (RMFF). The WAVE audio file format is closely related and can also be read using this module.

A chunk has the following structure:

<table>
<thead>
<tr>
<th>Offset</th>
<th>Length</th>
<th>Contents</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>4</td>
<td>Chunk ID</td>
</tr>
<tr>
<td>4</td>
<td>4</td>
<td>Size of chunk in big-endian byte order, not including the header</td>
</tr>
<tr>
<td>8</td>
<td>n</td>
<td>Data bytes, where n is the size given in the preceding field</td>
</tr>
<tr>
<td>8 + n</td>
<td>0 or 1</td>
<td>Pad byte needed if n is odd and chunk alignment is used</td>
</tr>
</tbody>
</table>

The ID is a 4-byte string which identifies the type of chunk.

The size field (a 32-bit value, encoded using big-endian byte order) gives the size of the chunk data, not including the 8-byte header.

Usually an IFF-type file consists of one or more chunks. The proposed usage of the Chunk class defined here is to instantiate an instance at the start of each chunk and read from the instance until it reaches the end, after which a new instance can be instantiated. At the end of the file, creating a new instance will fail with an EOFError exception.

class chunk.Chunk (file, align=True, bigendian=True, inclheader=False)

Class which represents a chunk. The file argument is expected to be a file-like object. An instance of this class is specifically allowed. The only method that is needed is read(). If the methods seek() and tell() are present and don't raise an exception, they are also used. If these methods are present and raise an exception, they are expected to not have altered the object. If the optional argument align is true, chunks are assumed to be aligned on 2-byte boundaries. If align is false, no alignment is assumed. The default value is true. If the optional argument bigendian is false, the chunk size is assumed to be in little-endian order. This is needed for WAVE audio files. The default value is true. If the optional argument inclheader is true, the size given in the chunk header includes the size of the header. The default value is false.

A Chunk object supports the following methods:

getname ()

Returns the name (ID) of the chunk. This is the first 4 bytes of the chunk.

getsize ()

Returns the size of the chunk.

close()

Close and skip to the end of the chunk. This does not close the underlying file.

The remaining methods will raise OSError if called after the close() method has been called. Before Python 3.3, they used to raise IOError, now an alias of OSError.

isatty()

Returns False.

seek(pos, whence=0)

Set the chunk’s current position. The whence argument is optional and defaults to 0 (absolute file positioning); other values are 1 (seek relative to the current position) and 2 (seek relative to the file’s end). There is no return value. If the underlying file does not allow seek, only forward seeks are allowed.

tell()

Return the current position into the chunk.

read(size=-1)

Read at most size bytes from the chunk (less if the read hits the end of the chunk before obtaining size bytes). If the size argument is negative or omitted, read all data until the end of the chunk. An empty bytes object is returned when the end of the chunk is encountered immediately.

skip()

Skip to the end of the chunk. All further calls to read() for the chunk will return b''. If you are not interested in the contents of the chunk, this method should be called so that the file points to the start of the next chunk.

35.8 crypt — Function to check Unix passwords

Source code: Lib/crypt.py

Deprecated since version 3.11: The crypt module is deprecated (see PEP 594 for details).

This module implements an interface to the crypt(3) routine, which is a one-way hash function based upon a modified DES algorithm; see the Unix man page for further details. Possible uses include storing hashed passwords so you can check passwords without storing the actual password, or attempting to crack Unix passwords with a dictionary.

Notice that the behavior of this module depends on the actual implementation of the crypt(3) routine in the running system. Therefore, any extensions available on the current implementation will also be available on this module.

Availability: Unix. Not available on VxWorks.

35.8.1 Hashing Methods

New in version 3.3.

The crypt module defines the list of hashing methods (not all methods are available on all platforms):

crypt.METHOD_SHA512

A Modular Crypt Format method with 16 character salt and 86 character hash based on the SHA-512 hash function. This is the strongest method.

crypt.METHOD_SHA256

Another Modular Crypt Format method with 16 character salt and 43 character hash based on the SHA-256 hash function.

crypt.METHOD_BLOWFISH

Another Modular Crypt Format method with 22 character salt and 31 character hash based on the Blowfish cipher.
New in version 3.7.

```
crypt.METHOD_MD5
```

Another Modular Crypt Format method with 8 character salt and 22 character hash based on the MD5 hash function.

```
crypt.METHOD_CRYPT
```

The traditional method with a 2 character salt and 13 characters of hash. This is the weakest method.

### 35.8.2 Module Attributes

New in version 3.3.

```
crypt.methods
```

A list of available password hashing algorithms, as `crypt.METHOD_*` objects. This list is sorted from strongest to weakest.

### 35.8.3 Module Functions

The `crypt` module defines the following functions:

```
crypt.crypt(word, salt=None)
```

`word` will usually be a user’s password as typed at a prompt or in a graphical interface. The optional `salt` is either a string as returned from `mksalt()`, one of the `crypt.METHOD_*` values (though not all may be available on all platforms), or a full encrypted password including salt, as returned by this function. If `salt` is not provided, the strongest method will be used (as returned by `methods()`).

Checking a password is usually done by passing the plain-text password as `word` and the full results of a previous `crypt()` call, which should be the same as the results of this call.

`salt` (either a random 2 or 16 character string, possibly prefixed with `$digit$` to indicate the method) which will be used to perturb the encryption algorithm. The characters in `salt` must be in the set `[./a-zA-Z0-9]`, with the exception of Modular Crypt Format which prefixes a `$digit$`.

Returns the hashed password as a string, which will be composed of characters from the same alphabet as the salt.

Since a few `crypt(3)` extensions allow different values, with different sizes in the `salt`, it is recommended to use the full encrypted password as salt when checking for a password.

Changed in version 3.3: Accept `crypt.METHOD_*` values in addition to strings for `salt`.

```
crypt.mksalt(method=None, *, rounds=None)
```

Return a randomly generated salt of the specified method. If no `method` is given, the strongest method available as returned by `methods()` is used.

The return value is a string suitable for passing as the `salt` argument to `crypt()`.

`rounds` specifies the number of rounds for `METHOD_SHA256`, `METHOD_SHA512` and `METHOD_BLOWFISH`. For `METHOD_SHA256` and `METHOD_SHA512` it must be an integer between 1000 and 999_999_999, the default is 5000. For `METHOD_BLOWFISH` it must be a power of two between 16 ($2^4$) and $2_{147,483,648} (2^{41})$, the default is 4096 ($2^{12}$).

New in version 3.3.

Changed in version 3.7: Added the `rounds` parameter.
35.8.4 Examples

A simple example illustrating typical use (a constant-time comparison operation is needed to limit exposure to timing attacks. `hmac.compare_digest()` is suitable for this purpose):

```python
import pwd
import crypt
import getpass
from hmac import compare_digest as compare_hash

def login():
    username = input('Python login: ')
cryptedpasswd = pwd.getpwnam(username)[1]
    if cryptedpasswd:
        if cryptedpasswd == 'x' or cryptedpasswd == '*':
            raise ValueError('no support for shadow passwords')
cleartext = getpass.getpass()
        return compare_hash(crypt.crypt(cleartext, cryptedpasswd), cryptedpasswd)
    else:
        return True
```

To generate a hash of a password using the strongest available method and check it against the original:

```python
import crypt
from hmac import compare_digest as compare_hash

hashed = crypt.crypt(plaintext)
if not compare_hash(hashed, crypt.crypt(plaintext, hashed)):
    raise ValueError("hashed version doesn't validate against original")
```

35.9 `imghdr` — Determine the type of an image

Source code: Lib/imghdr.py

Deprecated since version 3.11: The `imghdr` module is deprecated (see PEP 594 for details).

The `imghdr` module determines the type of image contained in a file or byte stream.

The `imghdr` module defines the following function:

`imghdr.what(file, h=None)`

Tests the image data contained in the file named by `file`, and returns a string describing the image type. If optional `h` is provided, the `file` argument is ignored and `h` is assumed to contain the byte stream to test.

Changed in version 3.6: Accepts a `path-like object`.

The following image types are recognized, as listed below with the return value from `what()`:
New in version 3.5: The `exr` and `webp` formats were added.

You can extend the list of file types `imghdr` can recognize by appending to this variable:

```python
imghdr.tests
```

A list of functions performing the individual tests. Each function takes two arguments: the byte-stream and an open file-like object. When `what()` is called with a byte-stream, the file-like object will be `None`.

The test function should return a string describing the image type if the test succeeded, or `None` if it failed.

Example:

```python
>>> import imghdr
>>> imghdr.what('bass.gif')
'gif'
```

### 35.10 `imp` — Access the import internals

Source code: Lib/imp.py

Deprecated since version 3.4: The `imp` module is deprecated in favor of `importlib`.

This module provides an interface to the mechanisms used to implement the `import` statement. It defines the following constants and functions:

```python
imp.get_magic()
```

Return the magic string value used to recognize byte-compiled code files (.pyc files). (This value may be different for each Python version.)

Deprecated since version 3.4: Use `importlib.util.MAGIC_NUMBER` instead.

```python
imp.get_suffixes()
```

Return a list of 3-element tuples, each describing a particular type of module. Each triple has the form `(suffix, mode, type)`, where `suffix` is a string to be appended to the module name to form the filename to search for, `mode` is the mode string to pass to the built-in `open()` function to open the file (this can be `'r'` for text files or `'rb'` for binary files), and `type` is the file type, which has one of the values `PY_SOURCE`, `PY_COMPILED`, or `C_EXTENSION`, described below.

Deprecated since version 3.3: Use the constants defined on `importlib.machinery` instead.

```python
imp.find_module(name[, path])
```

Try to find the module `name`. If `path` is omitted or `None`, the list of directory names given by `sys.path` is searched, but first a few special places are searched: the function tries to find a built-in module with the

---

<table>
<thead>
<tr>
<th>Value</th>
<th>Image format</th>
</tr>
</thead>
<tbody>
<tr>
<td>‘rgb’</td>
<td>SGI ImgLib Files</td>
</tr>
<tr>
<td>‘gif’</td>
<td>GIF 87a and 89a Files</td>
</tr>
<tr>
<td>‘pbm’</td>
<td>Portable Bitmap Files</td>
</tr>
<tr>
<td>‘pgm’</td>
<td>Portable Graymap Files</td>
</tr>
<tr>
<td>‘ppm’</td>
<td>Portable Pixmap Files</td>
</tr>
<tr>
<td>‘tiff’</td>
<td>TIFF Files</td>
</tr>
<tr>
<td>‘rast’</td>
<td>Sun Raster Files</td>
</tr>
<tr>
<td>‘xbm’</td>
<td>X Bitmap Files</td>
</tr>
<tr>
<td>‘jpeg’</td>
<td>JPEG data in JFIF or Exif formats</td>
</tr>
<tr>
<td>‘bmp’</td>
<td>BMP files</td>
</tr>
<tr>
<td>‘png’</td>
<td>Portable Network Graphics</td>
</tr>
<tr>
<td>‘webp’</td>
<td>WebP files</td>
</tr>
<tr>
<td>‘exr’</td>
<td>OpenEXR Files</td>
</tr>
</tbody>
</table>
given name (C_BUILTIN), then a frozen module (PY_FROZEN), and on some systems some other places are looked in as well (on Windows, it looks in the registry which may point to a specific file).

Otherwise, path must be a list of directory names; each directory is searched for files with any of the suffixes returned by get_suffixes() above. Invalid names in the list are silently ignored (but all list items must be strings).

If search is successful, the return value is a 3-element tuple (file, pathname, description):

- file is an open file object positioned at the beginning,
- pathname is the pathname of the file found, and
- description is a 3-element tuple as contained in the list returned by get_suffixes() describing the kind of module found.

If the module is built-in or frozen then file and pathname are both None and the description tuple contains empty strings for its suffix and mode; the module type is indicated as given in parentheses above. If the search is unsuccessful, ImportError is raised. Other exceptions indicate problems with the arguments or environment.

If the module is a package, file is None, pathname is the package path and the last item in the description tuple is PKG_DIRECTORY.

This function does not handle hierarchical module names (names containing dots). In order to find P.M, that is, submodule M of package P, use find_module() and load_module() to find and load package P, and then use find_module() with the path argument set to P.__path__. When P itself has a dotted name, apply this recipe recursively.

Deprecated since version 3.3: Use importlib.util.find_spec() instead unless Python 3.3 compatibility is required, in which case use importlib.find_loader(). For example usage of the former case, see the Examples section of the importlib documentation.

imp.load_module (name, file, pathname, description)
Load a module that was previously found by find_module() (or by an otherwise conducted search yielding compatible results). This function does more than importing the module: if the module was already imported, it will reload the module! The name argument indicates the full module name (including the package name, if this is a submodule of a package). The file argument is an open file, and pathname is the corresponding file name; these can be None and '' respectively, when the module is a package or not being loaded from a file.

The description argument is a tuple, as would be returned by get_suffixes(), describing what kind of module must be loaded.

If the load is successful, the return value is the module object; otherwise, an exception (usually ImportError) is raised.

Important: the caller is responsible for closing the file argument, if it was not None, even when an exception is raised. This is best done using a try ... finally statement.

Deprecated since version 3.3: If previously used in conjunction with imp.find_module() then consider using importlib.import_module(), otherwise use the loader returned by the replacement you chose for imp.find_module(). If you called imp.load_module() and related functions directly with file path arguments then use a combination of importlib.util.spec_from_file_location() and importlib.util.module_from_spec(). See the Examples section of the importlib documentation for details of the various approaches.

imp.new_module (name)
Return a new empty module object called name. This object is not inserted in sys.modules.

Deprecated since version 3.4: Use importlib.util.module_from_spec() instead.

imp.reload (module)
Reload a previously imported module. The argument must be a module object, so it must have been successfully imported before. This is useful if you have edited the module source file using an external editor and want to try out the new version without leaving the Python interpreter. The return value is the module object (the same as the module argument).

When reload(module) is executed:
• Python modules' code is recompiled and the module-level code reexecuted, defining a new set of objects which are bound to names in the module's dictionary. The `init` function of extension modules is not called a second time.

• As with all other objects in Python the old objects are only reclaimed after their reference counts drop to zero.

• The names in the module namespace are updated to point to any new or changed objects.

• Other references to the old objects (such as names external to the module) are not rebound to refer to the new objects and must be updated in each namespace where they occur if that is desired.

There are a number of other caveats:

When a module is reloaded, its dictionary (containing the module's global variables) is retained. Redefinitions of names will override the old definitions, so this is generally not a problem. If the new version of a module does not define a name that was defined by the old version, the old definition remains. This feature can be used to the module's advantage if it maintains a global table or cache of objects — with a `try` statement it can test for the table's presence and skip its initialization if desired:

```python
try:
    cache
except NameError:
    cache = {}
```

It is legal though generally not very useful to reload built-in or dynamically loaded modules, except for `sys`, `__main__` and `builtins`. In many cases, however, extension modules are not designed to be initialized more than once, and may fail in arbitrary ways when reloaded.

If a module imports objects from another module using `from ... import ...`, calling `reload()` for the other module does not redefine the objects imported from it — one way around this is to re-execute the `from` statement, another is to use `import` and qualified names (`module.*name*`) instead.

If a module instantiates instances of a class, reloading the module that defines the class does not affect the method definitions of the instances — they continue to use the old class definition. The same is true for derived classes.

Changed in version 3.3: Relies on both `__name__` and `__loader__` being defined on the module being reloaded instead of just `__name__`.

Depreciated since version 3.4: Use `importlib.reload()` instead.

The following functions are conveniences for handling PEP 3147 byte-compiled file paths.

New in version 3.2.

`imp.cache_from_source(path, debug_override=None)`

Return the PEP 3147 path to the byte-compiled file associated with the source `path`. For example, if `path` is `/foo/bar/baz.py` the return value would be `/foo/bar/__pycache__/baz.cpython-32.pyc` for Python 3.2. The `cpython-32` string comes from the current magic tag (see `get_tag()`); if `sys.implementation.cache_tag` is not defined then `NotImplementedError` will be raised.

By passing in `True` or `False` for `debug_override` you can override the system's value for `__debug__`, leading to optimized bytecode.

`path` need not exist.

Changed in version 3.3: If `sys.implementation.cache_tag` is None, then `NotImplementedError` is raised.

Deprecated since version 3.4: Use `importlib.util.cache_from_source()` instead.

Changed in version 3.5: The `debug_override` parameter no longer creates a `.pyc` file.

`imp.source_from_cache(path)`

Given the `path` to a PEP 3147 file name, return the associated source code file path. For example, if `path` is
The returned path would be `/foo/bar/baz.py`. If `path` need not exist, however if it does not conform to PEP 3147 format, a `ValueError` is raised. If `sys.implementation.cache_tag` is not defined, `NotImplementedError` is raised.

Changed in version 3.3: Raise `NotImplementedError` when `sys.implementation.cache_tag` is not defined.

Deprecated since version 3.4: Use `importlib.util.source_from_cache()` instead.

```python
imp.get_tag()
```

Return the PEP 3147 magic tag string matching this version of Python's magic number, as returned by `get_magic()`.

Deprecated since version 3.4: Use `sys.implementation.cache_tag` directly starting in Python 3.3.

The following functions help interact with the import system’s internal locking mechanism. Locking semantics of imports are an implementation detail which may vary from release to release. However, Python ensures that circular imports work without any deadlocks.

```python
imp.lock_held()
```

Return `True` if the global import lock is currently held, else `False`. On platforms without threads, always return `False`.

On platforms with threads, a thread executing an import first holds a global import lock, then sets up a per-module lock for the rest of the import. This blocks other threads from importing the same module until the original import completes, preventing other threads from seeing incomplete module objects constructed by the original thread. An exception is made for circular imports, which by construction have to expose an incomplete module object at some point.

Changed in version 3.3: The locking scheme has changed to per-module locks for the most part. A global import lock is kept for some critical tasks, such as initializing the per-module locks.

Deprecated since version 3.4.

```python
imp.acquire_lock()
```

Acquire the interpreter’s global import lock for the current thread. This lock should be used by import hooks to ensure thread-safety when importing modules.

Once a thread has acquired the import lock, the same thread may acquire it again without blocking: the thread must release it once for each time it has acquired it.

On platforms without threads, this function does nothing.

Changed in version 3.3: The locking scheme has changed to per-module locks for the most part. A global import lock is kept for some critical tasks, such as initializing the per-module locks.

Deprecated since version 3.4.

```python
imp.release_lock()
```

Release the interpreter’s global import lock. On platforms without threads, this function does nothing.

Changed in version 3.3: The locking scheme has changed to per-module locks for the most part. A global import lock is kept for some critical tasks, such as initializing the per-module locks.

Deprecated since version 3.4.

The following constants with integer values, defined in this module, are used to indicate the search result of `find_module()`.

```python
imp.PY_SOURCE
```

The module was found as a source file.

Deprecated since version 3.3.

```python
imp.PY_COMPILED
```

The module was found as a compiled code object file.

Deprecated since version 3.3.
imp.C_EXTENSION
The module was found as dynamically loadable shared library.
Deprecated since version 3.3.

imp.PKG_DIRECTORY
The module was found as a package directory.
Deprecated since version 3.3.

imp.C_BUILTIN
The module was found as a built-in module.
Deprecated since version 3.3.

imp.PY_FROZEN
The module was found as a frozen module.
Deprecated since version 3.3.

class imp.NullImporter(path_string)
The NullImporter type is a PEP 302 import hook that handles non-directory path strings by failing to find any modules. Calling this type with an existing directory or empty string raises ImportError. Otherwise, a NullImporter instance is returned.

Instances have only one method:
find_module(fullname[, path])
This method always returns None, indicating that the requested module could not be found.

Changed in version 3.3: None is inserted into sys.path_importer_cache instead of an instance of NullImporter.

Deprecated since version 3.4: Insert None into sys.path_importer_cache instead.

35.10.1 Examples
The following function emulates what was the standard import statement up to Python 1.4 (no hierarchical module names). (This implementation wouldn’t work in that version, since find_module() has been extended and load_module() has been added in 1.4.)

```python
import imp
import sys

def __import__(name, globals=None, locals=None, fromlist=None):
    # Fast path: see if the module has already been imported.
    try:
        return sys.modules[name]
    except KeyError:
        pass

    # If any of the following calls raises an exception,
    # there's a problem we can't handle -- let the caller handle it.
    fp, pathname, description = imp.find_module(name)

    try:
        return imp.load_module(name, fp, pathname, description)
    finally:
        # Since we may exit via an exception, close fp explicitly.
        if fp:
            fp.close()
```

Chapter 35. Superseded Modules
35.11 msilib — Read and write Microsoft Installer files

Source code: Lib/msilib/__init__.py

Deprecated since version 3.11: The msilib module is deprecated (see PEP 594 for details).

The msilib supports the creation of Microsoft Installer (.msi) files. Because these files often contain an embedded "cabinet" file (.cab), it also exposes an API to create CAB files. Support for reading .cab files is currently not implemented; read support for the .msi database is possible.

This package aims to provide complete access to all tables in an .msi file, therefore, it is a fairly low-level API. Two primary applications of this package are the distutils command bdist_msi, and the creation of Python installer package itself (although that currently uses a different version of msilib).

The package contents can be roughly split into four parts: low-level CAB routines, low-level MSI routines, higher-level MSI routines, and standard table structures.

msilib.FCICreate(cabname, files)
Create a new CAB file named cabname. files must be a list of tuples, each containing the name of the file on disk, and the name of the file inside the CAB file.

The files are added to the CAB file in the order they appear in the list. All files are added into a single CAB file, using the MSZIP compression algorithm.

Call backs to Python for the various steps of MSI creation are currently not exposed.

msilib.UuidCreate()
Return the string representation of a new unique identifier. This wraps the Windows API functions UuidCreate() and UuidToString().

msilib.OpenDatabase(path, persist)
Return a new database object by calling MsiOpenDatabase. path is the file name of the MSI file; persist can be one of the constants MSIDBOPEN_CREATEDIRECT, MSIDBOPEN>Create, MSIDBOPEN DIRECT, MSIDBOPEN_READONLY, or MSIDBOPEN TRANSACTION, and may include the flag MSIDBOPEN_PATCHFILE. See the Microsoft documentation for the meaning of these flags; depending on the flags, an existing database is opened, or a new one created.

msilib.CreateRecord(count)
Return a new record object by calling MSICreateRecord(). count is the number of fields of the record.

msilib.init_database(name, schema, ProductName, ProductCode, ProductVersion, Manufacturer)
Create and return a new database name, initialize it with schema, and set the properties ProductName, ProductCode, ProductVersion, and Manufacturer.

schema must be a module object containing tables and _Validation_records attributes; typically, msilib.schema should be used.

The database will contain just the schema and the validation records when this function returns.

msilib.add_data(database, table, records)
Add all records to the table named table in database.

The table argument must be one of the predefined tables in the MSI schema, e.g. 'Feature', 'File', 'Component', 'Dialog', 'Control', etc.

records should be a list of tuples, each one containing all fields of a record according to the schema of the table. For optional fields, None can be passed.

Field values can be ints, strings, or instances of the Binary class.

class msilib.Binary(filename)
Represents entries in the Binary table; inserting such an object using add_data() reads the file named filename into the table.
**msilib.add_tables** *(database, module)*

Add all table content from *module* to *database*. *module* must contain an attribute *tables* listing all tables for which content should be added, and one attribute per table that has the actual content.

This is typically used to install the sequence tables.

**msilib.add_stream** *(database, name, path)*

Add the file *path* into the _Stream table of *database*, with the stream name *name*.

**msilib.gen_uuid()**

Return a new UUID, in the format that MSI typically requires (i.e. in curly braces, and with all hexdigits in upper-case).

**See also:**

FCICreate UuidCreate UuidToString

### 35.11.1 Database Objects

**Database.OpenView** *(sql)*

Return a view object, by calling MSIDatabaseOpenView(). *sql* is the SQL statement to execute.

**Database.Commit**

Commit the changes pending in the current transaction, by calling MSIDatabaseCommit().

**Database.GetSummaryInformation** *(count)*

Return a new summary information object, by calling MsiGetSummaryInformation(). *count* is the maximum number of updated values.

**Database.Close**

Close the database object, through MsiCloseHandle().

New in version 3.7.

**See also:**

MSIDatabaseOpenView MSIDatabaseCommit MSIGetSummaryInformation MsiCloseHandle

### 35.11.2 View Objects

**View.Execute** *(params)*

Execute the SQL query of the view, through MSIViewExecute(). If *params* is not None, it is a record describing actual values of the parameter tokens in the query.

**View.GetColumnInfo** *(kind)*

Return a record describing the columns of the view, through calling MsiViewGetColumnInfo(). *kind* can be either MSICOLINFO_NAMES or MSICOLINFO_TYPES.

**View.Fetch**

Return a result record of the query, through calling MsiViewFetch().

**View.Modify** *(kind, data)*

Modify the view, by calling MsiViewModify(). *kind* can be one of MSIMODIFY_SEEK, MSIMODIFY_REFRESH, MSIMODIFY_INSERT, MSIMODIFY_UPDATE, MSIMODIFY_ASSIGN, MSIMODIFY_REPLACE, MSIMODIFY_MERGE, MSIMODIFY_DELETE, MSIMODIFY_INSERT_TEMPORARY, MSIMODIFY_VALIDATE, MSIMODIFY_VALIDATE_NEW, MSIMODIFY_VALIDATE_FIELD, or MSIMODIFY_VALIDATE_DELETE.

*data* must be a record describing the new data.

**View.Close**

Close the view, through MsiViewClose().
35.11.3 Summary Information Objects

**SummaryInformation.GetProperty(field)**
Return a property of the summary, through `MsiSummaryInfoGetProperty()`. `field` is the name of the property, and can be one of the constants `PID_CODEPAGE`, `PID_TITLE`, `PID_SUBJECT`, `PID_AUTHOR`, `PID_KEYWORDS`, `PID_COMMENTS`, `PID_TEMPLATE`, `PID_LASTAUTHOR`, `PID_REVNUMBER`, `PID_LASTPRINTED`, `PID_CREATE_DTM`, `PID_LASTSAVE_DTM`, `PID_PAGECOUNT`, `PID_WORDCOUNT`, `PID_CHARCOUNT`, `PID_APPNAME`, or `PID_SECURITY`.

**SummaryInformation.GetPropertyCount()**
Return the number of summary properties, through `MsiSummaryInfoGetPropertyCount()`.

**SummaryInformation SetProperty(field, value)**
Set a property through `MsiSummaryInfoSetProperty()`. `field` can have the same values as in `GetProperty()`, `value` is the new value of the property. Possible value types are integer and string.

**SummaryInformation Persist()**
Write the modified properties to the summary information stream, using `MsiSummaryInfoPersist()`.

See also:
`MsiSummaryInfoGetProperty` `MsiSummaryInfoGetPropertyCount` `MsiSummaryInfoSetProperty` `MsiSummaryInfoPersist`

35.11.4 Record Objects

**Record.GetFieldCount()**
Return the number of fields of the record, through `MsiRecordGetFieldCount()`.

**Record.GetInteger(field)**
Return the value of `field` as an integer where possible. `field` must be an integer.

**Record.GetString(field)**
Return the value of `field` as a string where possible. `field` must be an integer.

**Record.SetString(field, value)**
Set `field` to `value` through `MsiRecordSetString()`. `field` must be an integer; `value` a string.

**Record.SetStream(field, value)**
Set `field` to the contents of the file named `value`, through `MsiRecordSetStream()`. `field` must be an integer; `value` a string.

**Record.SetInteger(field, value)**
Set `field` to `value` through `MsiRecordSetInteger()`. Both `field` and `value` must be an integer.

**Record.ClearData()**
Set all fields of the record to 0, through `MsiRecordClearData()`.

See also:
`MsiRecordGetFieldCount` `MsiRecordSetString` `MsiRecordSetStream` `MsiRecordSetInteger` `MsiRecordClearData`
35.11.5 Errors

All wrappers around MSI functions raise `MSIError`; the string inside the exception will contain more detail.

35.11.6 CAB Objects

```python
class msilib.CAB(name)
```

The class `CAB` represents a CAB file. During MSI construction, files will be added simultaneously to the `Files` table, and to a CAB file. Then, when all files have been added, the CAB file can be written, then added to the MSI file.

`name` is the name of the CAB file in the MSI file.

```python
append(full, file, logical)
```

Add the file with the pathname `full` to the CAB file, under the name `logical`. If there is already a file named `logical`, a new file name is created.

Return the index of the file in the CAB file, and the new name of the file inside the CAB file.

```python
commit(database)
```

Generate a CAB file, add it as a stream to the MSI file, put it into the `Media` table, and remove the generated file from the disk.

35.11.7 Directory Objects

```python
class msilib.Directory(database, cab, basedir, physical, logical, default[, componentflags])
```

Create a new directory in the Directory table. There is a current component at each point in time for the directory, which is either explicitly created through `start_component()`, or implicitly when files are added for the first time. Files are added into the current component, and into the cab file. To create a directory, a base directory object needs to be specified (can be `None`), the path to the physical directory, and a logical directory name. `default` specifies the DefaultDir slot in the directory table. `componentflags` specifies the default flags that new components get.

```python
start_component(component=None, feature=None, flags=None, keyfile=None, uuid=None)
```

Add an entry to the Component table, and make this component the current component for this directory. If no component name is given, the directory name is used. If no `feature` is given, the current feature is used. If no `flags` are given, the directory’s default flags are used. If no `keyfile` is given, the KeyPath is left null in the Component table.

```python
add_file(file, src=None, version=None, language=None)
```

Add a file to the current component of the directory, starting a new one if there is no current component. By default, the file name in the source and the file table will be identical. If the `src` file is specified, it is interpreted relative to the current directory. Optionally, a `version` and a `language` can be specified for the entry in the File table.

```python
glob(pattern, exclude=None)
```

Add a list of files to the current component as specified in the glob pattern. Individual files can be excluded in the `exclude` list.

```python
remove_pyc()
```

Remove `.pyc` files on uninstall.

See also:

Directory Table File Table Component Table FeatureComponents Table
35.11.8 Features

class msilib.Feature(db, id, title, desc, display, level=1, parent=None, directory=None, attributes=0)
Add a new record to the Feature table, using the values id, parent.id, title, desc, display, level, directory, and attributes. The resulting feature object can be passed to the start_component() method of Directory.

set_current()
Make this feature the current feature of msilib. New components are automatically added to the default feature, unless a feature is explicitly specified.

See also:
Feature Table

35.11.9 GUI classes

msilib provides several classes that wrap the GUI tables in an MSI database. However, no standard user interface is provided; use bdist_msi to create MSI files with a user-interface for installing Python packages.

class msilib.Control(dlg, name)
Base class of the dialog controls. dlg is the dialog object the control belongs to, and name is the control's name.

event (event, argument, condition=1, ordering=None)
Make an entry into the ControlEvent table for this control.

mapping (event, attribute)
Make an entry into the EventMapping table for this control.

condition (action, condition)
Make an entry into the ControlCondition table for this control.

class msilib.RadioButtonGroup(dlg, name, property)
Create a radio button control named name. property is the installer property that gets set when a radio button is selected.

add (name, x, y, width, height, text, value=None)
Add a radio button named name to the group, at the coordinates x, y, width, height, and with the label text. If value is None, it defaults to name.

class msilib.Dialog(db, name, x, y, w, h, attr, title, first, default, cancel)
Return a new Dialog object. An entry in the Dialog table is made, with the specified coordinates, dialog attributes, title, name of the first, default, and cancel controls.

control (name, type, x, y, width, height, attributes, property, text, control_next, help)
 Return a new Control object. An entry in the Control table is made with the specified parameters.

This is a generic method; for specific types, specialized methods are provided.

text (name, x, y, width, height, attributes, text)
Add and return a Text control.

bitmap (name, x, y, width, height, text)
Add and return a Bitmap control.

line (name, x, y, width, height)
Add and return a Line control.

.pushButton (name, x, y, width, height, attributes, text, next_control)
Add and return a PushButton control.

.radioButton (name, x, y, width, height, attributes, property, text, next_control)
Add and return a RadioButtonGroup control.
**checkbox** *(name, x, y, width, height, attributes, property, text, next_control)*

Add and return a CheckBox control.

**See also:**
Dialog Table Control Table Control Types ControlCondition Table ControlEvent Table EventMapping Table RadioButton Table

### 35.11.10 Precomputed tables

`msilib` provides a few subpackages that contain only schema and table definitions. Currently, these definitions are based on MSI version 2.0.

- **msilib.schema**
  
  This is the standard MSI schema for MSI 2.0, with the `tables` variable providing a list of table definitions, and `_Validation_records` providing the data for MSI validation.

- **msilib.sequence**
  
  This module contains table contents for the standard sequence tables: `AdminExecuteSequence`, `AdminUISequence`, `AdvtExecuteSequence`, `InstallExecuteSequence`, and `InstallUISequence`.

- **msilib.text**
  
  This module contains definitions for the UIText and ActionText tables, for the standard installer actions.

### 35.12 nntplib — NNTP protocol client

**Source code:** `Lib/nntplib.py`

Deprecated since version 3.11: The `nntplib` module is deprecated (see PEP 594 for details).

This module defines the class `NNTP` which implements the client side of the Network News Transfer Protocol. It can be used to implement a news reader or poster, or automated news processors. It is compatible with RFC 3977 as well as the older RFC 977 and RFC 2980.

Here are two small examples of how it can be used. To list some statistics about a newsgroup and print the subjects of the last 10 articles:

```python
>>> s = nntplib.NNTP('news.gmane.io')
>>> resp, count, first, last, name = s.group('gmane.comp.python.committers')
>>> print('Group', name, 'has', count, 'articles, range', first, 'to', last)
Group gmane.comp.python.committers has 1096 articles, range 1 to 1096
>>> for id, over in s.overviews:
...    print(id, nntplib.decode_header(over['subject']))
...
1087 Re: Commit privileges for Łukasz Langa
1088 Re: 3.2 alpha 2 freeze
1089 Re: 3.2 alpha 2 freeze
1090 Re: Commit privileges for Łukasz Langa
1091 Re: Commit privileges for Łukasz Langa
1092 Updated ssh key
1093 Re: Updated ssh key
1094 Re: Updated ssh key
1095 Hello fellow committers!
1096 Re: Hello fellow committers!
>>> s.quit()
'205 Bye!'```

To post an article from a binary file (this assumes that the article has valid headers, and that you have right to post on the particular newsgroup):
```python
>>> s = nntplib.NNTP('news.gmane.io')
>>> f = open('article.txt', 'rb')
>>> s.post(f)
'240 Article posted successfully.'
>>> s.quit()
'205 Bye!
```

The module itself defines the following classes:

```python
class nntplib.NNTP (host, port=119, user=None, password=None, readermode=None, usenetrc=False, timeout )
```

Return a new `NNTP` object, representing a connection to the NNTP server running on host `host`, listening at port `port`. An optional `timeout` can be specified for the socket connection. If the optional `user` and `password` are provided, or if suitable credentials are present in `/netrc` and the optional flag `usenetrc` is true, the AUTHINFO USER and AUTHINFO PASS commands are used to identify and authenticate the user to the server. If the optional flag `readermode` is true, then a mode reader command is sent before authentication is performed. Reader mode is sometimes necessary if you are connecting to an NNTP server on the local machine and intend to call reader-specific commands, such as `group`. If you get unexpected `NNTPPermanentErrors`, you might need to set `readermode`. The `NNTP` class supports the `with` statement to unconditionally consume `OSError` exceptions and to close the NNTP connection when done, e.g.:

```python
>>> from nntplib import NNTP
>>> with NNTP('news.gmane.io') as n:
...     n.group('gmane.comp.python.committers')
...     ('211 1755 1 1755 gmane.comp.python.committers', 1755, 1, 1755, 'gmane.comp.python.committers')
```

Raises an `auditing event` `nntplib.connect` with arguments `self, host, port`.

All commands will raise an `auditing event` `nntplib.putline` with arguments `self` and `line`, where `line` is the bytes about to be sent to the remote host.

Changed in version 3.2: `usenetrc` is now `False` by default.

Changed in version 3.3: Support for the `with` statement was added.

Changed in version 3.9: If the `timeout` parameter is set to be zero, it will raise a `ValueError` to prevent the creation of a non-blocking socket.

```python
class nntplib.NNTP_SSL (host, port=563, user=None, password=None, ssl_context=None, readermode=None, usenetrc=False, timeout )
```

Return a new `NNTP_SSL` object, representing an encrypted connection to the NNTP server running on host `host`, listening at port `port`. `NNTP_SSL` objects have the same methods as `NNTP` objects. If `port` is omitted, port 563 (NNTPS) is used. `ssl_context` is also optional, and is a `SSLContext` object. Please read `Security considerations` for best practices. All other parameters behave the same as for `NNTP`.

Note that SSL-on-563 is discouraged per `RFC 4642`, in favor of STARTTLS as described below. However, some servers only support the former.

Raises an `auditing event` `nntplib.connect` with arguments `self, host, port`.

All commands will raise an `auditing event` `nntplib.putline` with arguments `self` and `line`, where `line` is the bytes about to be sent to the remote host.

New in version 3.2.

Changed in version 3.4: The class now supports hostname check with `ssl.SSLContext.check_hostname` and `Server Name Indication` (see `ssl.HAS_SNI`).

Changed in version 3.9: If the `timeout` parameter is set to be zero, it will raise a `ValueError` to prevent the creation of a non-blocking socket.
exception nntplib.NNTPError
   Derived from the standard exception Exception, this is the base class for all exceptions raised by the nntplib module. Instances of this class have the following attribute:
   
   response
      The response of the server if available, as a str object.

exception nntplib.NNTPReplyError
   Exception raised when an unexpected reply is received from the server.

exception nntplib.NNTPTemporaryError
   Exception raised when a response code in the range 400–499 is received.

exception nntplib.NNTPPermanentError
   Exception raised when a response code in the range 500–599 is received.

exception nntplib.NNTPProtocolError
   Exception raised when a reply is received from the server that does not begin with a digit in the range 1–5.

exception nntplib.NNTPDataError
   Exception raised when there is some error in the response data.

35.12.1 NNTP Objects

When connected, NNTP and NNTP_SSL objects support the following methods and attributes.

Attributes

NNTP.nntp_version
   An integer representing the version of the NNTP protocol supported by the server. In practice, this should be
   2 for servers advertising RFC 3977 compliance and 1 for others.

   New in version 3.2.

NNTP.nntp_implementation
   A string describing the software name and version of the NNTP server, or None if not advertised by the server.

   New in version 3.2.

Methods

The response that is returned as the first item in the return tuple of almost all methods is the server’s response: a string
beginning with a three-digit code. If the server’s response indicates an error, the method raises one of the above
exceptions.

Many of the following methods take an optional keyword-only argument file. When the file argument is supplied, it
must be either a file object opened for binary writing, or the name of an on-disk file to be written to. The method will
then write any data returned by the server (except for the response line and the terminating dot) to the file; any list of
lines, tuples or objects that the method normally returns will be empty.

Changed in version 3.2: Many of the following methods have been reworked and fixed, which makes them incom-
patible with their 3.1 counterparts.

NNTP.quit()
   Send a QUIT command and close the connection. Once this method has been called, no other methods of the
   NNTP object should be called.

NNTP.getwelcome()
   Return the welcome message sent by the server in reply to the initial connection. (This message sometimes
   contains disclaimers or help information that may be relevant to the user.)
NNTP.getCapabilities()  
Return the RFC 3977 capabilities advertised by the server, as a dict instance mapping capability names to (possibly empty) lists of values. On legacy servers which don’t understand the CAPABILITIES command, an empty dictionary is returned instead.

```python
>>> s = NNTP('news.gmane.io')
>>> 'POST' in s.getCapabilities()
True
```

New in version 3.2.

NNTP.login(user=None, password=None, usenetrc=True)  
Send AUTHINFO commands with the user name and password. If user and password are None and usenetrc is true, credentials from ~/.netrc will be used if possible.

Unless intentionally delayed, login is normally performed during the NNTP object initialization and separately calling this function is unnecessary. To force authentication to be delayed, you must not set user or password when creating the object, and must set usenetrc to False.

New in version 3.2.

NNTP.starttls(context=None)  
Send a STARTTLS command. This will enable encryption on the NNTP connection. The context argument is optional and should be a ssl.SSLContext object. Please read Security considerations for best practices.

Note that this may not be done after authentication information has been transmitted, and authentication occurs by default if possible during a NNTP object initialization. See NNTP.login() for information on suppressing this behavior.

New in version 3.2.

Changed in version 3.4: The method now supports hostname check with ssl.SSLContext.check_hostname and Server Name Indication (see ssl.HAS_SNI).

NNTP.newgroups(date, *, file=None)  
Send a NEWGROUPS command. The date argument should be a datetime.date or datetime.datetime object. Return a pair (response, groups) where groups is a list representing the groups that are new since the given date. If file is supplied, though, then groups will be empty.

```python
>>> from datetime import date, timedelta
>>> resp, groups = s.newgroups(date.today() - timedelta(days=3))
>>> len(groups)  
5
>>> groups[0]
GroupInfo(group='gmane.network.tor.devel', last='4', first='1', flag='m')
```

NNTP.newnews(group, date, *, file=None)  
Send a NEWNEWS command. Here, group is a group name or '*', and date has the same meaning as for newgroups(). Return a pair (response, articles) where articles is a list of message ids.

This command is frequently disabled by NNTP server administrators.

NNTP.list(group_pattern=None, *, file=None)  
Send a LIST or LIST ACTIVE command. Return a pair (response, list) where list is a list of tuples representing all the groups available from this NNTP server, optionally matching the pattern string group_pattern. Each tuple has the form (group, last, first, flag), where group is a group name, last and first are the last and first article numbers, and flag usually takes one of these values:

- y: Local postings and articles from peers are allowed.
- m: The group is moderated and all postings must be approved.
- n: No local postings are allowed, only articles from peers.
- j: Articles from peers are filed in the junk group instead.
- x: No local postings, and articles from peers are ignored.
• =foo.bar: Articles are filed in the foo.bar group instead.

If flag has another value, then the status of the newsgroup should be considered unknown.

This command can return very large results, especially if group_pattern is not specified. It is best to cache the results offline unless you really need to refresh them.

Changed in version 3.2: group_pattern was added.

NNTP descriptions (group_pattern)
Send a LIST NEWSGROUPS command, where group_pattern is a wildmat string as specified in RFC 3977 (it’s essentially the same as DOS or UNIX shell wildcard strings). Return a pair (response, descriptions), where descriptions is a dictionary mapping group names to textual descriptions.

```python
>>> resp, desc = a.descriptions('gmane.comp.python.*')
>>> len(desc)
295
>>> desc.popitem()
('gmane.comp.python.bio.general', 'BioPython discussion list (Moderated)')
```

NNTP description (group)
Get a description for a single group group. If more than one group matches (if ‘group’ is a real wildmat string), return the first match. If no group matches, return an empty string.

This elides the response code from the server. If the response code is needed, use descriptions().

NNTP group (name)
Send a GROUP command, where name is the group name. The group is selected as the current group, if it exists. Return a tuple (response, count, first, last, name) where count is the (estimated) number of articles in the group, first is the first article number in the group, last is the last article number in the group, and name is the group name.

NNTP over (message_spec, *, file=None)
Send an OVER command, or an XOVER command on legacy servers. message_spec can be either a string representing a message id, or a (first, last) tuple of numbers indicating a range of articles in the current group, or a (first, None) tuple indicating a range of articles starting from first to the last article in the current group, or None to select the current article in the current group.

Return a pair (response, overviews). overviews is a list of (article_number, overview) tuples, one for each article selected by message_spec. Each overview is a dictionary with the same number of items, but this number depends on the server. These items are either message headers (the key is then the lower-cased header name) or metadata items (the key is then the metadata name prepended with “:“). The following items are guaranteed to be present by the NNTP specification:

- the subject, from, date, message-id and references headers
- the :bytes metadata: the number of bytes in the entire raw article (including headers and body)
- the :lines metadata: the number of lines in the article body

The value of each item is either a string, or None if not present.

It is advisable to use the decode_header() function on header values when they may contain non-ASCII characters:

```python
>>> _, _, first, last, _ = s.group('gmane.comp.python.devel')
>>> resp, overviews = s.over((last, last))
>>> art_num, over = overviews[0]
>>> art_num
117216
>>> list(over.keys())
['xref', 'from', ':lines', ':bytes', 'references', 'date', 'message-id', :
'subject']
>>> over['from']
'=?UTF-8?B?Ik1hcnRpbjB2LiBMw7Z3axXMl?="martin@v.loewis.de"

(continues on next page)
nntplib.decode_header(over['from'])
"Martin v. Löwis" <martin@v.loewis.de>

New in version 3.2.

**NNTP.\_help\((*, file=None)\)**

Send a HELP command. Return a pair (response, list) where list is a list of help strings.

**NNTP.\_stat\((message\_spec=None)\)**

Send a STAT command, where message_spec is either a message id (enclosed in '<' and '>') or an article number in the current group. If message_spec is omitted or None, the current article in the current group is considered. Return a triple (response, number, id) where number is the article number and id is the message id.

```python
>>> _, _, first, last, _ = s.group('gmane.comp.python.devel')
>>> resp, number, message_id = s.stat(first)
>>> number, message_id
(9099, '<20030112190404.GE29873@epoch.metaslash.com>')
```

**NNTP.\_next\()**

Send a NEXT command. Return as for stat().

**NNTP.\_last\()**

Send a LAST command. Return as for stat().

**NNTP.\_article\((message\_spec=None, *, file=None)\)**

Send an ARTICLE command, where message_spec has the same meaning as for stat(). Return a tuple (response, info) where info is a namedtuple with three attributes number, message_id and lines (in that order). number is the article number in the group (or 0 if the information is not available), message_id the message id as a string, and lines a list of lines (without terminating newlines) comprising the raw message including headers and body.

```python
>>> resp, info = s.article('<20030112190404.GE29873@epoch.metaslash.com>')
>>> info.number
0
>>> info.message_id
'<20030112190404.GE29873@epoch.metaslash.com>'
>>> len(info.lines)
65
>>> info.lines[0]
b'Path: main.gmane.org!not-for-mail'
>>> info.lines[1]
b'From: Neal Norwitz <neal@metaslash.com>'
>>> info.lines[3:]
[b'There is a patch for 2.3 as well as 2.2.', b'', b'Neal']
```

**NNTP.\_head\((message\_spec=None, *, file=None)\)**

Same as article(), but sends a HEAD command. The lines returned (or written to file) will only contain the message headers, not the body.

**NNTP.\_body\((message\_spec=None, *, file=None)\)**

Same as article(), but sends a BODY command. The lines returned (or written to file) will only contain the message body, not the headers.

**NNTP.\_post\((data)\)**

Post an article using the POST command. The data argument is either a file object opened for binary reading, or any iterable of bytes objects (representing raw lines of the article to be posted). It should represent a well-formed news article, including the required headers. The post() method automatically escapes lines beginning with . and appendes the termination line.

If the method succeeds, the server’s response is returned. If the server refuses posting, a NNTPREplyError is raised.
**NNTP.\_ihave**(message\_id, data)

Send an IHAVE command. message\_id is the id of the message to send to the server (enclosed in '<' and '>'). The data parameter and the return value are the same as for post().

**NNTP.\_date()**

Return a pair (response, date). date is a datetime object containing the current date and time of the server.

**NNTP.\_slave()**

Send a SLAVE command. Return the server's response.

**NNTP.\_set\_debuglevel**(level)

Set the instance’s debugging level. This controls the amount of debugging output printed. The default, 0, produces no debugging output. A value of 1 produces a moderate amount of debugging output, generally a single line per request or response. A value of 2 or higher produces the maximum amount of debugging output, logging each line sent and received on the connection (including message text).

The following are optional NNTP extensions defined in RFC 2980. Some of them have been superseded by newer commands in RFC 3977.

**NNTP.\_xhdr**(hdr, str, *, file=None)

Send an XHDR command. The hdr argument is a header keyword, e.g. 'subject'. The str argument should have the form 'first-last' where first and last are the first and last article numbers to search. Return a pair (response, list), where list is a list of pairs (id, text), where id is an article number (as a string) and text is the text of the requested header for that article. If the file parameter is supplied, then the output of the XHDR command is stored in a file. If file is a string, then the method will open a file with that name, write to it then close it. If file is a file object, then it will start calling write() on it to store the lines of the command output. If file is supplied, then the returned list is an empty list.

**NNTP.\_xover**(start, end, *, file=None)

Send an XOVER command. start and end are article numbers delimiting the range of articles to select. The return value is the same of for over(). It is recommended to use over() instead, since it will automatically use the newer OVER command if available.

### 35.12.2 Utility functions

The module also defines the following utility function:

**ntplib.decode\_header**(header\_str)

Decode a header value, un-escaping any escaped non-ASCII characters. header\_str must be a str object. The unescaped value is returned. Using this function is recommended to display some headers in a human readable form:

```python
>>> decode_header("Some subject")
'Some subject'
'Débuter en Python'
>>> decode_header("Re: =?UTF-8?B?cHJvYmzDqG1lIGRlIG1hdHJpY2U=?=")
'Re: problème de matrice'
```
The nis module gives a thin wrapper around the NIS library, useful for central administration of several hosts.

Because NIS exists only on Unix systems, this module is only available for Unix.

The nis module defines the following functions:

**nis.match** *(key, mapname, domain=default_domain)*

Return the match for key in map mapname, or raise an error (**nis.error**) if there is none. Both should be strings, key is 8-bit clean. Return value is an arbitrary array of bytes (may contain NULL and other joys).

Note that mapname is first checked if it is an alias to another name.

The domain argument allows overriding the NIS domain used for the lookup. If unspecified, lookup is in the default NIS domain.

**nis.cat** *(mapname, domain=default_domain)*

Return a dictionary mapping key to value such that match(key, mapname)==value. Note that both keys and values of the dictionary are arbitrary arrays of bytes.

Note that mapname is first checked if it is an alias to another name.

The domain argument allows overriding the NIS domain used for the lookup. If unspecified, lookup is in the default NIS domain.

**nis.maps** *(domain=default_domain)*

Return a list of all valid maps.

The domain argument allows overriding the NIS domain used for the lookup. If unspecified, lookup is in the default NIS domain.

**nis.get_default_domain** *

Return the system default NIS domain.

The nis module defines the following exception:

**exception nis.error**

An error raised when a NIS function returns an error code.

### 35.14 optparse — Parser for command line options

**Source code:** Lib/optparse.py

Deprecated since version 3.2: The optparse module is deprecated and will not be developed further; development will continue with the argparse module.

optparse is a more convenient, flexible, and powerful library for parsing command-line options than the old getopt module. optparse uses a more declarative style of command-line parsing: you create an instance of OptionParser, populate it with options, and parse the command line. optparse allows users to specify options in the conventional GNU/POSIX syntax, and additionally generates usage and help messages for you.

Here’s an example of using optparse in a simple script:

```python
from optparse import OptionParser
...
parsed = OptionParser()
parsed.add_option("-f", "--file", dest="filename",
                 help="write report to FILE", metavar="FILE")
```

(continues on next page)
parser.add_option("-q", "--quiet",
    action="store_false", dest="verbose", default=True,
    help="don't print status messages to stdout")

(options, args) = parser.parse_args()

With these few lines of code, users of your script can now do the "usual thing" on the command-line, for example:

```python
<yourscript> --file=outfile -q
```

As it parses the command line, `optparse` sets attributes of the `options` object returned by `parse_args()` based on user-supplied command-line values. When `parse_args()` returns from parsing this command line, `options.filename` will be "outfile" and `options.verbose` will be False. `optparse` supports both long and short options, allows short options to be merged together, and allows options to be associated with their arguments in a variety of ways. Thus, the following command lines are all equivalent to the above example:

```python
<yourscript> -f outfile --quiet
<yourscript> --quiet --file outfile
<yourscript> -q --file=outfile
<yourscript> -q outfile
```

Additionally, users can run one of the following

```python
<yourscript> -h
<yourscript> --help
```

and `optparse` will print out a brief summary of your script's options:

```
Usage: <yourscript> [options]
Options:
  -h, --help             show this help message and exit
  -f FILE, --file=FILE   write report to FILE
  -q, --quiet            don't print status messages to stdout
```

where the value of `yourscript` is determined at runtime (normally from `sys.argv[0]`).

### 35.14.1 Background

`optparse` was explicitly designed to encourage the creation of programs with straightforward, conventional command-line interfaces. To that end, it supports only the most common command-line syntax and semantics conventionally used under Unix. If you are unfamiliar with these conventions, read this section to acquaint yourself with them.

#### Terminology

**argument** a string entered on the command-line, and passed by the shell to `excl()` or `execv()`. In Python, arguments are elements of `sys.argv[1:]` (`sys.argv[0]` is the name of the program being executed). Unix shells also use the term "word".

It is occasionally desirable to substitute an argument list other than `sys.argv[1:]`, so you should read "argument" as "an element of `sys.argv[1:]`, or of some other list provided as a substitute for `sys.argv[1:]`".

**option** an argument used to supply extra information to guide or customize the execution of a program. There are many different syntaxes for options; the traditional Unix syntax is a hyphen ("-"), followed by a single letter, e.g. `-x` or `-F`. Also, traditional Unix syntax allows multiple options to be merged into a single argument, e.g. `-x` `-F` is equivalent to `-xF`. The GNU project introduced -- followed by a series of hyphen-separated words, e.g. `--file` or `--dry-run`. These are the only two option syntaxes provided by `optparse`. 
Some other option syntaxes that the world has seen include:

- a hyphen followed by a few letters, e.g. `-pf` (this is *not* the same as multiple options merged into a single argument)
- a hyphen followed by a whole word, e.g. `-file` (this is technically equivalent to the previous syntax, but they aren’t usually seen in the same program)
- a plus sign followed by a single letter, or a few letters, or a word, e.g. `+f,+rgb`
- a slash followed by a letter, or a few letters, or a word, e.g. `/f,/file`

These option syntaxes are not supported by `optparse`, and they never will be. This is deliberate: the first three are non-standard on any environment, and the last only makes sense if you’re exclusively targeting VMS, MS-DOS, and/or Windows.

**option argument** an argument that follows an option, is closely associated with that option, and is consumed from the argument list when that option is. With `optparse`, option arguments may either be in a separate argument from their option:

```
-f foo
--file foo
```

or included in the same argument:

```
-f foo
--file=foo
```

Typically, a given option either takes an argument or it doesn’t. Lots of people want an “optional option arguments” feature, meaning that some options will take an argument if they see it, and won’t if they don’t. This is somewhat controversial, because it makes parsing ambiguous: if `-a` takes an optional argument and `-b` is another option entirely, how do we interpret `-ab`? Because of this ambiguity, `optparse` does not support this feature.

**positional argument** something leftover in the argument list after options have been parsed, i.e. after options and their arguments have been parsed and removed from the argument list.

**required option** an option that must be supplied on the command-line; note that the phrase “required option” is self-contradictory in English. `optparse` doesn’t prevent you from implementing required options, but doesn’t give you much help at it either.

For example, consider this hypothetical command-line:

```
prog -v --report report.txt foo bar
```

`-v` and `--report` are both options. Assuming that `--report` takes one argument, `report.txt` is an option argument. `foo` and `bar` are positional arguments.

### What are options for?

Options are used to provide extra information to tune or customize the execution of a program. In case it wasn’t clear, options are usually *optional*. A program should be able to run just fine with no options whatsoever. (Pick a random program from the Unix or GNU toolsets. Can it run without any options at all and still make sense? The main exceptions are `find`, `tar`, and `dd`—all of which are mutant oddballs that have been rightly criticized for their non-standard syntax and confusing interfaces.)

Lots of people want their programs to have “required options”. Think about it. If it’s required, then it’s *not optional*! If there is a piece of information that your program absolutely requires in order to run successfully, that’s what positional arguments are for.

As an example of good command-line interface design, consider the humble `cp` utility, for copying files. It doesn’t make much sense to try to copy files without supplying a destination and at least one source. Hence, `cp` fails if you run it with no arguments. However, it has a flexible, useful syntax that does not require any options at all:
You can get pretty far with just that. Most cp implementations provide a bunch of options to tweak exactly how the files are copied: you can preserve mode and modification time, avoid following symlinks, ask before clobbering existing files, etc. But none of this distracts from the core mission of cp, which is to copy either one file to another, or several files to another directory.

What are positional arguments for?

Positional arguments are for those pieces of information that your program absolutely, positively requires to run. A good user interface should have as few absolute requirements as possible. If your program requires 17 distinct pieces of information in order to run successfully, it doesn’t much matter how you get that information from the user—most people will give up and walk away before they successfully run the program. This applies whether the user interface is a command-line, a configuration file, or a GUI: if you make that many demands on your users, most of them will simply give up.

In short, try to minimize the amount of information that users are absolutely required to supply—use sensible defaults whenever possible. Of course, you also want to make your programs reasonably flexible. That’s what options are for. Again, it doesn’t matter if they are entries in a config file, widgets in the “Preferences” dialog of a GUI, or command-line options—the more options you implement, the more flexible your program is, and the more complicated its implementation becomes. Too much flexibility has drawbacks as well, of course; too many options can overwhelm users and make your code much harder to maintain.

35.14.2 Tutorial

While optparse is quite flexible and powerful, it’s also straightforward to use in most cases. This section covers the code patterns that are common to any optparse-based program.

First, you need to import the OptionParser class; then, early in the main program, create an OptionParser instance:

```
from optparse import OptionParser
...
parser = OptionParser()
```

Then you can start defining options. The basic syntax is:

```
parser.add_option(opt_str, ..., attr=value, ...)
```

Each option has one or more option strings, such as -f or --file, and several option attributes that tell optparse what to expect and what to do when it encounters that option on the command line.

Typically, each option will have one short option string and one long option string, e.g.:

```
parser.add_option("-f", "--file", ...)
```

You're free to define as many short option strings and as many long option strings as you like (including zero), as long as there is at least one option string overall.

The option strings passed to OptionParser.add_option() are effectively labels for the option defined by that call. For brevity, we will frequently refer to encountering an option on the command line; in reality, optparse encounters option strings and looks up options from them.

Once all of your options are defined, instruct optparse to parse your program’s command line:

```
(options, args) = parser.parse_args()
```
(If you like, you can pass a custom argument list to `parse_args()`, but that’s rarely necessary: by default it uses `sys.argv[1:]`.)

`parse_args()` returns two values:

- `options`, an object containing values for all of your options—e.g. if `--file` takes a single string argument, then `options.file` will be the filename supplied by the user, or `None` if the user did not supply that option
- `args`, the list of positional arguments leftover after parsing options

This tutorial section only covers the four most important option attributes: `action`, `type`, `dest` (destination), and `help`. Of these, `action` is the most fundamental.

**Understanding option actions**

Actions tell `optparse` what to do when it encounters an option on the command line. There is a fixed set of actions hard-coded into `optparse`; adding new actions is an advanced topic covered in section `Extending optparse`. Most actions tell `optparse` to store a value in some variable—for example, take a string from the command line and store it in an attribute of `options`.

If you don’t specify an option action, `optparse` defaults to `store`.

**The store action**

The most common option action is `store`, which tells `optparse` to take the next argument (or the remainder of the current argument), ensure that it is of the correct type, and store it to your chosen destination.

For example:

```
parser.add_option("-f", "--file",
    action="store", type="string", dest="filename")
```

Now let’s make up a fake command line and ask `optparse` to parse it:

```
args = ["-f", "foo.txt"]
(options, args) = parser.parse_args(args)
```

When `optparse` sees the option string `-f`, it consumes the next argument, `foo.txt`, and stores it in `options.filename`. So, after this call to `parse_args()`, `options.filename` is "foo.txt".

Some other option types supported by `optparse` are `int` and `float`. Here’s an option that expects an integer argument:

```
parser.add_option("-n", type="int", dest="num")
```

Note that this option has no long option string, which is perfectly acceptable. Also, there’s no explicit action, since the default is `store`.

Let’s parse another fake command-line. This time, we’ll jam the option argument right up against the option: since `-n42` (one argument) is equivalent to `-n 42` (two arguments), the code

```
(options, args) = parser.parse_args(['-n42'])
print(options.num)
```

will print 42.

If you don’t specify a type, `optparse` assumes `string`. Combined with the fact that the default action is `store`, that means our first example can be a lot shorter:

```
parser.add_option("-f", "--file", dest="filename")
```
If you don’t supply a destination, `optparse` figures out a sensible default from the option strings: if the first long option string is `--foo-bar`, then the default destination is `foo_bar`. If there are no long option strings, `optparse` looks at the first short option string: the default destination for `-f` is `f`.

`optparse` also includes the built-in `complex` type. Adding types is covered in section `Extending optparse`.

### Handling boolean (flag) options

Flag options—set a variable to true or false when a particular option is seen—are quite common. `optparse` supports them with two separate actions, `store_true` and `store_false`. For example, you might have a `verbose` flag that is turned on with `-v` and off with `-q`:

```python
default = True
parser.add_option("-v", action="store_true", dest="verbose", default=default)
default = False
parser.add_option("-q", action="store_false", dest="verbose", default=default)
```

Here we have two different options with the same destination, which is perfectly OK. (It just means you have to be a bit careful when setting default values—see below.)

When `optparse` encounters `-v` on the command line, it sets `options.verbose` to `True`; when it encounters `-q`, `options.verbose` is set to `False`.

### Other actions

Some other actions supported by `optparse` are:

- "store_const"  store a constant value
- "append"  append this option's argument to a list
- "count"  increment a counter by one
- "callback"  call a specified function

These are covered in section `Reference Guide`, and section `Option Callbacks`.

### Default values

All of the above examples involve setting some variable (the “destination”) when certain command-line options are seen. What happens if those options are never seen? Since we didn’t supply any defaults, they are all set to `None`. This is usually fine, but sometimes you want more control. `optparse` lets you supply a default value for each destination, which is assigned before the command line is parsed.

First, consider the `verbose/quiet` example. If we want `optparse` to set `verbose` to `True` unless `-q` is seen, then we can do this:

```python
default = True
parser.add_option("-v", action="store_true", dest="verbose", default=default)
default = False
parser.add_option("-q", action="store_false", dest="verbose", default=default)
```

Since default values apply to the `destination` rather than to any particular option, and these two options happen to have the same destination, this is exactly equivalent:

```python
default = True
parser.add_option("-v", action="store_true", dest="verbose", default=default)
default = False
parser.add_option("-q", action="store_false", dest="verbose", default=default)
```

Consider this:

```python
default = False
parser.add_option("-v", action="store_true", dest="verbose", default=default)
default = True
parser.add_option("-q", action="store_false", dest="verbose", default=default)
```
Again, the default value for `verbose` will be `True`: the last default value supplied for any particular destination is the one that counts.

A clearer way to specify default values is the `set_defaults()` method of OptionParser, which you can call at any time before calling `parse_args()`:

```python
parser.set_defaults(verbosetrue)
parserr.add_option(...)
(options, args) = parser.parse_args()
```

As before, the last value specified for a given option destination is the one that counts. For clarity, try to use one method or the other of setting default values, not both.

### Generating help

`optparse`'s ability to generate help and usage text automatically is useful for creating user-friendly command-line interfaces. All you have to do is supply a `help` value for each option, and optionally a short usage message for your whole program. Here’s an OptionParser populated with user-friendly (documented) options:

```python
usage = "usage: %prog [options] arg1 arg2"
parserr = OptionParser(usage=usage)
parserr.add_option("-v", "--verbose",
        action="store_true", dest="verbose", default=True,
        help="make lots of noise [default]")
parserr.add_option("-q", "--quiet",
        action="store_false", dest="verbose",
        help="be vewwy quiet (I'm hunting wabbits)")
parserr.add_option("-f", "--filename",
        metavar="FILE", help="write output to FILE")
parserr.add_option("-m", "--mode",
        default="intermediate",
        help="interaction mode: novice, intermediate, "
        "or expert [default: %default]"
)
```

If `optparse` encounters either `-h` or `--help` on the command-line, or if you just call `parser.print_help()`, it prints the following to standard output:

```
Usage: <yourscript> [options] arg1 arg2

Options:
    -h, --help             show this help message and exit
    -v, --verbose          make lots of noise [default]
    -q, --quiet            be vewwy quiet (I'm hunting wabbits)
    -f FILE, --filename=FILE
                          write output to FILE
    -m MODE, --mode=MODE   interaction mode: novice, intermediate, or
                          expert [default: intermediate]
```

(If the help output is triggered by a help option, `optparse` exits after printing the help text.)

There’s a lot going on here to help `optparse` generate the best possible help message:

- the script defines its own usage message:

```python
usage = "usage: %prog [options] arg1 arg2"
```

`optparse` expands `%prog` in the usage string to the name of the current program, i.e. `os.path.basename(sys.argv[0])`. The expanded string is then printed before the detailed option help.

If you don’t supply a usage string, `optparse` uses a bland but sensible default: "Usage: %prog [options]", which is fine if your script doesn’t take any positional arguments.
• every option defines a help string, and doesn’t worry about line-wrapping—`optparse` takes care of wrapping lines and making the help output look good.

• options that take a value indicate this fact in their automatically-generated help message, e.g. for the “mode” option:

```
-m MODE, --mode=MODE
```

Here, “MODE” is called the meta-variable: it stands for the argument that the user is expected to supply to `--mode`. By default, `optparse` converts the destination variable name to uppercase and uses that for the meta-variable. Sometimes, that’s not what you want—for example, the `--filename` option explicitly sets `metavar="FILE"`, resulting in this automatically-generated option description:

```
-f FILE, --filename=FILE
```

This is important for more than just saving space, though: the manually written help text uses the meta-variable `FILE` to clue the user in that there’s a connection between the semi-formal syntax `--filename FILE` and the informal semantic description “write output to FILE”. This is a simple but effective way to make your help text a lot clearer and more useful for end users.

• options that have a default value can include `%default` in the help string—`optparse` will replace it with `str()` of the option’s default value. If an option has no default value (or the default value is `None`), `%default` expands to `none`.

### Grouping Options

When dealing with many options, it is convenient to group these options for better help output. An `OptionParser` can contain several option groups, each of which can contain several options.

An option group is obtained using the class `OptionGroup`:

```
class optparse.OptionGroup(parser, title, description=None)
```

where

• `parser` is the `OptionParser` instance the group will be inserted in to

• `title` is the group title

• `description`, optional, is a long description of the group

`OptionGroup` inherits from `OptionContainer` (like `OptionParser`) and so the `add_option()` method can be used to add an option to the group.

Once all the options are declared, using the `OptionParser` method `add_option_group()` the group is added to the previously defined parser.

Continuing with the parser defined in the previous section, adding an `OptionGroup` to a parser is easy:

```
group = OptionGroup(parser, "Dangerous Options",
                    "Caution: use these options at your own risk."
                    "It is believed that some of them bite.")
group.add_option("-g", action="store_true", help="Group option.")
parser.add_option_group(group)
```

This would result in the following help output:

```
Usage: <yourscript> [options] arg1 arg2
Options:
  -h, --help    show this help message and exit
  -v, --verbose make lots of noise [default]
  -q, --quiet   be vewwy quiet (I'm hunting wabbits)
  -f FILE, --filename=FILE
```

(continues on next page)
write output to FILE

-m MODE, --mode=MODE interaction mode: novice, intermediate, or expert [default: intermediate]

Dangerous Options:
Caution: use these options at your own risk. It is believed that some of them bite.

-g Group option.

A bit more complete example might involve using more than one group: still extending the previous example:

```python
group = OptionGroup(parser, "Dangerous Options",
                    "Caution: use these options at your own risk. "
                    "It is believed that some of them bite.")
group.add_option("-g", action="store_true", help="Group option.")
parser.add_option_group(group)

group = OptionGroup(parser, "Debug Options")
group.add_option("-d", "--debug", action="store_true",
                 help="Print debug information")
group.add_option("-s", "--sql", action="store_true",
                 help="Print all SQL statements executed")
group.add_option("-e", action="store_true", help="Print every action done")
parser.add_option_group(group)
```

that results in the following output:

```
Usage: <yourscript> [options] arg1 arg2

Options:
   -h, --help    show this help message and exit
   -v, --verbose make lots of noise [default]
   -q, --quiet   be vewwy quiet (I'm hunting wabbits)
   -f FILE, --filename=FILE write output to FILE
   -m MODE, --mode=MODE interaction mode: novice, intermediate, or expert [default: intermediate]

Dangerous Options:
Caution: use these options at your own risk. It is believed that some of them bite.

   -g Group option.

Debug Options:
   -d, --debug Print debug information
   -s, --sql Print all SQL statements executed
   -e Print every action done
```

Another interesting method, in particular when working programmatically with option groups is:

```python
OptionParser.get_option_group(opt_str)
```

Return the `OptionGroup` to which the short or long option string `opt_str` (e.g. `'-o'` or `'--option'`) belongs. If there’s no such `OptionGroup`, return None.
Printing a version string

Similar to the brief usage string, `optparse` can also print a version string for your program. You have to supply the string as the `version` argument to `OptionParser`:

```python
parser = OptionParser(usage="%prog [-f] [-q]", version="%prog 1.0")
```

`%prog` is expanded just like it is in `usage`. Apart from that, `version` can contain anything you like. When you supply it, `optparse` automatically adds a `--version` option to your parser. If it encounters this option on the command line, it expands your version string (by replacing `%prog`), prints it to stdout, and exits.

For example, if your script is called `/usr/bin/foo`:

```bash
$ /usr/bin/foo --version
foo 1.0
```

The following two methods can be used to print and get the version string:

```python
OptionParser.print_version(file=None)
    Print the version message for the current program (self.version) to file (default stdout). As with
    print_usage(), any occurrence of %prog in self.version is replaced with the name of the current
    program. Does nothing if self.version is empty or undefined.

OptionParser.get_version()
    Same as print_version() but returns the version string instead of printing it.
```

How optparse handles errors

There are two broad classes of errors that `optparse` has to worry about: programmer errors and user errors. Programmer errors are usually erroneous calls to `OptionParser.add_option()`, e.g. invalid option strings, unknown option attributes, missing option attributes, etc. These are dealt with in the usual way: raise an exception (either `optparse.OptionError` or `TypeError`) and let the program crash.

Handling user errors is much more important, since they are guaranteed to happen no matter how stable your code is. `optparse` can automatically detect some user errors, such as bad option arguments (passing `-n 4x` where `-n` takes an integer argument), missing arguments (`-n` at the end of the command line, where `-n` takes an argument of any type). Also, you can call `OptionParser.error()` to signal an application-defined error condition:

```python
(options, args) = parser.parse_args()
...
if options.a and options.b:
    parser.error("options -a and -b are mutually exclusive")
```

In either case, `optparse` handles the error the same way: it prints the program’s usage message and an error message to standard error and exits with error status 2.

Consider the first example above, where the user passes `4x` to an option that takes an integer:

```bash
$ /usr/bin/foo -n 4x
Usage: foo [options]
foo: error: option -n: invalid integer value: '4x'
```

Or, where the user fails to pass a value at all:

```bash
$ /usr/bin/foo -n
Usage: foo [options]
foo: error: -n option requires an argument
```

`optparse`-generated error messages take care always to mention the option involved in the error; be sure to do the same when calling `OptionParser.error()` from your application code.
If `optparse`’s default error-handling behaviour does not suit your needs, you’ll need to subclass `OptionParser` and override its `exit()` and/or `error()` methods.

**Putting it all together**

Here’s what `optparse`-based scripts usually look like:

```python
from optparse import OptionParser

def main():
    usage = "usage: %prog [options] arg"
    parser = OptionParser(usage)
    parser.add_option("-f", "--file", dest="filename",
                      help="read data from FILENAME")
    parser.add_option("-v", "--verbose",
                      action="store_true", dest="verbose")
    parser.add_option("-q", "--quiet",
                      action="store_false", dest="verbose")

    (options, args) = parser.parse_args()
    if len(args) != 1:
        parser.error("incorrect number of arguments")
    if options.verbose:
        print("reading %s...

to prog if you passed that keyword argument). To suppress a usage message, pass the special value optparse.SUPPRESS_USAGE.

option_list (default: []) A list of Option objects to populate the parser with. The options in option_list are added after any options in standard_option_list (a class attribute that may be set by OptionParser subclasses), but before any version or help options. Deprecated; use add_option() after creating the parser instead.

option_class (default: optparse.Option) Class to use when adding options to the parser in add_option().

version (default: None) A version string to print when the user supplies a version option. If you supply a true value for version, `optparse` automatically adds a version option with the single option string --version. The substring %prog is expanded the same as for usage.

conflict_handler (default: "error") Specifies what to do when options with conflicting option strings are added to the parser; see section Conflicts between options.

...
description (default: None) A paragraph of text giving a brief overview of your program. optparse
reformats this paragraph to fit the current terminal width and prints it when the user requests help (after
usage, but before the list of options).

formatter (default: a new IndentedHelpFormatter) An instance of optparse.HelpFormatter that
will be used for printing help text. optparse provides two concrete classes for this purpose: Indent-
edHelpFormatter and TitledHelpFormatter.

add_help_option (default: True) If true, optparse will add a help option (with option strings -h
and --help) to the parser.

prog The string to use when expanding %prog in usage and version instead of os.path.
    basename(sys.argv[0]).

epilog (default: None) A paragraph of help text to print after the option help.

Populating the parser

There are several ways to populate the parser with options. The preferred way is by using OptionParser.
add_option(), as shown in section Tutorial. add_option() can be called in one of two ways:

• pass it an Option instance (as returned by make_option())
• pass it any combination of positional and keyword arguments that are acceptable to make_option() (i.e.,
to the Option constructor), and it will create the Option instance for you

The other alternative is to pass a list of pre-constructed Option instances to the OptionParser constructor, as in:

```python
option_list = [
    make_option("-f", "--filename",
        action="store", type="string", dest="filename"),
    make_option("-q", "--quiet",
        action="store_false", dest="verbose"),
]
parser = OptionParser(option_list=option_list)
```

(make_option()) is a factory function for creating Option instances; currently it is an alias for the Option con-
structor. A future version of optparse may split Option into several classes, and make_option() will pick the
right class to instantiate. Do not instantiate Option directly.)

Defining options

Each Option instance represents a set of synonymous command-line option strings, e.g. -f and --file. You can
specify any number of short or long option strings, but you must specify at least one overall option string.

The canonical way to create an Option instance is with the add_option() method of OptionParser.

OptionParser.add_option(option)
OptionParser.add_option("opt_str, attr=value, ...")

To define an option with only a short option string:

```
parser.add_option("-f", attr=value, ...)
```

And to define an option with only a long option string:

```
parser.add_option("--foo", attr=value, ...)
```

The keyword arguments define attributes of the new Option object. The most important option attribute is
action, and it largely determines which other attributes are relevant or required. If you pass irrelevant
option attributes, or fail to pass required ones, optparse raises an OptionError exception explaining
your mistake.
An option's action determines what optparse does when it encounters this option on the command-line. The standard option actions hard-coded into optparse are:

- "store": store this option's argument (default)
- "store_const": store a constant value
- "store_true": store True
- "store_false": store False
- "append": append this option's argument to a list
- "append_const": append a constant value to a list
- "count": increment a counter by one
- "callback": call a specified function
- "help": print a usage message including all options and the documentation for them

(If you don’t supply an action, the default is "store". For this action, you may also supply type and dest option attributes; see Standard option actions.)

As you can see, most actions involve storing or updating a value somewhere. optparse always creates a special object for this, conventionally called options (it happens to be an instance of optparse.Values). Option arguments (and various other values) are stored as attributes of this object, according to the dest (destination) option attribute.

For example, when you call

```python
parser.parse_args()
```

one of the first things optparse does is create the options object:

```python
options = Values()
```

If one of the options in this parser is defined with

```python
parser.add_option("-f", "--file", action="store", type="string", dest="filename")
```

and the command-line being parsed includes any of the following:

```bash
f f
-f foo
--file=foo
--file foo
```

then optparse, on seeing this option, will do the equivalent of

```python
options.filename = "foo"
```

The type and dest option attributes are almost as important as action, but action is the only one that makes sense for all options.
Option attributes

The following option attributes may be passed as keyword arguments to `OptionParser.add_option()`. If you pass an option attribute that is not relevant to a particular option, or fail to pass a required option attribute, `optparse` raises `OptionError`.

Option. **action**  
(default: "store")  
Determines `optparse`'s behaviour when this option is seen on the command line; the available options are documented here.

Option. **type**  
(default: "string")  
The argument type expected by this option (e.g., "string" or "int"); the available option types are documented here.

Option. **dest**  
(default: derived from option strings)  
If the option's action implies writing or modifying a value somewhere, this tells `optparse` where to write it: `dest` names an attribute of the `options` object that `optparse` builds as it parses the command line.

Option. **default**  
The value to use for this option’s destination if the option is not seen on the command line. See also `OptionParser.set_defaults()`.

Option. **nargs**  
(default: 1)  
How many arguments of type `type` should be consumed when this option is seen. If > 1, `optparse` will store a tuple of values to `dest`.

Option. **const**  
For actions that store a constant value, the constant value to store.

Option. **choices**  
For options of type "choice", the list of strings the user may choose from.

Option. **callback**  
For options with action "callback", the callable to call when this option is seen. See section `Option Callbacks` for detail on the arguments passed to the callable.

Option. **callback_args**  
Option. **callback_kwargs**  
Additional positional and keyword arguments to pass to `callback` after the four standard callback arguments.

Option. **help**  
Help text to print for this option when listing all available options after the user supplies a `help` option (such as `--help`). If no help text is supplied, the option will be listed without help text. To hide this option, use the special value `optparse.SUPPRESS_HELP`.

Option. **metavar**  
(default: derived from option strings)  
Stand-in for the option argument(s) to use when printing help text. See section `Tutorial` for an example.
**Standard option actions**

The various option actions all have slightly different requirements and effects. Most actions have several relevant option attributes which you may specify to guide `optparse`'s behaviour; a few have required attributes, which you must specify for any option using that action.

- **"store"** [relevant: `type`, `dest`, `nargs`, `choices`]
  
The option must be followed by an argument, which is converted to a value according to `type` and stored in `dest`. If `nargs` > 1, multiple arguments will be consumed from the command line; all will be converted according to `type` and stored to `dest` as a tuple. See the *Standard option types* section.

  If `choices` is supplied (a list or tuple of strings), the type defaults to "choice".

  If `type` is not supplied, it defaults to "string".

  If `dest` is not supplied, `optparse` derives a destination from the first long option string (e.g., `--foo-bar` implies `foo_bar`). If there are no long option strings, `optparse` derives a destination from the first short option string (e.g., `-f` implies `f`).

  Example:

  ```python
  parser.add_option("-f")
  parser.add_option("-p", type="float", nargs=3, dest="point")
  ```

  As it parses the command line

  ```
  -f foo.txt  -p 1 -3.5  4   -fbar.txt
  ```

  `optparse` will set

  ```
  options.f = "foo.txt"
  options.point = (1.0, -3.5, 4.0)
  options.f = "bar.txt"
  ```

- **"store_const"** [required: `const`; relevant: `dest`]
  
The value `const` is stored in `dest`.

  Example:

  ```python
  parser.add_option("-q", "--quiet",
             action="store_const", const=0, dest="verbose")
  parser.add_option("-v", "--verbose",
             action="store_const", const=1, dest="verbose")
  parser.add_option("--noisy",
             action="store_const", const=2, dest="verbose")
  ```

  If `--noisy` is seen, `optparse` will set

  ```
  options.verbose = 2
  ```

- **"store_true"** [relevant: `dest`]
  
  A special case of "store_const" that stores True to `dest`.

- **"store_false"** [relevant: `dest`]
  
  Like "store_true", but stores False.

  Example:

  ```python
  parser.add_option("--clobber", action="store_true", dest="clobber")
  parser.add_option("--no-clobber", action="store_false", dest="clobber")
  ```
• "append" [relevant: type, dest, nargs, choices]

The option must be followed by an argument, which is appended to the list in dest. If no default value for dest is supplied, an empty list is automatically created when optparse first encounters this option on the command-line. If nargs > 1, multiple arguments are consumed, and a tuple of length nargs is appended to dest.

The defaults for type and dest are the same as for the "store" action.

Example:

```python
parser.add_option("-t", "--tracks", action="append", type="int")
```

If -t3 is seen on the command-line, optparse does the equivalent of:

```python
options.tracks = []
optparse.parse_args(['-t', '3'])
options.tracks.append(int("3"))
```

If, a little later on, --tracks=4 is seen, it does:

```python
options.tracks.append(int("4"))
```

The append action calls the append method on the current value of the option. This means that any default value specified must have an append method. It also means that if the default value is non-empty, the default elements will be present in the parsed value for the option, with any values from the command line appended after those default values:

```python
>>> parser.add_option("--files", action="append", default=['~/mypkg/defaults - '])
>>> opts, args = parser.parse_args(['--files', 'overrides.mypkg'])
>>> opts.files
['~/mypkg/defaults', 'overrides.mypkg']
```

• "append_const" [required: const; relevant: dest]

Like "store_const", but the value const is appended to dest; as with "append", dest defaults to None, and an empty list is automatically created the first time the option is encountered.

• "count" [relevant: dest]

Increment the integer stored at dest. If no default value is supplied, dest is set to zero before being incremented the first time.

Example:

```python
parser.add_option("-v", action="count", dest="verbosity")
```

The first time -v is seen on the command line, optparse does the equivalent of:

```python
options.verbosity = 0
options.verbosity += 1
```

Every subsequent occurrence of -v results in

```python
options.verbosity += 1
```

• "callback" [required: callback; relevant: type, nargs, callback_args, callback_kwargs]

Call the function specified by callback, which is called as

```python
func(option, opt_str, value, parser, *args, **kwargs)
```

See section Option Callbacks for more detail.
• "help"

Prints a complete help message for all the options in the current option parser. The help message is constructed from the usage string passed to OptionParser’s constructor and the help string passed to every option.

If no help string is supplied for an option, it will still be listed in the help message. To omit an option entirely, use the special value optparse.SUPPRESS_HELP.

optparse automatically adds a help option to all OptionParsers, so you do not normally need to create one.

Example:

```python
from optparse import OptionParser, SUPPRESS_HELP

# usually, a help option is added automatically, but that can
# be suppressed using the add_help_option argument
parser = OptionParser(add_help_option=False)

parser.add_option("-h", "--help", action="help")
parser.add_option("-v", action="store_true", dest="verbose",
               help="Be moderately verbose")
parser.add_option("--file", dest="filename",
               help="Input file to read data from")
parser.add_option("--secret", help=SUPPRESS_HELP)
```

If optparse sees either -h or --help on the command line, it will print something like the following help message to stdout (assuming sys.argv[0] is "foo.py"):

```
Usage: foo.py [options]

Options:
  -h, --help       Show this help message and exit
  -v               Be moderately verbose
  --file=FILENAME  Input file to read data from
```

After printing the help message, optparse terminates your process with sys.exit(0).

• "version"

Prints the version number supplied to the OptionParser to stdout and exits. The version number is actually formatted and printed by the print_version() method of OptionParser. Generally only relevant if the version argument is supplied to the OptionParser constructor. As with help options, you will rarely create version options, since optparse automatically adds them when needed.

### Standard option types

optparse has five built-in option types: "string", "int", "choice", "float" and "complex". If you need to add new option types, see section Extending optparse.

Arguments to string options are not checked or converted in any way: the text on the command line is stored in the destination (or passed to the callback) as-is.

Integer arguments (type "int") are parsed as follows:

- if the number starts with 0x, it is parsed as a hexadecimal number
- if the number starts with 0, it is parsed as an octal number
- if the number starts with 0b, it is parsed as a binary number
- otherwise, the number is parsed as a decimal number

The conversion is done by calling int() with the appropriate base (2, 8, 10, or 16). If this fails, so will optparse, although with a more useful error message.
"float" and "complex" option arguments are converted directly with `float()` and `complex()`, with similar error-handling.

"choice" options are a subtype of "string" options. The choices option attribute (a sequence of strings) defines the set of allowed option arguments. `optparse.check_choice()` compares user-supplied option arguments against this master list and raises `OptionValueError` if an invalid string is given.

### Parsing arguments

The whole point of creating and populating an `OptionParser` is to call its `parse_args()` method:

```python
(options, args) = parser.parse_args(args=None, values=None)
```

where the input parameters are

- **args** the list of arguments to process (default: `sys.argv[1:]`)
- **values** an `optparse.Values` object to store option arguments in (default: a new instance of `Values`) – if you give an existing object, the option defaults will not be initialized on it

and the return values are

- **options** the same object that was passed in as `values`, or the `optparse.Values` instance created by `optparse`
- **args** the leftover positional arguments after all options have been processed

The most common usage is to supply neither keyword argument. If you supply `values`, it will be modified with repeated `setattr()` calls (roughly one for every option argument stored to an option destination) and returned by `parse_args()`.

If `parse_args()` encounters any errors in the argument list, it calls the OptionParser's `error()` method with an appropriate end-user error message. This ultimately terminates your process with an exit status of 2 (the traditional Unix exit status for command-line errors).

### Querying and manipulating your option parser

The default behavior of the option parser can be customized slightly, and you can also poke around your option parser and see what's there. OptionParser provides several methods to help you out:

- **OptionParser.disble_interspersed_args()**
  Set parsing to stop on the first non-option. For example, if `-a` and `-b` are both simple options that take no arguments, `optparse` normally accepts this syntax:

  ```plaintext
  prog -a arg1 -b arg2
  ```

  and treats it as equivalent to

  ```plaintext
  prog -a -b arg1 arg2
  ```

  To disable this feature, call `disable_interspersed_args()`. This restores traditional Unix syntax, where option parsing stops with the first non-option argument.

  Use this if you have a command processor which runs another command which has options of its own and you want to make sure these options don't get confused. For example, each command might have a different set of options.

- **OptionParser.enable_interspersed_args()**
  Set parsing to not stop on the first non-option, allowing interspersing switches with command arguments. This is the default behavior.

- **OptionParser.get_option(opt_str)**
  Returns the Option instance with the option string `opt_str`, or `None` if no options have that option string.
OptionParser\texttt{.has\_option}(\texttt{opt\_str})
Return True if the OptionParser has an option with option string \texttt{opt\_str} (e.g., \texttt{-q} or \texttt{--verbose}).

OptionParser\texttt{.remove\_option}(\texttt{opt\_str})
If the OptionParser has an option corresponding to \texttt{opt\_str}, that option is removed. If that option provided any other option strings, all of those option strings become invalid. If \texttt{opt\_str} does not occur in any option belonging to this OptionParser, raises \texttt{ValueError}.

Conflicts between options

If you’re not careful, it’s easy to define options with conflicting option strings:

```python
parser.add_option("-n", "--dry-run", ...)
...
parser.add_option("-n", "--noisy", ...)```

(This is particularly true if you’ve defined your own OptionParser subclass with some standard options.)

Every time you add an option, \texttt{optparse} checks for conflicts with existing options. If it finds any, it invokes the current conflict-handling mechanism. You can set the conflict-handling mechanism either in the constructor:

```python
parser = OptionParser(..., conflict_handler=handler)
```
or with a separate call:

```python
parser.set_conflict_handler(handler)
```

The available conflict handlers are:

"\texttt{error}\texttt{(default)}" assume option conflicts are a programming error and raise \texttt{OptionConflictError}

"\texttt{resolve}\texttt{" resolve option conflicts intelligently (see below)

As an example, let’s define an OptionParser that resolves conflicts intelligently and add conflicting options to it:

```python
parser = OptionParser(conflict_handler="resolve")
parser.add_option("-n", "--dry-run", ..., help="do no harm")
parser.add_option("-n", "--noisy", ..., help="be noisy")
```

At this point, \texttt{optparse} detects that a previously-added option is already using the \texttt{-n} option string. Since conflict_handler is "resolve", it resolves the situation by removing \texttt{-n} from the earlier option’s list of option strings. Now \texttt{--dry-run} is the only way for the user to activate that option. If the user asks for help, the help message will reflect that:

```
Options:
  --dry-run     do no harm
  ...
  -n, --noisy   be noisy
```

It’s possible to whittle away the option strings for a previously-added option until there are none left, and the user has no way of invoking that option from the command-line. In that case, \texttt{optparse} removes that option completely, so it doesn’t show up in help text or anywhere else. Carrying on with our existing OptionParser:

```python
parser.add_option("--dry-run", ..., help="new dry-run option")
```

At this point, the original \texttt{-n|--dry-run} option is no longer accessible, so \texttt{optparse} removes it, leaving this help text:

```
Options:
  ...
```
Cleanup

OptionParser instances have several cyclic references. This should not be a problem for Python's garbage collector, but you may wish to break the cyclic references explicitly by calling `destroy()` on your OptionParser once you are done with it. This is particularly useful in long-running applications where large object graphs are reachable from your OptionParser.

Other methods

OptionParser supports several other public methods:

OptionParser. `set_usage(usage)`
Set the usage string according to the rules described above for the usage constructor keyword argument. Passing `None` sets the default usage string; use `optparse.SUPPRESS_USAGE` to suppress a usage message.

OptionParser. `print_usage(file=None)`
Print the usage message for the current program (`self.usage`) to `file` (default stdout). Any occurrence of the string `%prog` in `self.usage` is replaced with the name of the current program. Does nothing if `self.usage` is empty or not defined.

OptionParser. `get_usage()`
Same as `print_usage()` but returns the usage string instead of printing it.

OptionParser. `set_defaults(dest=value, ...)`
Set default values for several option destinations at once. Using `set_defaults()` is the preferred way to set default values for options, since multiple options can share the same destination. For example, if several “mode” options all set the same destination, any one of them can set the default, and the last one wins:

```python
parser.add_option(“--advanced”, action=“store_const”,
    dest=“mode”, const=“advanced”,
    default=“novice”)  # overridden below
parser.add_option(“--novice”, action=“store_const”,
    dest=“mode”, const=“novice”,
    default=“advanced”)  # overrides above setting
```

To avoid this confusion, use `set_defaults()`:

```python
parser.set_defaults(mode=“advanced”)
parser.add_option(“--advanced”, action=“store_const”,
    dest=“mode”, const=“advanced”)
parser.add_option(“--novice”, action=“store_const”,
    dest=“mode”, const=“novice”)
```
### 35.14.4 Option Callbacks

When `optparse`'s built-in actions and types aren’t quite enough for your needs, you have two choices: extend `optparse` or define a callback option. Extending `optparse` is more general, but overkill for a lot of simple cases. Quite often a simple callback is all you need.

There are two steps to defining a callback option:

- define the option itself using the "callback" action
- write the callback; this is a function (or method) that takes at least four arguments, as described below

#### Defining a callback option

As always, the easiest way to define a callback option is by using the `OptionParser.add_option()` method. Apart from `action`, the only option attribute you must specify is `callback`, the function to call:

```python
parser.add_option("-c", action="callback", callback=my_callback)
```

callback is a function (or other callable object), so you must have already defined `my_callback()` when you create this callback option. In this simple case, `optparse` doesn’t even know if `-c` takes any arguments, which usually means that the option takes no arguments—the mere presence of `-c` on the command-line is all it needs to know. In some circumstances, though, you might want your callback to consume an arbitrary number of command-line arguments. This is where writing callbacks gets tricky; it’s covered later in this section.

`optparse` always passes four particular arguments to your callback, and it will only pass additional arguments if you specify them via `callback_args` and `callback_kwargs`. Thus, the minimal callback function signature is:

```python
def my_callback(option, opt, value, parser):
```

The four arguments to a callback are described below.

There are several other option attributes that you can supply when you define a callback option:

- `type` has its usual meaning: as with the "store" or "append" actions, it instructs `optparse` to consume one argument and convert it to `type`. Rather than storing the converted value(s) anywhere, though, `optparse` passes it to your callback function.

- `nargs` also has its usual meaning: if it is supplied and > 1, `optparse` will consume `nargs` arguments, each of which must be convertible to `type`. It then passes a tuple of converted values to your callback.

- `callback_args` a tuple of extra positional arguments to pass to the callback

- `callback_kwargs` a dictionary of extra keyword arguments to pass to the callback

#### How callbacks are called

All callbacks are called as follows:

```python
func(option, opt_str, value, parser, *args, **kwargs)
```

where

- `option` is the Option instance that’s calling the callback
- `opt_str` is the option string seen on the command-line that’s triggering the callback. (If an abbreviated long option was used, `opt_str` will be the full, canonical option string—e.g. if the user puts `--foo` on the command-line as an abbreviation for `--foobar`, then `opt_str` will be `"--foobar"`.)
- `value` is the argument to this option seen on the command-line. `optparse` will only expect an argument if `type` is set; the type of `value` will be the type implied by the option’s type. If `type` for this option is `None` (no argument expected), then `value` will be `None`. If `nargs` > 1, `value` will be a tuple of values of the appropriate type.
**parser** is the `OptionParser` instance driving the whole thing, mainly useful because you can access some other interesting data through its instance attributes:

- **parser.largs** the current list of leftover arguments, i.e. arguments that have been consumed but are neither options nor option arguments. Feel free to modify `parser.largs`, e.g. by adding more arguments to it. (This list will become `args`, the second return value of `parse_args()`.)

- **parser.rargs** the current list of remaining arguments, i.e. with `opt_str` and `value` (if applicable) removed, and only the arguments following them still there. Feel free to modify `parser.rargs`, e.g. by consuming more arguments.

- **parser.values** the object where option values are by default stored (an instance of `optparse.OptionValues`). This lets callbacks use the same mechanism as the rest of `optparse` for storing option values; you don’t need to mess around with globals or closures. You can also access or modify the value(s) of any options already encountered on the command-line.

**args** is a tuple of arbitrary positional arguments supplied via the `callback_args` option attribute.

**kwargs** is a dictionary of arbitrary keyword arguments supplied via `callback_kwargs`.

### Raising errors in a callback

The callback function should raise `OptionValueError` if there are any problems with the option or its argument(s). `optparse` catches this and terminates the program, printing the error message you supply to stderr. Your message should be clear, concise, accurate, and mention the option at fault. Otherwise, the user will have a hard time figuring out what they did wrong.

#### Callback example 1: trivial callback

Here’s an example of a callback option that takes no arguments, and simply records that the option was seen:

```python
def record_foo_seen(option, opt_str, value, parser):
    parser.values.saw_foo = True
parser.add_option("--foo", action="callback", callback=record_foo_seen)
```

Of course, you could do that with the "store_true" action.

#### Callback example 2: check option order

Here’s a slightly more interesting example: record the fact that `–a` is seen, but blow up if it comes after `–b` in the command-line.

```python
def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use -a after -b")
    parser.values.a = 1
...
parser.add_option("-a", action="callback", callback=check_order)
paper.add_option("-b", action="store_true", dest="b")
```
Callback example 3: check option order (generalized)

If you want to re-use this callback for several similar options (set a flag, but blow up if \(-b\) has already been seen), it needs a bit of work: the error message and the flag that it sets must be generalized.

```python
def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use \$s after \-b\ \% opt_str")
    setattr(parser.values, option.dest, 1)
...
parser.add_option("-a", action="callback", callback=check_order, dest='a')
parser.add_option("-b", action="store_true", dest='b')
parser.add_option("-c", action="callback", callback=check_order, dest='c')
```

Callback example 4: check arbitrary condition

Of course, you could put any condition in there—you're not limited to checking the values of already-defined options. For example, if you have options that should not be called when the moon is full, all you have to do is this:

```python
def check_moon(option, opt_str, value, parser):
    if is_moon_full():
        raise OptionValueError("\$s option invalid when moon is full" % opt_str)
    setattr(parser.values, option.dest, 1)
...
parser.add_option("--foo", action="callback", callback=check_moon, dest="foo")
```

(The definition of \texttt{is\_moon\_full()} is left as an exercise for the reader.)

Callback example 5: fixed arguments

Things get slightly more interesting when you define callback options that take a fixed number of arguments. Specifying that a callback option takes arguments is similar to defining a "\texttt{store}" or "\texttt{append}" option: if you define \texttt{type}, then the option takes one argument that must be convertible to that type; if you further define \texttt{nargs}, then the option takes \texttt{nargs} arguments.

Here's an example that just emulates the standard "\texttt{store}" action:

```python
def store_value(option, opt_str, value, parser):
    setattr(parser.values, option.dest, value)
...
parser.add_option("--foo",
    action="callback", callback=store_value,
    type="int", nargs=3, dest="foo")
```

Note that \texttt{optparse} takes care of consuming 3 arguments and converting them to integers for you; all you have to do is store them. (Or whatever; obviously you don’t need a callback for this example.)
Callback example 6: variable arguments

Things get hairy when you want an option to take a variable number of arguments. For this case, you must write a callback, as `optparse` doesn’t provide any built-in capabilities for it. And you have to deal with certain intricacies of conventional Unix command-line parsing that `optparse` normally handles for you. In particular, callbacks should implement the conventional rules for bare -- or – arguments:

- either -- or – can be option arguments
- bare -- (if not the argument to some option): halt command-line processing and discard the --
- bare – (if not the argument to some option): halt command-line processing but keep the – (append it to parser.largs)

If you want an option that takes a variable number of arguments, there are several subtle, tricky issues to worry about. The exact implementation you choose will be based on which trade-offs you’re willing to make for your application (which is why `optparse` doesn’t support this sort of thing directly).

Nevertheless, here’s a stab at a callback for an option with variable arguments:

```python
def vararg_callback(option, opt_str, value, parser):
    assert value is None
    value = []

def floatable(str):
    try:
        float(str)
        return True
    except ValueError:
        return False

for arg in parser.rargs:
    # stop on --foo like options
    if arg[:2] == "--" and len(arg) > 2:
        break
    # stop on -a, but not on -3 or -3.0
    if arg[:1] == "-" and len(arg) > 1 and not floatable(arg):
        break
    value.append(arg)

del parser.rargs[:len(value)]
setattr(parser.values, option.dest, value)

... parser.add_option("-c", "--callback", dest="vararg_attr",
    action="callback", callback=vararg_callback)
```
35.14.5 Extending `optparse`

Since the two major controlling factors in how `optparse` interprets command-line options are the action and type of each option, the most likely direction of extension is to add new actions and new types.

Adding new types

To add new types, you need to define your own subclass of `optparse`'s `Option` class. This class has a couple of attributes that define `optparse`'s types: `TYPES` and `TYPE_CHECKER`.

Option. `TYPES`  
A tuple of type names; in your subclass, simply define a new tuple `TYPES` that builds on the standard one.

Option. `TYPE_CHECKER`  
A dictionary mapping type names to type-checking functions. A type-checking function has the following signature:

```python
def check_mytype(option, opt, value)
```

where `option` is an `Option` instance, `opt` is an option string (e.g., `-f`), and `value` is the string from the command line that must be checked and converted to your desired type. `check_mytype()` should return an object of the hypothetical type `mytype`. The value returned by a type-checking function will wind up in the `OptionValues` instance returned by `OptionParser.parse_args()`, or be passed to a callback as the `value` parameter.

Your type-checking function should raise `OptionValueError` if it encounters any problems. `OptionValueError` takes as a single string argument, which is passed as-is to `OptionParser.error()` method, which in turn prepends the program name and the string "error:" and prints everything to stderr before terminating the process.

Here's a silly example that demonstrates adding a "`complex`" option type to parse Python-style complex numbers on the command line. (This is even sillier than it used to be, because `optparse 1.3` added built-in support for complex numbers, but never mind.)

First, the necessary imports:

```python
from copy import copy
from optparse import Option, OptionValueError
```

You need to define your type-checker first, since it's referred to later (in the `TYPE_CHECKER` class attribute of your `Option` subclass):

```python
def check_complex(option, opt, value):
    try:
        return complex(value)
    except ValueError:
        raise OptionValueError("option %s: invalid complex value: %r" % (opt, value))
```

Finally, the `Option` subclass:

```python
class MyOption (Option):
    TYPES = Option.TYPES + ("complex",)
    TYPE_CHECKER = copy(Option.TYPE_CHECKER)
    TYPE_CHECKER["complex"] = check_complex
```

(If we didn't make a `copy()` of `Option.TYPE_CHECKER`, we would end up modifying the `TYPE_CHECKER` attribute of `optparse`'s `Option` class. This being Python, nothing stops you from doing that except good manners and common sense.)

That's it! Now you can write a script that uses the new option type just like any other `optparse`-based script, except you have to instruct your `OptionParser` to use `MyOption` instead of `Option`:  

35.14. `optparse` — Parser for command line options
parser = OptionParser(option_class=MyOption)
parser.add_option("-c", type="complex")

Alternately, you can build your own option list and pass it to OptionParser; if you don’t use add_option() in the above way, you don’t need to tell OptionParser which option class to use:

```python
option_list = [MyOption("-c", action="store", type="complex", dest="c")]
parsed = OptionParser(option_list=option_list)
```

## Adding new actions

Adding new actions is a bit trickier, because you have to understand that optparse has a couple of classifications for actions:

- **“store” actions** actions that result in optparse storing a value to an attribute of the current OptionValues instance; these options require a dest attribute to be supplied to the Option constructor.
- **“typed” actions** actions that take a value from the command line and expect it to be of a certain type; or rather, a string that can be converted to a certain type. These options require a type attribute to the Option constructor.

These are overlapping sets: some default “store” actions are "store", "store_const", "append", and "count", while the default “typed” actions are "store", "append", and "callback".

When you add an action, you need to categorize it by listing it in at least one of the following class attributes of Option (all are lists of strings):

```python
Option.ACTIONS
    All actions must be listed in ACTIONS.
Option.STORE_ACTIONS
    "store" actions are additionally listed here.
Option.TYPED_ACTIONS
    "typed" actions are additionally listed here.
Option.ALWAYS_TYPED_ACTIONS
    Actions that always take a type (i.e. whose options always take a value) are additionally listed here. The only effect of this is that optparse assigns the default type, "string", to options with no explicit type whose action is listed in ALWAYS_TYPED_ACTIONS.
```

In order to actually implement your new action, you must override Option’s take_action() method and add a case that recognizes your action.

For example, let’s add an "extend" action. This is similar to the standard "append" action, but instead of taking a single value from the command-line and appending it to an existing list, "extend" will take multiple values in a single comma-delimited string, and extend an existing list with them. That is, if --names is an "extend" option of type "string", the command line

```
--names=foo,bar --names blah --names ding,dong
```

would result in a list

```python
["foo", "bar", "blah", "ding", "dong"]
```

Again we define a subclass of Option:

```python
class MyOption(Option):
    ACTIONS = Option.ACTIONS + ("extend",)
    STORE_ACTIONS = Option.STORE_ACTIONS + ("extend",)
    TYPED_ACTIONS = Option.TYPED_ACTIONS + ("extend",)
    ALWAYS_TYPED_ACTIONS = Option.ALWAYS_TYPED_ACTIONS + ("extend",)
```

(continues on next page)
def take_action(self, action, dest, opt, value, values, parser):
    if action == "extend":
        lvalue = value.split(",")
        values.ensure_value(dest, []).extend(lvalue)
    else:
        Option.take_action(
            self, action, dest, opt, value, values, parser)

Features of note:

• "extend" both expects a value on the command-line and stores that value somewhere, so it goes in both
  STORE_ACTIONS and TYPED_ACTIONS.

• to ensure that optparse assigns the default type of "string" to "extend" actions, we put the "extend" action in ALWAYS_TYPED_ACTIONS as well.

• MyOption.take_action() implements just this one new action, and passes control back to Option.
take_action() for the standard optparse actions.

• values is an instance of the optparse_values class, which provides the very useful
  ensure_value() method. ensure_value() is essentially getattr() with a safety valve; it is called as

  values.ensure_value(attr, value)

If the attr attribute of values doesn’t exist or is None, then ensure_value() first sets it to value, and
then returns value. This is very handy for actions like "extend", "append", and "count", all of which accumulate data in a variable and expect that variable to be of a certain type (a list for the first two, an integer
for the latter). Using ensure_value() means that scripts using your action don’t have to worry about
setting a default value for the option destinations in question; they can just leave the default as None and
ensure_value() will take care of getting it right when it’s needed.

35.15 ossaudiodev — Access to OSS-compatible audio devices

Deprecated since version 3.11: The ossaudiodev module is deprecated (see PEP 594 for details).

This module allows you to access the OSS (Open Sound System) audio interface. OSS is available for a wide range of
open-source and commercial Unices, and is the standard audio interface for Linux and recent versions of FreeBSD.

Changed in version 3.3: Operations in this module now raise OSError where IOError was raised.

See also:

Open Sound System Programmer’s Guide the official documentation for the OSS C API

The module defines a large number of constants supplied by the OSS device driver; see <sys/soundcard.h> on
either Linux or FreeBSD for a listing.

ossaudiodev defines the following variables and functions:

exception ossaudiodev.OSSAudioError

This exception is raised on certain errors. The argument is a string describing what went wrong.

   (If ossaudiodev receives an error from a system call such as open(), write(), or ioctl(), it raises
OSError. Errors detected directly by ossaudiodev result in OSSAudioError.)

   (For backwards compatibility, the exception class is also available as ossaudiodev.error.)

ossaudiodev.open(mode)
ossaudiodev.open (device, mode)
Open an audio device and return an OSS audio device object. This object supports many file-like methods, such as read(), write(), and fileno() (although there are subtle differences between conventional Unix read/write semantics and those of OSS audio devices). It also supports a number of audio-specific methods; see below for the complete list of methods.

device is the audio device filename to use. If it is not specified, this module first looks in the environment variable AUDIODEV for a device to use. If not found, it falls back to /dev/dsp.

mode is one of 'r' for read-only (record) access, 'w' for write-only (playback) access and 'rw' for both. Since many sound cards only allow one process to have the recorder or player open at a time, it is a good idea to open the device only for the activity needed. Further, some sound cards are half-duplex: they can be opened for reading or writing, but not both at once.

Note the unusual calling syntax: the first argument is optional, and the second is required. This is a historical artifact for compatibility with the older linuxaudiodev module which ossaudiodev supersedes.

ossaudiodev.openmixer ([device])
Open a mixer device and return an OSS mixer device object. device is the mixer device filename to use. If it is not specified, this module first looks in the environment variable MIXERDEV for a device to use. If not found, it falls back to /dev/mixer.

35.15.1 Audio Device Objects

Before you can write to or read from an audio device, you must call three methods in the correct order:

1. setfmt() to set the output format
2. channels() to set the number of channels
3. speed() to set the sample rate

Alternately, you can use the setparameters() method to set all three audio parameters at once. This is more convenient, but may not be as flexible in all cases.

The audio device objects returned by open() define the following methods and (read-only) attributes:

oss_audio_device.close()
Explicitly close the audio device. When you are done writing to or reading from an audio device, you should explicitly close it. A closed device cannot be used again.

oss_audio_device.fileno()
Return the file descriptor associated with the device.

oss_audio_device.read(size)
Read size bytes from the audio input and return them as a Python string. Unlike most Unix device drivers, OSS audio devices in blocking mode (the default) will block read() until the entire requested amount of data is available.

oss_audio_device.write(data)
Write a bytes-like object data to the audio device and return the number of bytes written. If the audio device is in blocking mode (the default), the entire data is always written (again, this is different from usual Unix device semantics). If the device is in non-blocking mode, some data may not be written—see writeall().

Changed in version 3.5: Writable bytes-like object is now accepted.

oss_audio_device.writeall(data)
Write a bytes-like object data to the audio device: waits until the audio device is able to accept data, writes as much data as it will accept, and repeats until data has been completely written. If the device is in blocking mode (the default), this has the same effect as write(); writeall() is only useful in non-blocking mode. Has no return value, since the amount of data written is always equal to the amount of data supplied.

Changed in version 3.5: Writable bytes-like object is now accepted.
Changed in version 3.2: Audio device objects also support the context management protocol, i.e. they can be used in a with statement.

The following methods each map to exactly one ioctl() system call. The correspondence is obvious: for example, setfmt() corresponds to the SNDCTL_DSP_SETFMT ioctl, and sync() to SNDCTL_DSP_SYNC (this can be useful when consulting the OSS documentation). If the underlying ioctl() fails, they all raise OSError.

oss_audio_device.nonblock()
Put the device into non-blocking mode. Once in non-blocking mode, there is no way to return it to blocking mode.

oss_audio_device.getfmts()
Return a bitmask of the audio output formats supported by the soundcard. Some of the formats supported by OSS are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>AFMT_MU_LAW</td>
<td>a logarithmic encoding (used by Sun .au files and /dev/audio)</td>
</tr>
<tr>
<td>AFMT_A_LAW</td>
<td>a logarithmic encoding</td>
</tr>
<tr>
<td>AFMT_IMA_ADPCM</td>
<td>a 4:1 compressed format defined by the Interactive Multimedia Association</td>
</tr>
<tr>
<td>AFMT_U8</td>
<td>Unsigned, 8-bit audio</td>
</tr>
<tr>
<td>AFMT_S16_LE</td>
<td>Signed, 16-bit audio, little-endian byte order (as used by Intel processors)</td>
</tr>
<tr>
<td>AFMT_S16_BE</td>
<td>Signed, 16-bit audio, big-endian byte order (as used by 68k, PowerPC, Sparc)</td>
</tr>
<tr>
<td>AFMT_S8</td>
<td>Signed, 8 bit audio</td>
</tr>
<tr>
<td>AFMT_U16_LE</td>
<td>Unsigned, 16-bit little-endian audio</td>
</tr>
<tr>
<td>AFMT_U16_BE</td>
<td>Unsigned, 16-bit big-endian audio</td>
</tr>
</tbody>
</table>

Consult the OSS documentation for a full list of audio formats, and note that most devices support only a subset of these formats. Some older devices only support AFMT_U8; the most common format used today is AFMT_S16_LE.

oss_audio_device.setfmt(format)
Try to set the current audio format to format—see getfmts() for a list. Returns the audio format that the device was set to, which may not be the requested format. May also be used to return the current audio format—do this by passing an “audio format” of AFMT_QUERY.

oss_audio_device.channels(nchannels)
Set the number of output channels to nchannels. A value of 1 indicates monophonic sound, 2 stereophonic. Some devices may have more than 2 channels, and some high-end devices may not support mono. Returns the number of channels the device was set to.

oss_audio_device.speed(samplerate)
Try to set the audio sampling rate to samplerate samples per second. Returns the rate actually set. Most sound devices don’t support arbitrary sampling rates. Common rates are:

<table>
<thead>
<tr>
<th>Rate</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>8000</td>
<td>default rate for /dev/audio</td>
</tr>
<tr>
<td>11025</td>
<td>speech recording</td>
</tr>
<tr>
<td>22050</td>
<td></td>
</tr>
<tr>
<td>44100</td>
<td>CD quality audio (at 16 bits/sample and 2 channels)</td>
</tr>
<tr>
<td>96000</td>
<td>DVD quality audio (at 24 bits/sample)</td>
</tr>
</tbody>
</table>

oss_audio_device.sync()
Wait until the sound device has played every byte in its buffer. (This happens implicitly when the device is closed.) The OSS documentation recommends closing and re-opening the device rather than using sync().

oss_audio_device.reset()
Immediately stop playing or recording and return the device to a state where it can accept commands. The OSS documentation recommends closing and re-opening the device after calling reset().

oss_audio_device.post()
Tell the driver that there is likely to be a pause in the output, making it possible for the device to handle the
pause more intelligently. You might use this after playing a spot sound effect, before waiting for user input, or
before doing disk I/O.

The following convenience methods combine several iocls, or one ioctl and some simple calculations.

oss_audio_device.setparameters(format, nchannels, samplerate[, strict=False])

Set the key audio sampling parameters—sample format, number of channels, and sampling rate—in one
method call. format, nchannels, and samplerate should be as specified in the setfmt(), channels(),
and speed() methods. If strict is true, setparameters() checks to see if each parameter was actually
set to the requested value, and raises OSSAudioError if not. Returns a tuple (format, nchannels, samplerate)
indicating the parameter values that were actually set by the device driver (i.e., the same as the return
values of setfmt(), channels(), and speed()).

For example,

```
(fmt, channels, rate) = dsp.setparameters(fmt, channels, rate)
```

is equivalent to

```
fmt = dsp.setfmt(fmt)
channels = dsp.channels(channels)
rate = dsp.rate(rate)
```

oss_audio_device.bufsize()

Returns the size of the hardware buffer, in samples.

oss_audio_device.obufcount()

Returns the number of samples that are in the hardware buffer yet to be played.

oss_audio_device.obuffree()

Returns the number of samples that could be queued into the hardware buffer to be played without blocking.

Audio device objects also support several read-only attributes:

oss_audio_device.closed

Boolean indicating whether the device has been closed.

oss_audio_device.name

String containing the name of the device file.

oss_audio_device.mode

The I/O mode for the file, either "r", "rw", or "w".

35.15.2 Mixer Device Objects

The mixer object provides two file-like methods:

oss.mixer_device.close()

This method closes the open mixer device file. Any further attempts to use the mixer after this file is closed
will raise an OSError.

oss.mixer_device.fileno()

Returns the file handle number of the open mixer device file.

Changed in version 3.2: Mixer objects also support the context management protocol.

The remaining methods are specific to audio mixing:

oss.mixer_device.controls()

This method returns a bitmask specifying the available mixer controls ("Control" being a specific mixable
“channel”, such as SOUND_MIXER_PCM or SOUND_MIXER_SYNTH). This bitmask indicates a subset of
all available mixer controls—the SOUND_MIXER_* constants defined at module level. To determine if, for
example, the current mixer object supports a PCM mixer, use the following Python code:
For most purposes, the \texttt{SOUND_MIXER_VOLUME} (master volume) and \texttt{SOUND_MIXER_PCM} controls should suffice—but code that uses the mixer should be flexible when it comes to choosing mixer controls. On the Gravis Ultrasound, for example, \texttt{SOUND_MIXER_VOLUME} does not exist.

\begin{verbatim}
mixer = ossaudiodev.openmixer()
if mixer.controls() & (1 << ossaudiodev.SOUND_MIXER_PCM):
    # PCM is supported
    ... code ...
\end{verbatim}

\texttt{oss_mixer_device.stereocontrols()}

Returns a bitmask indicating stereo mixer controls. If a bit is set, the corresponding control is stereo; if it is unset, the control is either monophonic or not supported by the mixer (use in combination with \texttt{controls()} to determine which).

See the code example for the \texttt{controls()} function for an example of getting data from a bitmask.

\texttt{oss_mixer_device.reccontrols()}

Returns a bitmask specifying the mixer controls that may be used to record. See the code example for \texttt{controls()} for an example of reading from a bitmask.

\texttt{oss_mixer_device.get(control)}

Returns the volume of a given mixer control. The returned volume is a 2-tuple \texttt{(left_volume, right_volume)}. Volumes are specified as numbers from 0 (silent) to 100 (full volume). If the control is monophonic, a 2-tuple is still returned, but both volumes are the same.

Raises \texttt{OSSAudioError} if an invalid control is specified, or \texttt{OSError} if an unsupported control is specified.

\texttt{oss_mixer_device.set(control, (left, right))}

Sets the volume for a given mixer control to \texttt{(left, right)}. \texttt{left} and \texttt{right} must be ints and between 0 (silent) and 100 (full volume). On success, the new volume is returned as a 2-tuple. Note that this may not be exactly the same as the volume specified, because of the limited resolution of some soundcard's mixers.

Raises \texttt{OSSAudioError} if an invalid mixer control was specified, or if the specified volumes were out-of-range.

\texttt{oss_mixer_device.get_recsrc()}

This method returns a bitmask indicating which control(s) are currently being used as a recording source.

\texttt{oss_mixer_device.set_recsrc(bitmask)}

Call this function to specify a recording source. Returns a bitmask indicating the new recording source (or sources) if successful; raises \texttt{OSError} if an invalid source was specified. To set the current recording source to the microphone input:

\begin{verbatim}
mixer.setrecsrc (1 << ossaudiodev.SOUND_MIXER_MIC)
\end{verbatim}

## 35.16 pipes — Interface to shell pipelines

**Source code:** Lib/pipes.py

Deprecated since version 3.11: The \texttt{pipes} module is deprecated (see PEP 594 for details).

The \texttt{pipes} module defines a class to abstract the concept of a pipeline — a sequence of converters from one file to another.

Because the module uses \texttt{/bin/sh} command lines, a POSIX or compatible shell for \texttt{os.system()} and \texttt{os.popen()} is required.

**Availability:** Unix. Not available on VxWorks.

The \texttt{pipes} module defines the following class:
class pipes.Template
An abstraction of a pipeline.

Example:

```python
>>> import pipes
>>> t = pipes.Template()
>>> t.append('tr a-z A-Z', '==')
>>> f = t.open('pipefile', 'w')
>>> f.write('hello world')
>>> f.close()
>>> open('pipefile').read()
'HELLO WORLD'
```

### 35.16.1 Template Objects

Template objects following methods:

Template.reset()
Restore a pipeline template to its initial state.

Template.clone()
Return a new, equivalent, pipeline template.

Template.debug(flag)
If flag is true, turn debugging on. Otherwise, turn debugging off. When debugging is on, commands to be executed are printed, and the shell is given `set -x` command to be more verbose.

Template.append(cmd, kind)
Append a new action at the end. The cmd variable must be a valid bourne shell command. The kind variable consists of two letters.

The first letter can be either of '－' (which means the command reads its standard input), 'f' (which means the commands reads a given file on the command line) or '.' (which means the commands reads no input, and hence must be first.)

Similarly, the second letter can be either of '－' (which means the command writes to standard output), 'f' (which means the command writes a file on the command line) or '.' (which means the command does not write anything, and hence must be last.)

Template.prepend(cmd, kind)
Add a new action at the beginning. See append() for explanations of the arguments.

Template.open(file, mode)
Return a file-like object, open to file, but read from or written to by the pipeline. Note that only one of 'r', 'w' may be given.

Template.copy(infile, outfile)
Copy infile to outfile through the pipe.

### 35.17 smtpd — SMTP Server

Source code: Lib/smtpd.py

This module offers several classes to implement SMTP (email) servers.

Deprecated since version 3.6: smtpd will be removed in Python 3.12 (PEP 594). The aiosmtpd package is a recommended replacement for this module. It is based on asyncio and provides a more straightforward API.

Several server implementations are present; one is a generic do-nothing implementation, which can be overridden, while the other two offer specific mail-sending strategies.
Additionally the SMTPChannel may be extended to implement very specific interaction behaviour with SMTP clients.

The code supports RFC 5321, plus the RFC 1870 SIZE and RFC 6531 SMTPUTF8 extensions.

### 35.17.1 SMTPServer Objects

**class smtplib.SMTPServer** *(localaddr, remoteaddr, data_size_limit=33554432, map=None, enable_SMTPUTF8=False, decode_data=False)*

Create a new **SMTPServer** object, which binds to local address `localaddr`. It will treat `remoteaddr` as an upstream SMTP relayer. Both `localaddr` and `remoteaddr` should be a `(host, port)` tuple. The object inherits from `asyncore.dispatcher`, and so will insert itself into `asyncore`'s event loop on instantiation.

* `data_size_limit` specifies the maximum number of bytes that will be accepted in a DATA command. A value of `None` or `0` means no limit.
* `map` is the socket map to use for connections (an initially empty dictionary is a suitable value). If not specified the `asyncore` global socket map is used.
* `enable_SMTPUTF8` determines whether the SMTPUTF8 extension (as defined in RFC 6531) should be enabled. The default is `False`. When `True`, SMTPUTF8 is accepted as a parameter to the MAIL command and when present is passed to `process_message()` in the `kwargs['mail_options']` list. `decode_data` and `enable_SMTPUTF8` cannot be set to `True` at the same time.
* `decode_data` specifies whether the data portion of the SMTP transaction should be decoded using UTF-8. When `decode_data` is `False` (the default), the server advertises the 8BITMIME extension (RFC 6152), accepts the BODY=8BITMIME parameter to the MAIL command, and when present passes it to `process_message()` in the `kwargs['mail_options']` list. `decode_data` and `enable_SMTPUTF8` cannot be set to `True` at the same time.

**process_message**(peer, mailfrom, rcpttos, data, **kwargs)

Raise a `NotImplementedError` exception. Override this in subclasses to do something useful with this message. Whatever was passed in the constructor as `remoteaddr` will be available as the `_remoteaddr` attribute. `peer` is the remote host's address, `mailfrom` is the envelope originator, `rcpttos` are the envelope recipients and `data` is a string containing the contents of the e-mail (which should be in RFC 5321 format).

If the `decode_data` constructor keyword is set to `True`, the `data` argument will be a unicode string. If it is set to `False`, it will be a bytes object.

* `kwargs` is a dictionary containing additional information. It is empty if `decode_data=True` was given as an init argument, otherwise it contains the following keys:
  * `mail_options`: a list of all received parameters to the MAIL command (the elements are upper-case strings; example: `['BODY=8BITMIME', 'SMTPUTF8']`).
  * `rcpt_options`: same as `mail_options` but for the RCPT command. Currently no RCPT TO options are supported, so for now this will always be an empty list.

Implementations of `process_message` should use the `**kwargs` signature to accept arbitrary key-word arguments, since future feature enhancements may add keys to the kwargs dictionary.

Return `None` to request a normal 250 OK response; otherwise return the desired response string in RFC 5321 format.

**channel_class**

Override this in subclasses to use a custom `SMTPChannel` for managing SMTP clients.

New in version 3.4: The `map` constructor argument.

Changed in version 3.5: `localaddr` and `remoteaddr` may now contain IPv6 addresses.

New in version 3.5: The `decode_data` and `enable_SMTPUTF8` constructor parameters, and the `kwars` parameter to `process_message()` when `decode_data` is `False`.

Changed in version 3.6: `decode_data` is now `False` by default.
35.17.2 DebuggingServer Objects

class smtpd.DebuggingServer (localaddr, remoteaddr)
Create a new debugging server. Arguments are as per SMTPServer. Messages will be discarded, and printed on stdout.

35.17.3 PureProxy Objects

class smtpd.PureProxy (localaddr, remoteaddr)
Create a new pure proxy server. Arguments are as per SMTPServer. Everything will be relayed to remoteaddr. Note that running this has a good chance to make you into an open relay, so please be careful.

35.17.4 MailmanProxy Objects

class smtpd.MailmanProxy (localaddr, remoteaddr)
Deprecated since version 3.9, will be removed in version 3.11: MailmanProxy is deprecated, it depends on a Mailman module which no longer exists and therefore is already broken.

Create a new pure proxy server. Arguments are as per SMTPServer. Everything will be relayed to remoteaddr, unless local mailman configurations knows about an address, in which case it will be handled via mailman. Note that running this has a good chance to make you into an open relay, so please be careful.

35.17.5 SMTPChannel Objects

class smtpd.SMTPChannel (server, conn, addr, data_size_limit=33554432, map=None, enable_SMTPUTF8=False, decode_data=False)
Create a new SMTPChannel object which manages the communication between the server and a single SMTP client.

conn and addr are as per the instance variables described below.

data_size_limit specifies the maximum number of bytes that will be accepted in a DATA command. A value of None or 0 means no limit.

enable_SMTPUTF8 determines whether the SMTPUTF8 extension (as defined in RFC 6531) should be enabled. The default is False. decode_data and enable_SMTPUTF8 cannot be set to True at the same time.

A dictionary can be specified in map to avoid using a global socket map.

decode_data specifies whether the data portion of the SMTP transaction should be decoded using UTF-8. The default is False. decode_data and enable_SMTPUTF8 cannot be set to True at the same time.

To use a custom SMTPChannel implementation you need to override the SMTPServer.channel_class of your SMTPServer.

Changed in version 3.5: The decode_data and enable_SMTPUTF8 parameters were added.

Changed in version 3.6: decode_data is now False by default.

The SMTPChannel has the following instance variables:

smtp_server
Holds the SMTPServer that spawned this channel.

conn
Holds the socket object connecting to the client.

addr
Holds the address of the client, the second value returned by socket.accept

received_lines
Holds a list of the line strings (decoded using UTF-8) received from the client. The lines have their "\r\n" line ending translated to "\n".
smtp_state
Holds the current state of the channel. This will be either COMMAND initially and then DATA after the client sends a “DATA” line.

seen_greeting
Holds a string containing the greeting sent by the client in its “HELO”.

mailfrom
Holds a string containing the address identified in the “MAIL FROM:” line from the client.

rcpttos
Holds a list of strings containing the addresses identified in the “RCPT TO:” lines from the client.

received_data
Holds a string containing all of the data sent by the client during the DATA state, up to but not including the terminating "\r\n\r\n".

fqdn
Holds the fully-qualified domain name of the server as returned by socket.getfqdn().

peer
Holds the name of the client peer as returned by conn.getpeername() where conn is conn.

The SMTPChannel operates by invoking methods named smtp_<command> upon reception of a command line from the client. Built into the base SMTPChannel class are methods for handling the following commands (and responding to them appropriately):

<table>
<thead>
<tr>
<th>Command</th>
<th>Action taken</th>
</tr>
</thead>
<tbody>
<tr>
<td>HELO</td>
<td>Accepts the greeting from the client and stores it in seen_greeting. Sets server to base command mode.</td>
</tr>
<tr>
<td>EHLO</td>
<td>Accepts the greeting from the client and stores it in seen_greeting. Sets server to extended command mode.</td>
</tr>
<tr>
<td>NOOP</td>
<td>Takes no action.</td>
</tr>
<tr>
<td>QUIT</td>
<td>Closes the connection cleanly.</td>
</tr>
<tr>
<td>MAIL</td>
<td>Accepts the “MAIL FROM:” syntax and stores the supplied address as mailfrom. In extended command mode, accepts the RFC 1870 SIZE attribute and responds appropriately based on the value of data_size_limit.</td>
</tr>
<tr>
<td>RCPT</td>
<td>Accepts the “RCPT TO:” syntax and stores the supplied addresses in the rcpttos list.</td>
</tr>
<tr>
<td>RSET</td>
<td>Resets the mailfrom, rcpttos, and received_data, but not the greeting.</td>
</tr>
<tr>
<td>DATA</td>
<td>Sets the internal state to DATA and stores remaining lines from the client in received_data until the terminator &quot;\r\n\r\n&quot; is received.</td>
</tr>
<tr>
<td>HELP</td>
<td>Returns minimal information on command syntax</td>
</tr>
<tr>
<td>VRFY</td>
<td>Returns code 252 (the server doesn’t know if the address is valid)</td>
</tr>
<tr>
<td>EXPN</td>
<td>Reports that the command is not implemented.</td>
</tr>
</tbody>
</table>

35.18 sndhdr — Determine type of sound file

Source code: Lib/sndhdr.py
Deprecated since version 3.11: The sndhdr module is deprecated (see PEP 594 for details).

The sndhdr provides utility functions which attempt to determine the type of sound data which is in a file. When these functions are able to determine what type of sound data is stored in a file, they return a namedtuple(), containing five attributes: (filetype, framerate, nchannels, nframes, sampwidth). The value for type indicates the data type and will be one of the strings 'aifc', 'aiff', 'au', 'hcom', 'sndr', 'sndt', 'voc', 'wav', '8svx', 'sb', 'ub', or 'ul'. The sampling_rate will be either the actual value or 0 if unknown or difficult to decode. Similarly, channels will be either the number of channels or 0 if it cannot be determined or if
the value is difficult to decode. The value for frames will be either the number of frames or \(-1\). The last item in the tuple, bits\_per\_sample, will either be the sample size in bits or ‘A’ for A-LAW or ‘U’ for u-LAW.

sndhdr.\texttt{what} (filename)
Determines the type of sound data stored in the file \texttt{filename} using \texttt{whathdr()}. If it succeeds, returns a namedtuple as described above, otherwise None is returned.

Changed in version 3.5: Result changed from a tuple to a namedtuple.

sndhdr.\texttt{whathdr} (filename)
Determines the type of sound data stored in a file based on the file header. The name of the file is given by \texttt{filename}. This function returns a namedtuple as described above on success, or None.

Changed in version 3.5: Result changed from a tuple to a namedtuple.

\section{35.19 \texttt{spwd} — The shadow password database}

Deprecated since version 3.11: The \texttt{spwd} module is deprecated (see PEP 594 for details).

This module provides access to the Unix shadow password database. It is available on various Unix versions.

You must have enough privileges to access the shadow password database (this usually means you have to be root).

Shadow password database entries are reported as a tuple-like object, whose attributes correspond to the members of the \texttt{spwd} structure (Attribute field below, see \texttt{<shadow.h>}):

<table>
<thead>
<tr>
<th>Index</th>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>sp_namp</td>
<td>Login name</td>
</tr>
<tr>
<td>1</td>
<td>sp_pwdp</td>
<td>Encrypted password</td>
</tr>
<tr>
<td>2</td>
<td>sp_lstchg</td>
<td>Date of last change</td>
</tr>
<tr>
<td>3</td>
<td>sp_min</td>
<td>Minimal number of days between changes</td>
</tr>
<tr>
<td>4</td>
<td>sp_max</td>
<td>Maximum number of days between changes</td>
</tr>
<tr>
<td>5</td>
<td>sp_warn</td>
<td>Number of days before password expires to warn user about it</td>
</tr>
<tr>
<td>6</td>
<td>sp_inact</td>
<td>Number of days after password expires until account is disabled</td>
</tr>
<tr>
<td>7</td>
<td>sp_expire</td>
<td>Number of days since 1970-01-01 when account expires</td>
</tr>
<tr>
<td>8</td>
<td>sp_flag</td>
<td>Reserved</td>
</tr>
</tbody>
</table>

The sp\_namp and sp\_pwdp items are strings, all others are integers. \texttt{KeyError} is raised if the entry asked for cannot be found.

The following functions are defined:

\texttt{spwd.getspnam} (name)
Return the shadow password database entry for the given user name.

Changed in version 3.6: Raises a \texttt{PermissionError} instead of \texttt{KeyError} if the user doesn’t have privileges.

\texttt{spwd.getspall} ()
Return a list of all available shadow password database entries, in arbitrary order.

See also:

Module \texttt{grp} An interface to the group database, similar to this.

Module \texttt{pwd} An interface to the normal password database, similar to this.
35.20  sunau — Read and write Sun AU files

Source code: Lib/sunau.py

Deprecated since version 3.11: The `sunau` module is deprecated (see PEP 594 for details).

The `sunau` module provides a convenient interface to the Sun AU sound format. Note that this module is interface-compatible with the modules `aifc` and `wave`.

An audio file consists of a header followed by the data. The fields of the header are:

<table>
<thead>
<tr>
<th>Field</th>
<th>Contents</th>
</tr>
</thead>
<tbody>
<tr>
<td>magic word</td>
<td>The four bytes <code>.snd</code>.</td>
</tr>
<tr>
<td>header size</td>
<td>Size of the header, including info, in bytes.</td>
</tr>
<tr>
<td>data size</td>
<td>Physical size of the data, in bytes.</td>
</tr>
<tr>
<td>encoding</td>
<td>Indicates how the audio samples are encoded.</td>
</tr>
<tr>
<td>sample rate</td>
<td>The sampling rate.</td>
</tr>
<tr>
<td># of channels</td>
<td>The number of channels in the samples.</td>
</tr>
<tr>
<td>info</td>
<td>ASCII string giving a description of the audio file (padded with null bytes).</td>
</tr>
</tbody>
</table>

Apart from the info field, all header fields are 4 bytes in size. They are all 32-bit unsigned integers encoded in big-endian byte order.

The `sunau` module defines the following functions:

```python
sunau.open(file, mode)
```

If `file` is a string, open the file by that name, otherwise treat it as a seekable file-like object. `mode` can be any of `'r'` Read only mode.

- `'w'` Write only mode.

Note that it does not allow read/write files.

A `mode` of `'r'` returns an `AU_read` object, while a `mode` of `'w'` or `'wb'` returns an `AU_write` object.

The `sunau` module defines the following exception:

```python
exception sunau.Error
```

An error raised when something is impossible because of Sun AU specs or implementation deficiency.

The `sunau` module defines the following data items:

```python
sunau.AUDIO_FILE_MAGIC
```

An integer every valid Sun AU file begins with, stored in big-endian form. This is the string `.snd` interpreted as an integer.

```python
sunau.AUDIO_FILE_ENCODING_MULAW_8
sunau.AUDIO_FILE_ENCODING_LINEAR_8
sunau.AUDIO_FILE_ENCODING_LINEAR_16
sunau.AUDIO_FILE_ENCODING_LINEAR_24
sunau.AUDIO_FILE_ENCODING_LINEAR_32
sunau.AUDIO_FILE_ENCODING_ALAW_8
```

Values of the encoding field from the AU header which are supported by this module.

```python
sunau.AUDIO_FILE_ENCODING_FLOAT
sunau.AUDIO_FILE_ENCODING_DOUBLE
sunau.AUDIO_FILE_ENCODING_ADPCM_G721
sunau.AUDIO_FILE_ENCODING_ADPCM_G722
sunau.AUDIO_FILE_ENCODING_ADPCM_G723_3
sunau.AUDIO_FILE_ENCODING_ADPCM_G723_5
```

Additional known values of the encoding field from the AU header, but which are not supported by this module.
35.20.1 AU_read Objects

AU_read objects, as returned by `open()` above, have the following methods:

**AU_read.close()**
- Close the stream, and make the instance unusable. (This is called automatically on deletion.)

**AU_read.getnchannels()**
- Returns number of audio channels (1 for mono, 2 for stereo).

**AU_read.getsampwidth()**
- Returns sample width in bytes.

**AU_read.getframerate()**
- Returns sampling frequency.

**AU_read.getnframes()**
- Returns number of audio frames.

**AU_read.getcomptype()**
- Returns compression type. Supported compression types are 'ULAW', 'ALAW' and 'NONE'.

**AU_read.getcompname()**
- Human-readable version of `getcomptype()`. The supported types have the respective names 'CCITT G.711 u-law', 'CCITT G.711 A-law' and 'not compressed'.

**AU_read.getparams()**
- Returns a `namedtuple()` (nchannels, sampwidth, framerate, nframes, comptype, compname), equivalent to output of the `get*()` methods.

**AU_read.readframes(n)**
- Reads and returns at most $n$ frames of audio, as a `bytes` object. The data will be returned in linear format. If the original data is in u-LAW format, it will be converted.

**AU_read.rewind()**
- Rewind the file pointer to the beginning of the audio stream.

The following two methods define a term “position” which is compatible between them, and is otherwise implementation dependent.

**AU_read.setpos(pos)**
- Set the file pointer to the specified position. Only values returned from `tell()` should be used for `pos`.

**AU_read.tell()**
- Return current file pointer position. Note that the returned value has nothing to do with the actual position in the file.

The following two functions are defined for compatibility with the `aifc`, and don’t do anything interesting.

**AU_read.getmarkers()**
- Returns None.

**AU_read.getmark(id)**
- Raise an error.
35.20.2 AU_write Objects

AU_write objects, as returned by `open()` above, have the following methods:

**AU_write.setnchannels**(n)
Set the number of channels.

**AU_write.setsampwidth**(n)
Set the sample width (in bytes.)

Changed in version 3.4: Added support for 24-bit samples.

**AU_write.setframerate**(n)
Set the frame rate.

**AU_write.setnframes**(n)
Set the number of frames. This can be later changed, when and if more frames are written.

**AU_write.setcomptype**(type, name)
Set the compression type and description. Only 'NONE' and 'ULAW' are supported on output.

**AU_write.setparams**(tuple)
The tuple should be (nchannels, sampwidth, framerate, nframes, comptype, comp-name), with values valid for the set*() methods. Set all parameters.

**AU_write.tell()**
Return current position in the file, with the same disclaimer for the AU_read.tell() and AU_read. setpos() methods.

**AU_write.writeframesraw**(data)
Write audio frames, without correcting nframes.

Changed in version 3.4: Any bytes-like object is now accepted.

**AU_write.writeframes**(data)
Write audio frames and make sure nframes is correct.

Changed in version 3.4: Any bytes-like object is now accepted.

**AU_write.close()**
Make sure nframes is correct, and close the file.

This method is called upon deletion.

Note that it is invalid to set any parameters after calling writeframes() or writeframesraw().

35.21 telnetlib — Telnet client

Source code: Lib/telnetlib.py

Deprecated since version 3.11: The telnetlib module is deprecated (see PEP 594 for details).

The telnetlib module provides a Telnet class that implements the Telnet protocol. See RFC 854 for details about the protocol. In addition, it provides symbolic constants for the protocol characters (see below), and for the telnet options. The symbolic names of the telnet options follow the definitions in arpa/telnet.h, with the leading TELOPT_ removed. For symbolic names of options which are traditionally not included in arpa/telnet.h, see the module source itself.

The symbolic constants for the telnet commands are: IAC, DONT, DO, WONT, WILL, SE (Subnegotiation End), NOP (No Operation), DM (Data Mark), BRK (Break), IP (Interrupt process), AO (Abort output), AYT (Are You There), EC (Erase Character), EL (Erase Line), GA (Go Ahead), SB (Subnegotiation Begin).
class telnetlib.Telnet (host=None, port=0[, timeout])

Telnet represents a connection to a Telnet server. The instance is initially not connected by default; the open() method must be used to establish a connection. Alternatively, the host name and optional port number can be passed to the constructor too, in which case the connection to the server will be established before the constructor returns. The optional timeout parameter specifies a timeout in seconds for blocking operations like the connection attempt (if not specified, the global default timeout setting will be used).

Do not reopen an already connected instance.

This class has many read_*() methods. Note that some of them raise EOFError when the end of the connection is read, because they can return an empty string for other reasons. See the individual descriptions below.

A Telnet object is a context manager and can be used in a with statement. When the with block ends, the close() method is called:

```python
>>> from telnetlib import Telnet
>>> with Telnet('localhost', 23) as tn:
...    tn.interact()
...```

Changed in version 3.6: Context manager support added

See also:

35.21.1 Telnet Objects

Telnet instances have the following methods:

Telnet.read_until (expected, timeout=None)
Read until a given byte string, expected, is encountered or until timeout seconds have passed.

When no match is found, return whatever is available instead, possibly empty bytes. Raise EOFError if the connection is closed and no cooked data is available.

Telnet.read_all ()
Read all data until EOF as bytes; block until connection closed.

Telnet.read_some ()
Read at least one byte of cooked data unless EOF is hit. Return b'' if EOF is hit. Block if no data is immediately available.

Telnet.read_very_eager ()
Read everything that can be without blocking in I/O (eager).

Raise EOFError if connection closed and no cooked data available. Return b'' if no cooked data available otherwise. Do not block unless in the midst of an IAC sequence.

Telnet.read_eager ()
Read readily available data.

Raise EOFError if connection closed and no cooked data available. Return b'' if no cooked data available otherwise. Do not block unless in the midst of an IAC sequence.

Telnet.read_lazy ()
Process and return data already in the queues (lazy).

Raise EOFError if connection closed and no data available. Return b'' if no cooked data available otherwise. Do not block unless in the midst of an IAC sequence.

Telnet.read_very_lazy ()
Return any data available in the cooked queue (very lazy).
Raise `EOFError` if connection closed and no data available. Return `b''` if no cooked data available otherwise. This method never blocks.

```
Telnet.read_sb_data()
```
Return the data collected between a SB/SE pair (suboption begin/end). The callback should access these data when it was invoked with a SE command. This method never blocks.

```
Telnet.open (host, port=0, timeout)
```
Connect to a host. The optional second argument is the port number, which defaults to the standard Telnet port (23). The optional `timeout` parameter specifies a timeout in seconds for blocking operations like the connection attempt (if not specified, the global default timeout setting will be used).

Do not try to reopen an already connected instance.

Raises an auditing event `telnetlib.Telnet.open` with arguments `self, host, port`.

```
Telnet.msg (msg, *args)
```
Print a debug message when the debug level is > 0. If extra arguments are present, they are substituted in the message using the standard string formatting operator.

```
Telnet.set_debuglevel (debuglevel)
```
Set the debug level. The higher the value of `debuglevel`, the more debug output you get (on `sys.stdout`).

```
Telnet.close()
```
Close the connection.

```
Telnet.get_socket()
```
Return the socket object used internally.

```
Telnet.fileno()
```
Return the file descriptor of the socket object used internally.

```
Telnet.write (buffer)
```
Write a byte string to the socket, doubling any IAC characters. This can block if the connection is blocked. May raise `OSError` if the connection is closed.

Raises an auditing event `telnetlib.Telnet.write` with arguments `self, buffer`.

Changed in version 3.3: This method used to raise `socket.error`, which is now an alias of `OSError`.

```
Telnet.interact ()
```
Interaction function, emulates a very dumb Telnet client.

```
Telnet.mt_interact ()
```
Multithreaded version of `interact()`.

```
Telnet.expect (list, timeout=None)
```
Read until one from a list of a regular expressions matches.

The first argument is a list of regular expressions, either compiled (`regex objects`) or uncompiled (byte strings). The optional second argument is a timeout, in seconds; the default is to block indefinitely.

Return a tuple of three items: the index in the list of the first regular expression that matches; the match object returned; and the bytes read up till and including the match.

If end of file is found and no bytes were read, raise `EOFError`. Otherwise, when nothing matches, return `(-1, None, data)` where `data` is the bytes received so far (may be empty bytes if a timeout happened).

If a regular expression ends with a greedy match (such as `.*`) or if more than one expression can match the same input, the results are non-deterministic, and may depend on the I/O timing.

```
Telnet.set_option_negotiation_callback (callback)
```
Each time a telnet option is read on the input flow, this `callback` (if set) is called with the following parameters: `callback(telnet socket, command (DO/DONT/WILL/WONT), option)`. No other action is done afterwards by telnetlib.
35.21.2 Telnet Example

A simple example illustrating typical use:

```python
import getpass
import telnetlib

HOST = "localhost"
user = input("Enter your remote account: ")
password = getpass.getpass()

tn = telnetlib.Telnet(HOST)

tn.read_until(b"login: ")
if password:
    tn.read_until(b"Password: ")
    tn.write(password.encode('ascii') + b"
"

tn.write(b"ls
")

print(tn.read_all().decode('ascii'))
```

35.22 uu — Encode and decode uuencode files

Source code: Lib/uu.py

Deprecated since version 3.11: The uu module is deprecated (see PEP 594 for details).

This module encodes and decodes files in uuencode format, allowing arbitrary binary data to be transferred over ASCII-only connections. Wherever a file argument is expected, the methods accept a file-like object. For backwards compatibility, a string containing a pathname is also accepted, and the corresponding file will be opened for reading and writing; the pathname `'-'` is understood to mean the standard input or output. However, this interface is deprecated; it’s better for the caller to open the file itself, and be sure that, when required, the mode is `'rb'` or `'wb'` on Windows.

This code was contributed by Lance Ellinghouse, and modified by Jack Jansen.

The `uu` module defines the following functions:

- `uu.encode (in_file, out_file, name=None, mode=None, *, backtick=False)`
  
  Uuencode file `in_file` into file `out_file`. The uuencoded file will have the header specifying `name` and `mode` as the defaults for the results of decoding the file. The default defaults are taken from `in_file`, or `'-'` and `0666` respectively. If `backtick` is true, zeros are represented by `'` instead of spaces.

  Changed in version 3.7: Added the `backtick` parameter.

- `uu.decode (in_file, out_file=None, mode=None, quiet=False)`
  
  This call decodes uuencoded file `in_file` placing the result on file `out_file`. If `out_file` is a pathname, `mode` is used to set the permission bits if the file must be created. Defaults for `out_file` and `mode` are taken from the uuencode header. However, if the file specified in the header already exists, a `uu.Error` is raised.

  `decode()` may print a warning to standard error if the input was produced by an incorrect uuencoder and Python could recover from that error. Setting `quiet` to a true value silences this warning.

**exception** `uu.Error`

Subclass of Exception, this can be raised by `uu.decode()` under various situations, such as described above, but also including a badly formatted header, or truncated input file.

Module `binascii` Support module containing ASCII-to-binary and binary-to-ASCII conversions.

### 35.23 `xdrlib` — Encode and decode XDR data

**Source code:** Lib/xdrlib.py

Deprecated since version 3.11: The `xdrlib` module is deprecated (see PEP 594 for details).

The `xdrlib` module supports the External Data Representation Standard as described in RFC 1014, written by Sun Microsystems, Inc. June 1987. It supports most of the data types described in the RFC.

The `xdrlib` module defines two classes, one for packing variables into XDR representation, and another for unpacking from XDR representation. There are also two exception classes.

```python
class xdrlib.Packer
    Packer is the class for packing data into XDR representation. The Packer class is instantiated with no arguments.

class xdrlib.Unpacker(data)
    Unpacker is the complementary class which unpacks XDR data values from a string buffer. The input buffer is given as data.
```

See also:

- RFC 1014 - XDR: External Data Representation Standard This RFC defined the encoding of data which was XDR at the time this module was originally written. It has apparently been obsoleted by RFC 1832.
- RFC 1832 - XDR: External Data Representation Standard Newer RFC that provides a revised definition of XDR.

#### 35.23.1 Packer Objects

`Packer` instances have the following methods:

- `Packer.get_buffer()` Returns the current pack buffer as a string.
- `Packer.reset()` Resets the pack buffer to the empty string.

In general, you can pack any of the most common XDR data types by calling the appropriate `pack_type()` method. Each method takes a single argument, the value to pack. The following simple data type packing methods are supported: `pack_uint()`, `pack_int()`, `pack_enum()`, `pack_bool()`, `pack_uhyper()`, and `pack_hyper()`.

- `Packer.pack_float(value)` Packs the single-precision floating point number `value`.
- `Packer.pack_double(value)` Packs the double-precision floating point number `value`.

The following methods support packing strings, bytes, and opaque data:

- `Packer.pack_fstring(n, s)` Packs a fixed length string, `s`. `n` is the length of the string but it is not packed into the data buffer. The string is padded with null bytes if necessary to guaranteed 4 byte alignment.
- `Packer.pack_fopaque(n, data)` Packs a fixed length opaque data stream, similarly to `pack_fstring()`.
Packer.\texttt{pack_string}(s)
   Packs a variable length string, \textit{s}. The length of the string is first packed as an unsigned integer, then the string data is packed with \texttt{pack_fstring()}.

Packer.\texttt{pack_opaque}(data)
   Packs a variable length opaque data string, similarly to \texttt{pack_string()}.

Packer.\texttt{pack_bytes}(bytes)
   Packs a variable length byte stream, similarly to \texttt{pack_string()}.

The following methods support packing arrays and lists:

Packer.\texttt{pack_list}(list, \texttt{pack_item})
   Packs a \texttt{list} of homogeneous items. This method is useful for lists with an indeterminate size; i.e. the size is not available until the entire list has been walked. For each item in the list, an unsigned integer \texttt{1} is packed first, followed by the data value from the list. \texttt{pack_item} is the function that is called to pack the individual item. At the end of the list, an unsigned integer \texttt{0} is packed.

   For example, to pack a list of integers, the code might appear like this:

   \begin{verbatim}
   import xdrlib
   p = xdrlib.Packer()
   p.pack_list([1, 2, 3], p.pack_int)
   \end{verbatim}

Packer.\texttt{pack_farray}(n, array, \texttt{pack_item})
   Packs a fixed length list (array) of homogeneous items. \texttt{n} is the length of the list; it is \textit{not} packed into the buffer, but a \texttt{ValueError} exception is raised if \texttt{len(array)} is not equal to \texttt{n}. As above, \texttt{pack_item} is the function used to pack each element.

Packer.\texttt{pack_array}(list, \texttt{pack_item})
   Packs a variable length \texttt{list} of homogeneous items. First, the length of the list is packed as an unsigned integer, then each element is packed as in \texttt{pack_farray()} above.

35.23.2 Unpacker Objects

The \texttt{Unpacker} class offers the following methods:

Unpacker.\texttt{reset}(data)
   Resets the string buffer with the given \textit{data}.

Unpacker.\texttt{get_position}()
   Returns the current unpack position in the data buffer.

Unpacker.\texttt{set_position}(position)
   Sets the data buffer unpack position to \textit{position}. You should be careful about using \texttt{get_position()} and \texttt{set_position()}.

Unpacker.\texttt{get_buffer}()
   Returns the current unpack data buffer as a string.

Unpacker.\texttt{done}()
   Indicates unpack completion. Raises an \texttt{Error} exception if all of the data has not been unpacked.

In addition, every data type that can be packed with a \texttt{Packer}, can be unpacked with an \texttt{Unpacker}. Unpacking methods are of the form \texttt{unpack_type()}, and take no arguments. They return the unpacked object.

Unpacker.\texttt{unpack_float}()
   Unpacks a single-precision floating point number.

Unpacker.\texttt{unpack_double}()
   Unpacks a double-precision floating point number, similarly to \texttt{unpack_float()}.

In addition, the following methods unpack strings, bytes, and opaque data:
Unpacker.\texttt{unpack\_fstring}(n)

Unpacks and returns a fixed length string. \(n\) is the number of characters expected. Padding with null bytes to guaranteed 4 byte alignment is assumed.

Unpacker.\texttt{unpack\_fopaque}(n)

Unpacks and returns a fixed length opaque data stream, similarly to \texttt{unpack\_fstring()}.

Unpacker.\texttt{unpack\_string}()

Unpacks and returns a variable length string. The length of the string is first unpacked as an unsigned integer, then the string data is unpacked with \texttt{unpack\_fstring()}.

Unpacker.\texttt{unpack\_opaque}()

Unpacks and returns a variable length opaque data string, similarly to \texttt{unpack\_string()}.

Unpacker.\texttt{unpack\_bytes}()

Unpacks and returns a variable length byte stream, similarly to \texttt{unpack\_string()}.

The following methods support unpacking arrays and lists:

Unpacker.\texttt{unpack\_list}(\texttt{unpack\_item})

Unpacks and returns a list of homogeneous items. The list is unpacked one element at a time by first unpacking an unsigned integer flag. If the flag is 1, then the item is unpacked and appended to the list. A flag of 0 indicates the end of the list. \texttt{unpack\_item} is the function that is called to unpack the items.

Unpacker.\texttt{unpack\_farray}(n, \texttt{unpack\_item})

Unpacks and returns (as a list) a fixed length array of homogeneous items. \(n\) is number of list elements to expect in the buffer. As above, \texttt{unpack\_item} is the function used to unpack each element.

Unpacker.\texttt{unpack\_array}(\texttt{unpack\_item})

Unpacks and returns a variable length list of homogeneous items. First, the length of the list is unpacked as an unsigned integer, then each element is unpacked as in \texttt{unpack\_farray()} above.

\section*{35.23.3 Exceptions}

Exceptions in this module are coded as class instances:

\begin{description}
\item[exception \texttt{xdrlib.Error}] The base exception class. \texttt{Error} has a single public attribute \texttt{msg} containing the description of the error.
\item[exception \texttt{xdrlib.ConversionError}] Class derived from \texttt{Error}. Contains no additional instance variables.
\end{description}

Here is an example of how you would catch one of these exceptions:

\begin{verbatim}
import xdrlib
p = xdrlib.Packer()
try:
p.pack_double(8.01)
except xdrlib.ConversionError as instance:
    print('packing the double failed:', instance.msg)
\end{verbatim}
Here’s a quick listing of modules that are currently undocumented, but that should be documented. Feel free to contribute documentation for them! (Send via email to docs@python.org.)

The idea and original contents for this chapter were taken from a posting by Fredrik Lundh; the specific contents of this chapter have been substantially revised.

36.1 Platform specific modules

These modules are used to implement the os.path module, and are not documented beyond this mention. There’s little need to document these.

- ntpath — Implementation of os.path on Win32 and Win64 platforms.
- posixpath — Implementation of os.path on POSIX.
The following modules have specific security considerations:

- **base64**: [base64 security considerations](https://tools.ietf.org/html/rfc4648)
- **cgi**: CGI security considerations
- **hashlib**: all constructors take a “usedforsecurity” keyword-only argument disabling known insecure and blocked algorithms
- **http.server**: is not suitable for production use, only implementing basic security checks
- **logging**: Logging configuration uses `eval()`
- **multiprocessing**: `Connection.recv()` uses `pickle`
- **pickle**: Restricting globals in `pickle`
- **random**: shouldn’t be used for security purposes, use `secrets` instead
- **shelve**: `shelve` is based on `pickle` and thus unsuitable for dealing with untrusted sources
- **ssl**: SSL/TLS security considerations
- **subprocess**: Subprocess security considerations
- **tempfile**: `mktemp` is deprecated due to vulnerability to race conditions
- **xml**: XML vulnerabilities
- **zipfile**: maliciously prepared `.zip` files can cause disk volume exhaustion
The default Python prompt of the interactive shell. Often seen for code examples which can be executed interactively in the interpreter.

Can refer to:

* The default Python prompt of the interactive shell when entering the code for an indented code block, when within a pair of matching left and right delimiters (parentheses, square brackets, curly braces or triple quotes), or after specifying a decorator.

* The Ellipsis built-in constant.

2to3 A tool that tries to convert Python 2.x code to Python 3.x code by handling most of the incompatibilities which can be detected by parsing the source and traversing the parse tree.

2to3 is available in the standard library as lib2to3; a standalone entry point is provided as Tools/scripts/2to3. See 2to3 - Automated Python 2 to 3 code translation.

Abstract base classes complement duck-typing by providing a way to define interfaces when other techniques like `hasattr()` would be clumsy or subtly wrong (for example with magic methods). ABCs introduce virtual subclasses, which are classes that don’t inherit from a class but are still recognized by `isinstance()` and `issubclass()`; see the abc module documentation. Python comes with many built-in ABCs for data structures (in the collections.abc module), numbers (in the numbers module), streams (in the io module), import finders and loaders (in the importlib.abc module). You can create your own ABCs with the abc module.

Annotation A label associated with a variable, a class attribute or a function parameter or return value, used by convention as a type hint.

Annotations of local variables cannot be accessed at runtime, but annotations of global variables, class attributes, and functions are stored in the `__annotations__` special attribute of modules, classes, and functions, respectively.

See variable annotation, function annotation, PEP 484 and PEP 526, which describe this functionality. Also see annotations-howto for best practices on working with annotations.

Argument A value passed to a function (or method) when calling the function. There are two kinds of argument:

* keyword argument: an argument preceded by an identifier (e.g. `name=`) in a function call or passed as a value in a dictionary preceded by `**`. For example, 3 and 5 are both keyword arguments in the following calls to `complex()`:

  ```python
  complex(real=3, imag=5)
  complex(**{'real': 3, 'imag': 5})
  ```

* positional argument: an argument that is not a keyword argument. Positional arguments can appear at the beginning of an argument list and/or be passed as elements of an iterable preceded by `*`. For example, 3 and 5 are both positional arguments in the following calls:

  ```python
  complex(3, 5)
  complex(*{3, 5})
  ```
Arguments are assigned to the named local variables in a function body. See the calls section for the rules governing this assignment. Syntactically, any expression can be used to represent an argument; the evaluated value is assigned to the local variable.

See also the parameter glossary entry, the FAQ question on the difference between arguments and parameters, and PEP 362.

**asynchronous context manager** An object which controls the environment seen in an `async with` statement by defining `__aenter__()` and `__aexit__()` methods. Introduced by PEP 492.

**asynchronous generator** A function which returns an asynchronous generator iterator. It looks like a coroutine function defined with `async def` except that it contains `yield` expressions for producing a series of values usable in an `async for` loop.

Usually refers to an asynchronous generator function, but may refer to an asynchronous generator iterator in some contexts. In cases where the intended meaning isn’t clear, using the full terms avoids ambiguity.

An asynchronous generator function may contain `await` expressions as well as `async for`, and `async with` statements.

**asynchronous generator iterator** An object created by an asynchronous generator function.

This is an asynchronous iterator which when called using the `__anext__()` method returns an awaitable object which will execute the body of the asynchronous generator function until the next `yield` expression.

Each `yield` temporarily suspends processing, remembering the location execution state (including local variables and pending try-statements). When the asynchronous generator iterator effectively resumes with another awaitable returned by `__anext__()`, it picks up where it left off. See PEP 492 and PEP 525.

**asynchronous iterable** An object, that can be used in an `async for` statement. Must return an asynchronous iterator from its `__aiter__()` method. Introduced by PEP 492.

**asynchronous iterator** An object that implements the `__aiter__()` and `__anext__()` methods. `__anext__` must return an awaitable object. `async for` resolves the awaitables returned by an asynchronous iterator’s `__anext__()` method until it raises a `StopAsyncIteration` exception. Introduced by PEP 492.

**attribute** A value associated with an object which is referenced by name using dotted expressions. For example, if an object `o` has an attribute `a` it would be referenced as `o.a`.

**awaitable** An object that can be used in an `await` expression. Can be a coroutine or an object with an `__await__()` method. See also PEP 492.

**BDFL** Benevolent Dictator For Life, a.k.a. Guido van Rossum, Python’s creator.

**binary file** A file object able to read and write bytes-like objects. Examples of binary files are files opened in binary mode ("rb", "wb" or "rb+"), `sys.stdin.buffer`, `sys.stdout.buffer`, and instances of `io.BytesIO` and `gzip.GzipFile`.

See also text file for a file object able to read and write `str` objects.

**borrowed reference** In Python’s C API, a borrowed reference is a reference to an object. It does not modify the object reference count. It becomes a dangling pointer if the object is destroyed. For example, a garbage collection can remove the last `strong reference` to the object and so destroy it.

Calling `Py_INCREF()` on the borrowed reference is recommended to convert it to a `strong reference` in-place, except when the object cannot be destroyed before the last usage of the borrowed reference. The `Py_NewRef()` function can be used to create a new `strong reference`.

**bytes-like object** An object that supports the buffer objects and can export a C-contiguous buffer. This includes all `bytes`, `bytearray`, and `array.array` objects, as well as many common `memoryview` objects. Bytes-like objects can be used for various operations that work with binary data; these include compression, saving to a binary file, and sending over a socket.

Some operations need the binary data to be mutable. The documentation often refers to these as “read-write bytes-like objects”. Example mutable buffer objects include `bytearray` and a `memoryview` of a `bytearray`. Other operations require the binary data to be stored in immutable objects (“read-only bytes-like objects”); examples of these include `bytes` and a `memoryview` of a `bytes` object.
bytecode  Python source code is compiled into bytecode, the internal representation of a Python program in the CPython interpreter. The bytecode is also cached in .pyc files so that executing the same file is faster the second time (recompilation from source to bytecode can be avoided). This “intermediate language” is said to run on a virtual machine that executes the machine code corresponding to each bytecode. Do note that bytecodes are not expected to work between different Python virtual machines, nor to be stable between Python releases.

A list of bytecode instructions can be found in the documentation for the dis module.

callback  A subroutine function which is passed as an argument to be executed at some point in the future.

class  A template for creating user-defined objects. Class definitions normally contain method definitions which operate on instances of the class.

class variable  A variable defined in a class and intended to be modified only at class level (i.e., not in an instance of the class).

coevolution  The implicit conversion of an instance of one type to another during an operation which involves two arguments of the same type. For example, int(3.15) converts the floating point number to the integer 3, but in 3+4.5, each argument is of a different type (one int, one float), and both must be converted to the same type before they can be added or it will raise a TypeError. Without coercion, all arguments of even compatible types would have to be normalized to the same value by the programmer, e.g., float(3)+4.5 rather than just 3+4.5.

complex number  An extension of the familiar real number system in which all numbers are expressed as a sum of a real part and an imaginary part. Imaginary numbers are real multiples of the imaginary unit (the square root of -1), often written j in mathematics or i in engineering. Python has built-in support for complex numbers, which are written with this latter notation; the imaginary part is written with a j suffix, e.g., 3+1j. To get access to complex equivalents of the math module, use cmath. Use of complex numbers is a fairly advanced mathematical feature. If you’re not aware of a need for them, it’s almost certain you can safely ignore them.

coroutine  Coroutines are a more generalized form of subroutines. Subroutines are entered at one point and exited at another point. Coroutines can be entered, exited, and resumed at many different points. They can be implemented with the async def statement. See also PEP 492.

coroutine function  A function which returns a coroutine object. A coroutine function may be defined with the async def statement, and may contain await, async for, and async with keywords. These were introduced by PEP 492.

CPython  The canonical implementation of the Python programming language, as distributed on python.org. The term “CPython” is used when necessary to distinguish this implementation from others such as Jython or IronPython.

decorator  A function returning another function, usually applied as a function transformation using the @wrapper syntax. Common examples for decorators are classmethod() and staticmethod().

The decorator syntax is merely syntactic sugar, the following two function definitions are semantically equivalent:

```
def f(arg):
    ...
```
The same concept exists for classes, but is less commonly used there. See the documentation for function
definitions and class definitions for more about decorators.

descriptor Any object which defines the methods __get__(), __set__() or __delete__() When a class
attribute is a descriptor, its special binding behavior is triggered upon attribute lookup. Normally, using 
a.b to
get, set or delete an attribute looks up the object named b in the class dictionary for a, but if b is a descriptor,
the respective descriptor method gets called. Understanding descriptors is a key to a deep understanding of
Python because they are the basis for many features including functions, methods, properties, class methods,
static methods, and reference to super classes.

For more information about descriptors’ methods, see descriptors or the Descriptor How To Guide.

dictionary An associative array, where arbitrary keys are mapped to values. The keys can be any object with
__hash__() and __eq__() methods. Called a hash in Perl.
dictionary comprehension A compact way to process all or part of the elements in an iterable and return a dictionary
with the results.
results = {n: n ** 2 for n in range(10)} generates a dictionary containing
key n mapped to value n ** 2. See comprehensions.
dictionary view The objects returned from dict.keys(), dict.values(), and dict.items() are called
dictionary views. They provide a dynamic view on the dictionary’s entries, which means that when the dic-
tionary changes, the view reflects these changes. To force the dictionary view to become a full list use
list(dictview). See Dictionary view objects.
docstring A string literal which appears as the first expression in a class, function or module. While ignored when
the suite is executed, it is recognized by the compiler and put into the __doc__ attribute of the enclosing
class, function or module. Since it is available via introspection, it is the canonical place for documentation of
the object.
duck-typing A programming style which does not look at an object’s type to determine if it has the right interface;
instead, the method or attribute is simply called or used (“If it looks like a duck and quacks like a duck, it must
be a duck.”) By emphasizing interfaces rather than specific types, well-designed code improves its flexibility
by allowing polymorphic substitution. Duck-typing avoids tests using type() or isinstance(). (Note,
however, that duck-typing can be complemented with abstract base classes.) Instead, it typically employs
hasattr() tests or EAFP programming.

EAFP Easier to ask for forgiveness than permission. This common Python coding style assumes the existence of
valid keys or attributes and catches exceptions if the assumption proves false. This clean and fast style is
characterized by the presence of many try and except statements. The technique contrasts with the LBYL
style common to many other languages such as C.

expression A piece of syntax which can be evaluated to some value. In other words, an expression is an accumulation
of expression elements like literals, names, attribute access, operators or function calls which all return a value.
In contrast to many other languages, not all language constructs are expressions. There are also statements
which cannot be used as expressions, such as while. Assignments are also statements, not expressions.
extension module A module written in C or C++, using Python’s C API to interact with the core and with user code.
f-string String literals prefixed with ‘f’ or ‘F’ are commonly called “f-strings” which is short for formatted string
literals. See also PEP 498.

file object An object exposing a file-oriented API (with methods such as read() or write()) to an underlying
resource. Depending on the way it was created, a file object can mediate access to a real on-disk file or to another
type of storage or communication device (for example standard input/output, in-memory buffers, sockets,
pipes, etc.). File objects are also called file-like objects or streams.

There are actually three categories of file objects: raw binary files, buffered binary files and text files. Their
interfaces are defined in the io module. The canonical way to create a file object is by using the open()
function.

file-like object  A synonym for file object.

filesystem encoding and error handler  Encoding and error handler used by Python to decode bytes from the operating system and encode Unicode to the operating system.

The filesystem encoding must guarantee to successfully decode all bytes below 128. If the file system encoding fails to provide this guarantee, API functions can raise UnicodeError.

The sys.getfilesystemencoding() and sys.getfilesystemencodeerrors() functions can be used to get the filesystem encoding and error handler.

The filesystem encoding and error handler are configured at Python startup by the PyConfig_Read() function: see filesystem_encoding and filesystem_errors members of PyConfig.

See also the locale encoding.

finder  An object that tries to find the loader for a module that is being imported.

Since Python 3.3, there are two types of finder: meta path finders for use with sys.meta_path, and path entry finders for use with sys.path_hooks.

See PEP 302, PEP 420 and PEP 451 for much more detail.

floor division  Mathematical division that rounds down to nearest integer. The floor division operator is // . For example, the expression 11 // 4 evaluates to 2 in contrast to the 2.75 returned by float true division. Note that (-11) // 4 is -3 because that is -2.75 rounded downward. See PEP 238.

function  A series of statements which returns some value to a caller. It can also be passed zero or more arguments which may be used in the execution of the body. See also parameter, method, and the function section.

function annotation  An annotation of a function parameter or return value.

Function annotations are usually used for type hints: for example, this function is expected to take two int arguments and is also expected to have an int return value:

```python
def sum_two_numbers(a: int, b: int) -> int:
    return a + b
```

Function annotation syntax is explained in section function.

See variable annotation and PEP 484, which describe this functionality. Also see annotations-howto for best practices on working with annotations.

__future__  A future statement, from __future__ import <feature>, directs the compiler to compile the current module using syntax or semantics that will become standard in a future release of Python. The __future__ module documents the possible values of feature. By importing this module and evaluating its variables, you can see when a new feature was first added to the language and when it will (or did) become the default:

```python
>>> import __future__
>>> __future__.division
_Feature((2, 2, 0, 'alpha', 2), (3, 0, 0, 'alpha', 0), 8192)
```

garbage collection  The process of freeing memory when it is not used anymore. Python performs garbage collection via reference counting and a cyclic garbage collector that is able to detect and break reference cycles. The garbage collector can be controlled using the gc module.

generator  A function which returns a generator iterator. It looks like a normal function except that it contains yield expressions for producing a series of values usable in a for-loop or that can be retrieved one at a time with the next() function.

Usually refers to a generator function, but may refer to a generator iterator in some contexts. In cases where the intended meaning isn’t clear, using the full terms avoids ambiguity.

generator iterator  An object created by a generator function.
Each `yield` temporarily suspends processing, remembering the location execution state (including local variables and pending try-statements). When the `generator iterator` resumes, it picks up where it left off (in contrast to functions which start fresh on every invocation).

**generator expression** An expression that returns an iterator. It looks like a normal expression followed by a `for` clause defining a loop variable, range, and an optional `if` clause. The combined expression generates values for an enclosing function:

```python
>>> sum(i*i for i in range(10))  # sum of squares 0, 1, 4, ... 81
285
```

**generic function** A function composed of multiple functions implementing the same operation for different types. Which implementation should be used during a call is determined by the dispatch algorithm.

See also the `single dispatch` glossary entry, the `functools.singledispatch()` decorator, and PEP 443.

**generic type** A `type` that can be parameterized; typically a container class such as `list` or `dict`. Used for `type hints` and `annotations`.

For more details, see `generic alias types`, PEP 483, PEP 484, PEP 585, and the `typing` module.

**GIL** See `global interpreter lock`.

**global interpreter lock** The mechanism used by the `CPython` interpreter to assure that only one thread executes Python `bytecode` at a time. This simplifies the CPython implementation by making the object model (including critical built-in types such as `dict`) implicitly safe against concurrent access. Locking the entire interpreter makes it easier for the interpreter to be multi-threaded, at the expense of much of the parallelism afforded by multi-processor machines.

However, some extension modules, either standard or third-party, are designed so as to release the GIL when doing computationally-intensive tasks such as compression or hashing. Also, the GIL is always released when doing I/O.

Past efforts to create a “free-threaded” interpreter (one which locks shared data at a much finer granularity) have not been successful because performance suffered in the common single-processor case. It is believed that overcoming this performance issue would make the implementation much more complicated and therefore costlier to maintain.

**hash-based pyc** A bytecode cache file that uses the hash rather than the last-modified time of the corresponding source file to determine its validity. See pyc-invalidation.

**hashable** An object is `hashable` if it has a hash value which never changes during its lifetime (it needs a `__hash__()` method), and can be compared to other objects (it needs an `__eq__()` method). Hashable objects which compare equal must have the same hash value.

Hashability makes an object usable as a dictionary key and a set member, because these data structures use the hash value internally.

Most of Python’s immutable built-in objects are hashable; mutable containers (such as lists or dictionaries) are not; immutable containers (such as tuples and frozensets) are only hashable if their elements are hashable. Objects which are instances of user-defined classes are hashable by default. They all compare unequal (except with themselves), and their hash value is derived from their `id()`.

**IDLE** An Integrated Development Environment for Python. IDLE is a basic editor and interpreter environment which ships with the standard distribution of Python.

**immutable** An object with a fixed value. Immutable objects include numbers, strings and tuples. Such an object cannot be altered. A new object has to be created if a different value has to be stored. They play an important role in places where a constant hash value is needed, for example as a key in a dictionary.

**import path** A list of locations (or `path entries`) that are searched by the `path based finder` for modules to import.

During import, this list of locations usually comes from `sys.path`, but for subpackages it may also come from the parent package’s `__path__` attribute.

**importing** The process by which Python code in one module is made available to Python code in another module.
importer  An object that both finds and loads a module; both a finder and loader object.

interactive  Python has an interactive interpreter which means you can enter statements and expressions at the interpreter prompt, immediately execute them and see their results. Just launch python with no arguments (possibly by selecting it from your computer’s main menu). It is a very powerful way to test out new ideas or inspect modules and packages (remember help(x)).

interpreted  Python is an interpreted language, as opposed to a compiled one, though the distinction can be blurry because of the presence of the bytecode compiler. This means that source files can be run directly without explicitly creating an executable which is then run. Interpreted languages typically have a shorter development/debug cycle than compiled ones, though their programs generally also run more slowly. See also interactive.

interpreter shutdown  When asked to shut down, the Python interpreter enters a special phase where it gradually releases all allocated resources, such as modules and various critical internal structures. It also makes several calls to the garbage collector. This can trigger the execution of code in user-defined destructors or weakref callbacks. Code executed during the shutdown phase can encounter various exceptions as the resources it relies on may not function anymore (common examples are library modules or the warnings machinery).

The main reason for interpreter shutdown is that the __main__ module or the script being run has finished executing.

iterable  An object capable of returning its members one at a time. Examples of iterables include all sequence types (such as list, str, and tuple) and some non-sequence types like dict, file objects, and objects of any classes you define with an __iter__() method or with a __getitem__() method that implements Sequence semantics.

Iterables can be used in a for loop and in many other places where a sequence is needed (zip(), map(), ...). When an iterable object is passed as an argument to the built-in function iter(), it returns an iterator for the object. This iterator is good for one pass over the set of values. When using iterables, it is usually not necessary to call iter() or deal with iterator objects yourself. The for statement does that automatically for you, creating a temporary unnamed variable to hold the iterator for the duration of the loop. See also iterator, sequence, and generator.

iterator  An object representing a stream of data. Repeated calls to the iterator’s __next__() method (or passing it to the built-in function next()) return successive items in the stream. When no more data are available a StopIteration exception is raised instead. At this point, the iterator object is exhausted and any further calls to its __next__() method just raise StopIteration again. Iterators are required to have an __iter__() method that returns the iterator object itself so every iterator is also iterable and may be used in most places where other iterables are accepted. One notable exception is code which attempts multiple iteration passes. A container object (such as a list) produces a fresh new iterator each time you pass it to the iter() function or use it in a for loop. Attempting this with an iterator will just return the same exhausted iterator object used in the previous iteration pass, making it appear like an empty container.

More information can be found in Iterator Types.

CPython implementation detail: CPython does not consistently apply the requirement that an iterator define __iter__().

key function  A key function or collation function is a callable that returns a value used for sorting or ordering. For example, locale.strxfrm() is used to produce a sort key that is aware of locale specific sort conventions.

A number of tools in Python accept key functions to control how elements are ordered or grouped. They include min(), max(), sorted(), list.sort(), heapq.merge(), heapq.nsmallest(), heapq.nlargest(), and itertools.groupby().

There are several ways to create a key function. For example, the str.lower() method can serve as a key function for case insensitive sorts. Alternatively, a key function can be built from a lambda expression such as lambda r: (r[0], r[2]). Also, the operator module provides three key function constructors: attrgetter(), itemgetter(), and methodcaller(). See the Sorting HOW TO for examples of how to create and use key functions.

keyword argument  See argument.

lambda  An anonymous inline function consisting of a single expression which is evaluated when the function is called. The syntax to create a lambda function is lambda [parameters]: expression
LBYL  Look before you leap. This coding style explicitly tests for pre-conditions before making calls or lookups. This style contrasts with the EAFP approach and is characterized by the presence of many `if` statements.

In a multi-threaded environment, the LBYL approach can risk introducing a race condition between “the looking” and “the leaping”. For example, the code, `if key in mapping: return mapping[key]` can fail if another thread removes `key` from `mapping` after the test, but before the lookup. This issue can be solved with locks or by using the EAFP approach.

locale encoding  On Unix, it is the encoding of the LC_CTYPE locale. It can be set with `locale.setlocale(locale.LC_CTYPE, new_locale)`.

On Windows, it is the ANSI code page (ex: cp1252).

`locale.getpreferredencoding(False)` can be used to get the locale encoding.

Python uses the `filesystem encoding and error handler` to convert between Unicode filenames and bytes filenames.

list  A built-in Python sequence. Despite its name it is more akin to an array in other languages than to a linked list since access to elements is O(1).

list comprehension  A compact way to process all or part of the elements in a sequence and return a list with the results. `result = [':#04x'.'format(x) for x in range(256) if x % 2 == 0]` generates a list of strings containing even hex numbers (0x..) in the range from 0 to 255. The `if` clause is optional. If omitted, all elements in `range(256)` are processed.

loader  An object that loads a module. It must define a method named `load_module()`. A loader is typically returned by a `finder`. See PEP 302 for details and `importlib.abc.Loader` for an abstract base class.

magic method  An informal synonym for special method.

mapping  A container object that supports arbitrary key lookups and implements the methods specified in the `Mapping` or `MutableMapping abstract base classes`. Examples include `dict, collections.defaultdict, collections.OrderedDict and collections.Counter`.

meta path finder  A `finder` returned by a search of `sys.meta_path`. Meta path finders are related to, but different from `path entry finders`.

See `importlib.abc.MetaPathFinder` for the methods that meta path finders implement.

metaclass  The class of a class. Class definitions create a class name, a class dictionary, and a list of base classes. The metaclass is responsible for taking those three arguments and creating the class. Most object oriented programming languages provide a default implementation. What makes Python special is that it is possible to create custom metaclasses. Most users never need this tool, but when the need arises, metaclasses can provide powerful, elegant solutions. They have been used for logging attribute access, adding thread-safety, tracking object creation, implementing singletons, and many other tasks.

More information can be found in metaclasses.

method  A function which is defined inside a class body. If called as an attribute of an instance of that class, the method will get the instance object as its first argument (which is usually called `self`). See `function` and `nested scope`.

method resolution order  Method Resolution Order is the order in which base classes are searched for a member during lookup. See The Python 2.3 Method Resolution Order for details of the algorithm used by the Python interpreter since the 2.3 release.

module  An object that serves as an organizational unit of Python code. Modules have a namespace containing arbitrary Python objects. Modules are loaded into Python by the process of `importing`.

See also `package`.

module spec  A namespace containing the import-related information used to load a module. An instance of `importlib.machinery.ModuleSpec`.

MRO  See `method resolution order`.

mutable  Mutable objects can change their value but keep their `id()`. See also `immutable`.
**named tuple**  The term “named tuple” applies to any type or class that inherits from tuple and whose indexable elements are also accessible using named attributes. The type or class may have other features as well.

Several built-in types are named tuples, including the values returned by `time.localtime()` and `os.stat()`. Another example is `sys.float_info`:

```python
>>> sys.float_info[1]            # indexed access
1024
>>> sys.float_info.max_exp      # named field access
1024
>>> isinstance(sys.float_info, tuple) # kind of tuple
True
```

Some named tuples are built-in types (such as the above examples). Alternatively, a named tuple can be created from a regular class definition that inherits from `tuple` and that defines named fields. Such a class can be written by hand or it can be created with the factory function `collections.namedtuple()`.

**namespace**  The place where a variable is stored. Namespaces are implemented as dictionaries. There are the local, global and built-in namespaces as well as nested namespaces in objects (in methods). Namespaces support modularity by preventing naming conflicts. For instance, the functions `builtins.open` and `os.open()` are distinguished by their namespaces. Namespaces also aid readability and maintainability by making it clear which module implements a function. For instance, writing `random.seed()` or `itertools.islice()` makes it clear that those functions are implemented by the `random` and `itertools` modules, respectively.

**namespace package**  A PEP 420 package which serves only as a container for subpackages. Namespace packages may have no physical representation, and specifically are not like a regular package because they have no `__init__.py` file.

See also module.

**nested scope**  The ability to refer to a variable in an enclosing definition. For instance, a function defined inside another function can refer to variables in the outer function. Note that nested scopes by default work only for reference and not for assignment. Local variables both read and write in the innermost scope. Likewise, global variables read and write to the global namespace. The `nonlocal` allows writing to outer scopes.

**new-style class**  Old name for the flavor of classes now used for all class objects. In earlier Python versions, only new-style classes could use Python’s newer, versatile features like `__slots__`, descriptors, properties, `__getattribute__()` , class methods, and static methods.

**object**  Any data with state (attributes or value) and defined behavior (methods). Also the ultimate base class of any new-style class.

**package**  A Python module which can contain submodules or recursively, subpackages. Technically, a package is a Python module with an `__path__` attribute.

See also regular package and namespace package.

**parameter**  A named entity in a function (or method) definition that specifies an argument (or in some cases, arguments) that the function can accept. There are five kinds of parameter:

- **positional-or-keyword**: specifies an argument that can be passed either **positionally** or as a keyword argument. This is the default kind of parameter, for example `foo` and `bar` in the following:

  ```python
def func(foo, bar=None): ...
  ```

- **positional-only**: specifies an argument that can be supplied only by position. Positional-only parameters can be defined by including a `/` character in the parameter list of the function definition after them, for example `posonly1` and `posonly2` in the following:

  ```python
def func(posonly1, posonly2, /, positional_or_keyword): ...
  ```

- **keyword-only**: specifies an argument that can be supplied only by keyword. Keyword-only parameters can be defined by including a single `var-positional` parameter or bare `*` in the parameter list of the function definition before them, for example `kw_only1` and `kw_only2` in the following:

  ```python
def func(posonly1, posonly2, *, positional_or_keyword): ...
  ```
• **var-positional**: specifies that an arbitrary sequence of positional arguments can be provided (in addition to any positional arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with `*`, for example `args` in the following:

```python
def func(arg, *args, kw_only1, kw_only2): ...
```

• **var-keyword**: specifies that arbitrarily many keyword arguments can be provided (in addition to any keyword arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with `**`, for example `kwargs` in the example above.

Parameters can specify both optional and required arguments, as well as default values for some optional arguments.

See also the argument glossary entry, the FAQ question on the difference between arguments and parameters, the `inspect.Parameter` class, the function section, and PEP 362.

**path entry** A single location on the *import path* which the *path based finder* consults to find modules for importing.

**path entry finder** A finder returned by a callable on `sys.path_hooks` (i.e. a *path entry hook*) which knows how to locate modules given a *path entry*.

See `importlib.abc.PathEntryFinder` for the methods that path entry finders implement.

**path entry hook** A callable on the `sys.path_hook` list which returns a *path entry finder* if it knows how to find modules on a specific *path entry*.

**path based finder** One of the default *meta path finders* which searches an *import path* for modules.

**path-like object** An object representing a file system path. A path-like object is either a *str* or *bytes* object representing a path, or an object implementing the `os.PathLike` protocol. An object that supports the `os.PathLike` protocol can be converted to a *str* or *bytes* file system path by calling the `os.fspath()` function; `os.fsdecode()` and `os.fsencode()` can be used to guarantee a *str* or *bytes* result instead, respectively. Introduced by PEP 519.

**PEP** Python Enhancement Proposal. A PEP is a design document providing information to the Python community, or describing a new feature for Python or its processes or environment. PEPs should provide a concise technical specification and a rationale for proposed features.

PEPs are intended to be the primary mechanisms for proposing major new features, for collecting community input on an issue, and for documenting the design decisions that have gone into Python. The PEP author is responsible for building consensus within the community and documenting dissenting opinions.

See PEP 1.

**portion** A set of files in a single directory (possibly stored in a zip file) that contribute to a namespace package, as defined in PEP 420.

**positional argument** See argument.

**provisional API** A provisional API is one which has been deliberately excluded from the standard library’s backwards compatibility guarantees. While major changes to such interfaces are not expected, as long as they are marked provisional, backwards incompatible changes (up to and including removal of the interface) may occur if deemed necessary by core developers. Such changes will not be made gratuitously – they will occur only if serious fundamental flaws are uncovered that were missed prior to the inclusion of the API.

Even for provisional APIs, backwards incompatible changes are seen as a “solution of last resort” - every attempt will still be made to find a backwards compatible resolution to any identified problems.

This process allows the standard library to continue to evolve over time, without locking in problematic design errors for extended periods of time. See PEP 411 for more details.

**provisional package** See provisional API.

**Python 3000** Nickname for the Python 3.x release line (coined long ago when the release of version 3 was something in the distant future.) This is also abbreviated “Py3k”.

---

**1976 Appendix A. Glossary**
**Pythonic** An idea or piece of code which closely follows the most common idioms of the Python language, rather than implementing code using concepts common to other languages. For example, a common idiom in Python is to loop over all elements of an iterable using a `for` statement. Many other languages don’t have this type of construct, so people unfamiliar with Python sometimes use a numerical counter instead:

```python
for i in range(len(food)):
    print(food[i])
```

As opposed to the cleaner, Pythonic method:

```python
for piece in food:
    print(piece)
```

**qualified name** A dotted name showing the “path” from a module’s global scope to a class, function or method defined in that module, as defined in PEP 3155. For top-level functions and classes, the qualified name is the same as the object’s name:

```python
>>> class C:
...     ...     class D:
...         ...         def meth(self):
...             ...             pass
...         ...
...     ...
...     C.__qualname__
'C'
>>> C.D.__qualname__
'C.D'
>>> C.D.meth.__qualname__
'C.D.meth'
```

When used to refer to modules, the *fully qualified name* means the entire dotted path to the module, including any parent packages, e.g. `email.mime.text`:

```python
>>> import email.mime.text
>>> email.mime.text.__name__
'email.mime.text'
```

**reference count** The number of references to an object. When the reference count of an object drops to zero, it is deallocated. Reference counting is generally not visible to Python code, but it is a key element of the CPython implementation. The `sys` module defines a `getrefcount()` function that programmers can call to return the reference count for a particular object.

**regular package** A traditional *package*, such as a directory containing an `__init__.py` file.

See also *namespace package*.

**__slots__** A declaration inside a class that saves memory by pre-declaring space for instance attributes and eliminating instance dictionaries. Though popular, the technique is somewhat tricky to get right and is best reserved for rare cases where there are large numbers of instances in a memory-critical application.

**sequence** An *iterable* which supports efficient element access using integer indices via the `__getitem__()` special method and defines a `__len__()` method that returns the length of the sequence. Some built-in sequence types are `list`, `str`, `tuple`, and `bytes`. Note that `dict` also supports `__getitem__()` and `__len__()`, but is considered a mapping rather than a sequence because the lookups use arbitrary immutable keys rather than integers.

The `collections.abc.Sequence` abstract base class defines a much richer interface that goes beyond just `__getitem__()` and `__len__()`, adding `count()`, `index()`, `__contains__()` and `__reversed__()`. Types that implement this expanded interface can be registered explicitly using `register()`.

**set comprehension** A compact way to process all or part of the elements in an iterable and return a set with the results. `results = {c for c in 'abracadabra' if c not in 'abc'}` generates the set of strings (`'r', 'd'`). See comprehensions.
**single dispatch** A form of *generic function* dispatch where the implementation is chosen based on the type of a single argument.

**slice** An object usually containing a portion of a *sequence*. A slice is created using the subscript notation, `[]` with colons between numbers when several are given, such as in `variable_name[1:3:5]`. The bracket (subscript) notation uses `slice` objects internally.

**special method** A method that is called implicitly by Python to execute a certain operation on a type, such as addition. Such methods have names starting and ending with double underscores. Special methods are documented in `specialnames`.

**statement** A statement is part of a suite (a “block” of code). A statement is either an *expression* or one of several constructs with a keyword, such as `if`, `while` or `for`.

**strong reference** In Python’s C API, a strong reference is a reference to an object which increments the object’s reference count when it is created and decrements the object’s reference count when it is deleted.

The `Py_NewRef()` function can be used to create a strong reference to an object. Usually, the `Py_DECREF()` function must be called on the strong reference before exiting the scope of the strong reference, to avoid leaking one reference.

See also *borrowed reference*.

**text encoding** A codec which encodes Unicode strings to bytes.

**text file** A *file object* able to read and write `str` objects. Often, a text file actually accesses a byte-oriented data stream and handles the *text encoding* automatically. Examples of text files are files opened in text mode (`'r'` or `'w'`), `sys.stdin`, `sys.stdout`, and instances of `io.StringIO`.

See also *binary file* for a file object able to read and write bytes-like objects.

**triple-quoted string** A string which is bounded by three instances of either a quotation mark (") or an apostrophe (‘). While they don’t provide any functionality not available with single-quoted strings, they are useful for a number of reasons. They allow you to include unescapedsingle and double quotes within a string and they can span multiple lines without the use of the continuation character, making them especially useful when writing docstrings.

**type** The type of a Python object determines what kind of object it is; every object has a type. An object’s type is accessible as its `__class__` attribute or can be retrieved with `type(obj)`.

**type alias** A synonym for a type, created by assigning the type to an identifier.

Type aliases are useful for simplifying *type hints*. For example:

```python
def remove_gray_shades(
    colors: list[tuple[int, int, int]]) -> list[tuple[int, int, int]]:
    pass
```

could be made more readable like this:

```python
Color = tuple[int, int, int]

def remove_gray_shades(colors: list[Color]) -> list[Color]:
    pass
```

See *typing* and PEP 484, which describe this functionality.

**type hint** An *annotation* that specifies the expected type for a variable, a class attribute, or a function parameter or return value.

Type hints are optional and are not enforced by Python but they are useful to static type analysis tools, and aid IDEs with code completion and refactoring.

Type hints of global variables, class attributes, and functions, but not local variables, can be accessed using `typing.get_type_hints()`.

See *typing* and PEP 484, which describe this functionality.
universal newlines A manner of interpreting text streams in which all of the following are recognized as ending a line: the Unix end-of-line convention '\n', the Windows convention '\r\n', and the old Macintosh convention '\r'. See PEP 278 and PEP 3116, as well as `bytes.splitlines()` for an additional use.

variable annotation An annotation of a variable or a class attribute.

When annotating a variable or a class attribute, assignment is optional:

```python
class C:
    field: 'annotation'
```

Variable annotations are usually used for type hints: for example this variable is expected to take `int` values:

```python
count: int = 0
```

Variable annotation syntax is explained in section `annassign`.

See function annotation, PEP 484 and PEP 526, which describe this functionality. Also see annotations-howto for best practices on working with annotations.

virtual environment A cooperatively isolated runtime environment that allows Python users and applications to install and upgrade Python distribution packages without interfering with the behaviour of other Python applications running on the same system.

See also `venv`.

virtual machine A computer defined entirely in software. Python’s virtual machine executes the `bytecode` emitted by the bytecode compiler.

Zen of Python Listing of Python design principles and philosophies that are helpful in understanding and using the language. The listing can be found by typing "import this" at the interactive prompt.
ABOUT THESE DOCUMENTS

These documents are generated from reStructuredText sources by Sphinx, a document processor specifically written for the Python documentation.

Development of the documentation and its toolchain is an entirely volunteer effort, just like Python itself. If you want to contribute, please take a look at the reporting-bugs page for information on how to do so. New volunteers are always welcome!

Many thanks go to:

- Fred L. Drake, Jr., the creator of the original Python documentation toolset and writer of much of the content;
- the Docutils project for creating reStructuredText and the Docutils suite;
- Fredrik Lundh for his Alternative Python Reference project from which Sphinx got many good ideas.

B.1 Contributors to the Python Documentation

Many people have contributed to the Python language, the Python standard library, and the Python documentation. See Misc/ACKS in the Python source distribution for a partial list of contributors.

It is only with the input and contributions of the Python community that Python has such wonderful documentation – Thank You!
C.1 History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see https://www.cwi.nl/) in the Netherlands as a successor of a language called ABC. Guido remains Python’s principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see https://www.cnri.reston.va.us/) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen Python-Labs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see https://www.zope.org/). In 2001, the Python Software Foundation (PSF, see https://www.python.org/psf/) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see https://opensource.org/ for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

Note: GPL-compatible doesn’t mean that we’re distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don’t.

Thanks to the many outside volunteers who have worked under Guido’s direction to make these releases possible.
C.2 Terms and conditions for accessing or otherwise using Python

Python software and documentation are licensed under the PSF License Agreement.

Starting with Python 3.8.6, examples, recipes, and other code in the documentation are dual licensed under the PSF License Agreement and the Zero-Clause BSD license.

Some software incorporated into Python is under different licenses. The licenses are listed with code falling under that license. See Licenses and Acknowledgements for Incorporated Software for an incomplete list of these licenses.

C.2.1 PSF LICENSE AGREEMENT FOR PYTHON 3.10.4

1. This LICENSE AGREEMENT is between the Python Software Foundation ("PSF"), and
   the Individual or Organization ("Licensee") accessing and otherwise using Python 3.10.4 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 3.10.4 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., "Copyright © 2001-2022 Python Software Foundation; All Rights Reserved" are retained in Python 3.10.4 alone or in any derivative version prepared by Licensee.

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 3.10.4 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 3.10.4.

4. PSF is making Python 3.10.4 available to Licensee on an "AS IS" basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 3.10.4 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 3.10.4 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 3.10.4, OR ANY DERIVATIVE
THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By copying, installing or otherwise using Python 3.10.4, Licensee agrees to be bound by the terms and conditions of this License Agreement.

C.2.2 BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com ("BeOpen"), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization ("Licensee") accessing and otherwise using this software in source or binary form and its associated documentation ("the Software").

2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.

3. BeOpen is making the Software available to Licensee on an "AS IS" basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the "BeOpen Python" logos available at http://www.pythonlabs.com/logos.html may be used according to the permissions granted on that web page.

(continues on next page)
### C.2.3 CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 ("CNRI"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., "Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): "Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the internet using the following URL: http://hdl.handle.net/1895.22/1013."

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.

4. CNRI is making Python 1.6.1 available to Licensee on an "AS IS" basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. This License Agreement shall be governed by the federal intellectual property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.
8. By clicking on the "ACCEPT" button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

C.2.4 CWI LICENSE AGREEMENT FOR PYTHON 0.9.0 THROUGH 1.2

Copyright © 1991 – 1995, Stichting Mathematisch Centrum Amsterdam, The Netherlands. All rights reserved.

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Stichting Mathematisch Centrum or CWI not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

STICHTING MATHEMATISCH CENTRUM DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL STICHTING MATHEMATISCH CENTRUM BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

C.2.5 ZERO-CLAUSE BSD LICENSE FOR CODE IN THE PYTHON 3.10.4 DOCUMENTATION

Permission to use, copy, modify, and/or distribute this software for any purpose with or without fee is hereby granted.

THE SOFTWARE IS PROVIDED "AS IS" AND THE AUTHOR DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS. IN NO EVENT SHALL THE AUTHOR BE LIABLE FOR ANY SPECIAL, DIRECT, INDIRECT, OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
C.3 Licenses and Acknowledgements for Incorporated Software

This section is an incomplete, but growing list of licenses and acknowledgements for third-party software incorporated in the Python distribution.

C.3.1 Mersenne Twister

The _random module includes code based on a download from http://www.math.sci.hiroshima-u.ac.jp/~m-mat/MT/MT2002/emt19937ar.html. The following are the verbatim comments from the original code:

A C-program for MT19937, with initialization improved 2002/1/26.
Coded by Takuji Nishimura and Makoto Matsumoto.

Before using, initialize the state by using init_genrand(seed)
or init_by_array(init_key, key_length).

Copyright (C) 1997 - 2002, Makoto Matsumoto and Takuji Nishimura,
All rights reserved.

Redistribution and use in source and binary forms, with or without
modification, are permitted provided that the following conditions
are met:

1. Redistributions of source code must retain the above copyright
   notice, this list of conditions and the following disclaimer.

2. Redistributions in binary form must reproduce the above copyright
   notice, this list of conditions and the following disclaimer in the
   documentation and/or other materials provided with the distribution.

3. The names of its contributors may not be used to endorse or promote
   products derived from this software without specific prior written
   permission.

THIS SOFTWARE IS PROVIDED BY THE COPYRIGHT HOLDERS AND CONTRIBUTORS
"AS IS" AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT
LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR
A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE COPYRIGHT OWNER OR
CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL,
EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO,
PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR
PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY THEORY OF
LIABILITY, WHETHER IN CONTRACT, STRICT LIABILITY, OR TORT (INCLUDING
NEGLIGENCE OR OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF THIS
SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.

Any feedback is very welcome.
http://www.math.sci.hiroshima-u.ac.jp/~m-mat/MT/emt.html
email: m-mat @ math.sci.hiroshima-u.ac.jp (remove space)
C.3.2 Sockets

The `socket` module uses the functions, `getaddrinfo()`, and `getnameinfo()`, which are coded in separate source files from the WIDE Project, [http://www.wide.ad.jp/](http://www.wide.ad.jp/).

<table>
<thead>
<tr>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>All rights reserved.</td>
</tr>
</tbody>
</table>

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following conditions are met:

1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.
2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in the documentation and/or other materials provided with the distribution.
3. Neither the name of the project nor the names of its contributors may be used to endorse or promote products derived from this software without specific prior written permission.

THIS SOFTWARE IS PROVIDED BY THE PROJECT AND CONTRIBUTORS `AS IS' AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE PROJECT OR CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL, EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO, PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY THEORY OF LIABILITY, WHETHER IN CONTRACT, STRICT LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.

C.3.3 Asynchronous socket services

The `asynchat` and `asyncore` modules contain the following notice:

<table>
<thead>
<tr>
<th>Copyright 1996 by Sam Rushing</th>
</tr>
</thead>
<tbody>
<tr>
<td>All Rights Reserved</td>
</tr>
</tbody>
</table>

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Sam Rushing not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

SAM RUSHING DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL SAM RUSHING BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
C.3.4 Cookie management

The `http.cookies` module contains the following notice:

```
Copyright 2000 by Timothy O'Malley <timo@alum.mit.edu>
   All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Timothy O'Malley not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

Timothy O'Malley DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL Timothy O'Malley BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.
```

C.3.5 Execution tracing

The `trace` module contains the following notice:

```
portions copyright 2001, Autonomous Zones Industries, Inc., all rights...
err... reserved and offered to the public under the terms of the
Python 2.2 license.
Author: Zooko O'Whielacronx
http://zooko.com/
mailto:zooko@zooko.com

Copyright 2000, Mojam Media, Inc., all rights reserved.
Author: Skip Montanaro

Copyright 1999, Bioreason, Inc., all rights reserved.
Author: Andrew Dalke

Copyright 1995-1997, Automatrix, Inc., all rights reserved.
Author: Skip Montanaro

Copyright 1991-1995, Stichting Mathematisch Centrum, all rights reserved.

Permission to use, copy, modify, and distribute this Python software and its associated documentation for any purpose without fee is hereby granted, provided that the above copyright notice appears in all copies, and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of neither Automatrix, Bioreason or Mojam Media be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.
```
C.3.6 UUencode and UUdecode functions

The uu module contains the following notice:

Copyright 1994 by Lance Ellinghouse
Cathedral City, California Republic, United States of America.
All Rights Reserved
Permission to use, copy, modify, and distribute this software and its
documentation for any purpose and without fee is hereby granted,
provided that the above copyright notice appear in all copies and that
both that copyright notice and this permission notice appear in
supporting documentation, and that the name of Lance Ellinghouse
not be used in advertising or publicity pertaining to distribution
of the software without specific, written prior permission.
LANE ELLINGHOUSE DISCLAIMS ALL WARRANTIES WITH REGARD TO
THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND
FITNESS, IN NO EVENT SHALL LANCE ELLINGHOUSE CENTRUM BE LIABLE
FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES
WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN
ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT
OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

Modified by Jack Jansen, CWI, July 1995:
- Use binascii module to do the actual line-by-line conversion
  between ascii and binary. This results in a 1000-fold speedup. The C
  version is still 5 times faster, though.
- Arguments more compliant with Python standard

C.3.7 XML Remote Procedure Calls

The xmlrpc.client module contains the following notice:

The XML-RPC client interface is

Copyright (c) 1999-2002 by Secret Labs AB
Copyright (c) 1999-2002 by Fredrik Lundh

By obtaining, using, and/or copying this software and/or its
associated documentation, you agree that you have read, understood,
and will comply with the following terms and conditions:

Permission to use, copy, modify, and distribute this software and
its associated documentation for any purpose and without fee is
hereby granted, provided that the above copyright notice appears in
all copies, and that both that copyright notice and this permission
notice appear in supporting documentation, and that the name of
Secret Labs AB or the author not be used in advertising or publicity
pertaining to distribution of the software without specific, written
prior permission.

SECRET LABS AB AND THE AUTHOR DISCLAIMS ALL WARRANTIES WITH REGARD
TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND
FITNESS. IN NO EVENT SHALL SECRET LABS AB OR THE AUTHOR
BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY
DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS,
WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS
ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE
OF THIS SOFTWARE.

C.3. Licenses and Acknowledgements for Incorporated Software 1991
C.3.8 test_epoll

The test_epoll module contains the following notice:

Copyright (c) 2001-2006 Twisted Matrix Laboratories.

Permission is hereby granted, free of charge, to any person obtaining a copy of this software and associated documentation files (the "Software"), to deal in the Software without restriction, including without limitation the rights to use, copy, modify, merge, publish, distribute, sublicense, and/or sell copies of the Software, and to permit persons to whom the Software is furnished to do so, subject to the following conditions:

The above copyright notice and this permission notice shall be included in all copies or substantial portions of the Software.

THE SOFTWARE IS PROVIDED "AS IS", WITHOUT WARRANTY OF ANY KIND, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO THE WARRANTIES OF MERCHANTABILITY, FITNESS FOR A PARTICULAR PURPOSE AND NONINFRINGEMENT. IN NO EVENT SHALL THE AUTHORS OR COPYRIGHT HOLDERS BE LIABLE FOR ANY CLAIM, DAMAGES OR OTHER LIABILITY, WHETHER IN AN ACTION OF CONTRACT, TORT OR OTHERWISE, ARISING FROM, OUT OF OR IN CONNECTION WITH THE SOFTWARE OR THE USE OR OTHER DEALINGS IN THE SOFTWARE.

C.3.9 Select kqueue

The select module contains the following notice for the kqueue interface:

Copyright (c) 2000 Doug White, 2006 James Knight, 2007 Christian Heimes
All rights reserved.

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following conditions are met:
1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.
2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in the documentation and/or other materials provided with the distribution.

THIS SOFTWARE IS PROVIDED BY THE AUTHOR AND CONTRIBUTORS "AS IS" AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE AUTHOR OR CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL, EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED TO, PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA, OR PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY THEORY OF LIABILITY, WHETHER IN CONTRACT, STRICT LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.
C.3.10 SipHash24

The file `Python/pyhash.c` contains Marek Majkowski’ implementation of Dan Bernstein’s SipHash24 algorithm. It contains the following note:

```
<MIT License>
Copyright (c) 2013 Marek Majkowski <marek@popcount.org>

Permission is hereby granted, free of charge, to any person obtaining a copy
of this software and associated documentation files (the "Software"), to deal
in the Software without restriction, including without limitation the rights
to use, copy, modify, merge, publish, distribute, sublicense, and/or sell
copies of the Software, and to permit persons to whom the Software is
furnished to do so, subject to the following conditions:

The above copyright notice and this permission notice shall be included in
all copies or substantial portions of the Software.
</MIT License>

Original location:
https://github.com/majek/csiphash/

Solution inspired by code from:
Samuel Neves (supercop/crypto_auth/siphash24/little)
djb (supercop/crypto_auth/siphash24/little2)
Jean-Philippe Aumasson (https://131002.net/siphash/siphash24.c)
```

C.3.11 strtod and dtoa

The file `Python/dtoa.c`, which supplies C functions dtoa and strtod for conversion of C doubles to and from strings, is derived from the file of the same name by David M. Gay, currently available from http://www.netlib.org/fp/. The original file, as retrieved on March 16, 2009, contains the following copyright and licensing notice:

```
 /**************************************************************************
 * The author of this software is David M. Gay.
 * Copyright (c) 1991, 2000, 2001 by Lucent Technologies.
 * Permission to use, copy, modify, and distribute this software for any
 * purpose without fee is hereby granted, provided that this entire notice
 * is included in all copies of any software which is or includes a copy
 * or modification of this software and in all copies of the supporting
 * documentation for such software.
 * THIS SOFTWARE IS BEING PROVIDED "AS IS", WITHOUT ANY EXPRESS OR IMPLIED
 * WARRANTY. IN PARTICULAR, NEITHER THE AUTHOR NOR LUCENT MAKES ANY
 * REPRESENTATION OR WARRANTY OF ANY KIND CONCERNING THE MERCHANTABILITY
 * OF THIS SOFTWARE OR ITS FITNESS FOR ANY PARTICULAR PURPOSE.
 */
```
C.3.12 OpenSSL

The modules `hashlib`, `posix`, `ssl`, `crypt` use the OpenSSL library for added performance if made available by the operating system. Additionally, the Windows and macOS installers for Python may include a copy of the OpenSSL libraries, so we include a copy of the OpenSSL license here:

```
/* ====================================================================

 * HOWEVER CAUSED AND ON ANY THEORY OF LIABILITY, WHETHER IN CONTRACT,
 * STRICT LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR OTHERWISE)
 */
```

LICENSE ISSUES
-------------

The OpenSSL toolkit stays under a dual license, i.e. both the conditions of the OpenSSL License and the original SSLeay license apply to the toolkit. See below for the actual license texts. Actually both licenses are BSD-style Open Source licenses. In case of any license issues related to OpenSSL please contact openssl-core@openssl.org.

C.3.13 expat

The `pyexpat` extension is built using an included copy of the expat sources unless the build is configured `--with-system-expat`:

Copyright (c) 1998, 1999, 2000 Thai Open Source Software Center Ltd and Clark Cooper

Permission is hereby granted, free of charge, to any person obtaining a copy of this software and associated documentation files (the "Software"), to deal in the Software without restriction, including without limitation the rights to use, copy, modify, merge, publish, distribute, sublicense, and/or sell copies of the Software, and to permit persons to whom the Software is furnished to do so, subject to the following conditions:

The above copyright notice and this permission notice shall be included in all copies or substantial portions of the Software.

THE SOFTWARE IS PROVIDED "AS IS", WITHOUT WARRANTY OF ANY KIND, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO THE WARRANTIES OF MERCHANTABILITY, FITNESS FOR A PARTICULAR PURPOSE AND NONINFRINGEMENT. IN NO EVENT SHALL THE AUTHORS OR COPYRIGHT HOLDERS BE LIABLE FOR ANY CLAIM, DAMAGES OR OTHER LIABILITY, WHETHER IN AN ACTION OF CONTRACT, TORT OR OTHERWISE, ARISING FROM, OUT OF OR IN CONNECTION WITH THE SOFTWARE OR THE USE OR OTHER DEALINGS IN THE SOFTWARE.

C.3.14 libffi

The `_ctypes` extension is built using an included copy of the libffi sources unless the build is configured `--with-system-libffi`:

Copyright (c) 1996-2008 Red Hat, Inc and others.

Permission is hereby granted, free of charge, to any person obtaining a copy of this software and associated documentation files (the `"Software"`), to deal in the Software without restriction, including without limitation the rights to use, copy, modify, merge, publish, distribute, sublicense, and/or sell copies of the Software, and to permit persons to whom the Software is furnished to do so, subject to the following conditions:

The above copyright notice and this permission notice shall be included in all copies or substantial portions of the Software.

THE SOFTWARE IS PROVIDED `"AS IS"`, WITHOUT WARRANTY OF ANY KIND, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO THE WARRANTIES OF MERCHANTABILITY, FITNESS FOR A PARTICULAR PURPOSE AND
The Python Library Reference, Release 3.10.4

C.3.15 zlib

The `zlib` extension is built using an included copy of the zlib sources if the zlib version found on the system is too old to be used for the build:

```
Copyright (C) 1995-2011 Jean-loup Gailly and Mark Adler

This software is provided 'as-is', without any express or implied warranty. In no event will the authors be held liable for any damages arising from the use of this software.

Permission is granted to anyone to use this software for any purpose, including commercial applications, and to alter it and redistribute it freely, subject to the following restrictions:

1. The origin of this software must not be misrepresented; you must not claim that you wrote the original software. If you use this software in a product, an acknowledgment in the product documentation would be appreciated but is not required.

2. Altered source versions must be plainly marked as such, and must not be misrepresented as being the original software.

3. This notice may not be removed or altered from any source distribution.

Jean-loup Gailly         Mark Adler
jloup@gzip.org           madler@alumni.caltech.edu
```

C.3.16 cfuhash

The implementation of the hash table used by the `tracemalloc` is based on the cfuhash project:

```

C.3.17 libmpdec

The _decimal module is built using an included copy of the libmpdec library unless the build is configured -- with-system-libmpdec:

Copyright (c) 2008-2020 Stefan Krah. All rights reserved.

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following conditions are met:

1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.

2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in the documentation and/or other materials provided with the distribution.

THIS SOFTWARE IS PROVIDED BY THE AUTHOR AND CONTRIBUTORS "AS IS" AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE ARE DISCLAIMED.
